# The Theory and Practice of Induction by Alignment 

CJ McCartney

April 2020

#### Abstract

Induction is the discovery of models given samples. This paper demonstrates formally from first principles that there exists an optimally likely model for any sample, given certain general assumptions. Also, there exists a type of encoding, parameterised by the model, that compresses the sample. Further, if the model has certain entropy properties then it is insensitive to small changes. In this case, approximations to the model remain well-fitted to the sample. That is, accurate classification is practicable for some samples.

Then the paper derives directly from theory a practicable unsupervised machine learning algorithm that optimises the likelihood of the model by maximising the alignment of the model variables. Alignment is a statistic which measures the law-likeness or the degree of dependency between variables. It is similar to mutual entropy but is a better measure for small samples. If the sample variables are not independent then the resultant models are well-fitted. Furthermore, the models are structures that can be analysed because they consist of trees of context-contingent sub-models that are built layer by layer upwards from the substrate variables. In the top layers the variables tend to be diagonalised or equational. In this way, the model variables are meaningful in the problem domain.

If there exist causal alignments between the induced model variables and a label variable, then a semi-supervised sub-model can be obtained by minimising the conditional entropy. Similar to a Bayesian network, this sub-model can then make predictions of the label.

The paper shows that this semi-supervised method is related to the supervised method of optimising artificial neural networks by leastsquares gradient-descent. That is, some gradient-descent parameterisations satisfy the entropy properties required to obtain likely and well-fitted neural nets.

## 1 Preface

Although this document is still in the format of a paper, it has grown to be the length of a book. In order to be more accessible there is an 'Overview' section at the beginning that covers the important points of the theory and some interesting parts of the practice. The overview also has a summary of the set-theoretic notation used throughout. The complete theory and various practical implementations are the following sections. The section 'Induction' also begins with a review of relevant parts of the earlier sections. The paper finishes with some appendices on various related issues, including an appendix 'Useful functions'.

Readers interested mainly in implementation should focus on sections 'Overview', 'Substrate structures', 'Shuffled history', 'Rolls', 'Computation time and representation space', 'Rolled alignment', 'Decomposition alignment', 'Computation of alignment', 'Tractable alignment-bounding' and 'Practicable alignment-bounding'.

Terms in italics have a mathematical definition to avoid ambiguity. So 'independent' is a well defined property, whereas 'independent' has its dictionary definition.

For further discussion see https://greenlake.co.uk/.

## 2 Overview

This section provides an overview of the main points of the paper. Detailed explanations are excluded for brevity. The overview is presented as a series of assertions of fact, but only some are proven and many are conjectured, especially statements regarding correlations. In some cases, however, there are multiple strands of evidence that corroborate a conjecture. This is particularly true for the conjectures regarding the general induction of models given samples. Given a set of induction assumptions these conjectures relate (i) the maximisation of the likelihood of a sample, and also the minimisation of the likelihood's sensitivity to model and distribution, to (ii) properties such as encoding space, entropy and alignment. The different sets of induction assumptions can be categorised in various complementary ways: (a) classical induction versus aligned induction, (b) law-like conditional draws of samples from distributions versus the compression of encodings of samples by model,
(c) simple transform models versus layered, contingent models, and (d) intractable theoretical induction assumptions versus tractable and practicable induction assumptions. The existence of working implementations of practicable induction such as artificial neural networks and alignment inducers provides concrete support to the theory.

### 2.1 Notation

The notation is briefly summarised below. The appendices contain further details.

The notation used throughout this discussion is conventional set-theoretic with some additions. Sets are often defined using set-builder notation, for example $Z=\{\mathrm{f}(x): x \in X, \mathrm{p}(x)\}$ where $\mathrm{f}(x)$ is a function, $X$ is another set and $\mathrm{p}(x)$ is a predicate.

Tuples, or lists, can be defined similarly where the order is not important, for example, $\sum(\mathrm{f}(x): x \in X, \mathrm{p}(x))$.

The powerset function is defined as $\mathrm{P}(A):=\{X: X \subseteq A\}$.
The partition function B is the set of all partitions of an argument set. A partition is a set of non-empty disjoint subsets, called components, which union to equal the argument, $\forall P \in \mathrm{~B}(A) \forall C \in P(C \neq \emptyset), \forall P \in \mathrm{~B}(A) \forall C, D \in$ $P(C \neq D \Longrightarrow C \cap D=\emptyset)$ and $\forall P \in \mathrm{~B}(A)(\bigcup P=A)$.

A relation $A \in \mathrm{P}(\mathcal{X} \times \mathcal{Y})$ between the set $\mathcal{X}$ and the set $\mathcal{Y}$ is a set of pairs, $\forall(x, y) \in A(x \in \mathcal{X} \wedge y \in \mathcal{Y})$. The domain of a relation is $\operatorname{dom}(A):=\{x:$ $(x, y) \in A\}$ and the range is $\operatorname{ran}(A):=\{y:(x, y) \in A\}$.

Functions are special cases of relations such that each element of the domain appears exactly once. Functions can be finite or infinite. For example, $\{(1,2),(2,4)\} \subset\{(x, 2 x): x \in \mathbf{R}\}$. The powerset of functional relations between sets is denoted $\rightarrow$. For example, $\{(x, 2 x): x \in \mathbf{R}\} \in \mathbf{R} \rightarrow \mathbf{R}$. The application of the function $F \in \mathcal{X} \rightarrow \mathcal{Y}$ to an argument $x \in \mathcal{X}$ is denoted by $F(x) \in \mathcal{Y}$ or $F_{x} \in \mathcal{Y}$. Functions $F \in \mathcal{X} \rightarrow \mathcal{Y}$ and $G \in \mathcal{Y} \rightarrow \mathcal{Z}$ can be composed $G \circ F \in \mathcal{X} \rightarrow \mathcal{Z}$. The inverse of a function, inverse $\in(\mathcal{X} \rightarrow$ $\mathcal{Y}) \rightarrow(\mathcal{Y} \rightarrow \mathrm{P}(\mathcal{X}))$, is defined inverse $(F):=\{(y,\{x:(x, z) \in F, z=y\}):$ $y \in \operatorname{ran}(F)\}$, and is sometimes denoted $F^{-1}$. The range of the inverse is a partition of the domain, $\operatorname{ran}\left(F^{-1}\right) \in \mathrm{B}(\operatorname{dom}(F))$.

Functions may be recursive. Algorithms are represented as recursive functions.

The powerset of bi-directional relations, or one-to-one functions, is denoted $\leftrightarrow$. The cardinality of the domain of a bi-directional function equals the range, $F \in \operatorname{dom}(F) \leftrightarrow \operatorname{ran}(F) \Longrightarrow|\operatorname{dom}(F)|=|\operatorname{ran}(F)|$.

Total functions are denoted with a colon. For example, the left total function $F \in X: \rightarrow Y$ requires that $\operatorname{dom}(F)=X$ but only that $\operatorname{ran}(F) \subseteq Y$.

An order $D$ on some set $X$ is a choice of the enumerations, $D \in X: \leftrightarrow$ : $\{1 \ldots|X|\}$. Given the order, any subset $Y \subseteq X$ can be enumerated. Define $\operatorname{order}(D, Y) \in Y: \leftrightarrow:\{1 \ldots|Y|\}$ such that $\forall a, b \in Y\left(D_{a} \leq D_{b} \Longrightarrow\right.$ $\operatorname{order}(D, Y)(a) \leq \operatorname{order}(D, Y)(b))$.

The set of natural numbers $\mathbf{N}$ is taken to include 0 . The set $\mathbf{N}_{>0}$ excludes 0 . The space of a non-zero natural number is the natural logarithm, space $(n):=$ $\ln n$. The set of rational numbers is denoted $\mathbf{Q}$. The set of log-rational numbers is denoted $\ln \mathbf{Q}_{>0}=\left\{\ln q: q \in \mathbf{Q}_{>0}\right\}$. The set of real numbers is denoted $\mathbf{R}$.

The factorial of a non-zero natural number $n \in \mathbf{N}_{>0}$ is written $n!=$ $\prod\{1 \ldots n\}$.

The unit-translated gamma function is the real function that corresponds to the factorial function. It is defined $\left(\Gamma_{!}\right) \in \mathbf{R} \rightarrow \mathbf{R}$ as $\Gamma!x=\Gamma(x+1)$ which is such that $\forall n \in \mathbf{N}_{>0}(\Gamma!n=\Gamma(n+1)=n!)$.

Given a relation $A \subset \mathcal{X} \times \mathcal{Y}$ such that an order operator is defined on the range, $\mathcal{Y}$, the max function returns the maximum subset, $\max \in \mathrm{P}(\mathcal{X} \times \mathcal{Y}) \rightarrow$ $(\mathcal{X} \rightarrow \mathcal{Y})$

$$
\max (A):=\{(x, y):(x, y) \in A, \forall(r, s) \in A(s \leq y)\}
$$

For convenience define the functions $\operatorname{maxd}(A):=\operatorname{dom}(\max (A))$ and $\operatorname{maxr}(A):=$ $m$, where $\{m\}=\operatorname{ran}(\max (A))$. The corresponding functions for minimum, min, mind and minr, are similarly defined.

Given a relation $A \subset \mathcal{X} \times \mathcal{Y}$ such that the arithmetic operators are defined on the range, $\mathcal{Y}$, the sum function is defined $\operatorname{sum}(A):=\sum(y:(x, y) \in A)$. The
relation can be normalised, normalise $(A):=\{(x, y / \operatorname{sum}(A)):(x, y) \in A\}$. Define notation $\hat{A}:=$ normalise $(A)$. A normalised relation is such that its sum is one, $\operatorname{sum}(\hat{A})=1$.

The set of probability functions $\mathcal{P}$ is the set of rational valued functions such that the values are bounded $[0,1]$ and sum to $1, \mathcal{P} \subset \mathcal{X} \rightarrow \mathbf{Q}_{[0,1]}$ and $\forall P \in \mathcal{P}(\operatorname{sum}(P)=1)$. The normalisation of a positive rational valued function $F \in \mathcal{X} \rightarrow \mathbf{Q}_{\geq 0}$ is a probability function, $\hat{F} \in \mathcal{P}$.

The entropy of positive rational valued functions, entropy $\in\left(\mathcal{X} \rightarrow \mathbf{Q}_{\geq 0}\right) \rightarrow$ $\mathbf{Q}_{\geq 0} \ln \mathbf{Q}_{>0}$, is defined as entropy $(N):=-\sum\left(\hat{N}_{x} \ln \hat{N}_{x}: x \in \operatorname{dom}(N), N_{x}>\right.$ 0 ). The entropy of a singleton is zero, entropy $(\{(\cdot, 1)\})=0$. Entropy is maximised in uniform functions as the cardinality tends to infinity, entropy $(X \times$ $\{1 /|X|\})=\ln |X|$.

Given some finite function $F \in \mathcal{X} \rightarrow \mathcal{Y}$, where $0<|F|<\infty$, a probability function may be constructed from its distribution, $\{(y,|X|):(y, X) \in$ $\left.F^{-1}\right\}^{\wedge} \in\left(\mathcal{Y} \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$. The probability function of an arbitrarily chosen finite function is likely to have high entropy.

A probability function $P(z) \in\left(X: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$, parameterised by some parameter $z \in Z=\operatorname{dom}(P)$, has a corresponding likelihood function $L(x) \in$ $Z: \rightarrow \mathbf{Q}_{\geq 0}$, parameterised by coordinate $x \in X$, such that $L(x)(z)=$ $P(z)(x)$. The maximum likelihood estimate $\tilde{z}$ of the parameter, $z$, at coordinate $x \in X$ is the mode of the likelihood function,

$$
\begin{aligned}
\{\tilde{z}\} & =\operatorname{maxd}(L(x)) \\
& =\operatorname{maxd}(\{(z, P(z)(x)): z \in Z\}) \\
& =\left\{z: z \in Z, \forall z^{\prime} \in Z\left(P(z)(x) \geq P\left(z^{\prime}\right)(x)\right)\right\}
\end{aligned}
$$

A list is a object valued function of the natural numbers $\mathcal{L}(\mathcal{X}) \subset \mathbf{N} \rightarrow \mathcal{X}$, such that $\forall L \in \mathcal{L}(\mathcal{X})(L \neq \emptyset \Longrightarrow \operatorname{dom}(L)=\{1 \ldots|L|\})$. Two lists $L, M \in$ $\mathcal{L}(\mathcal{X})$ may be concatenated, concat $(L, M):=L \cup\{(|L|+i, x):(i, x) \in M\}$.

A tree is recursively defined as a tree valued function of objects, $\operatorname{trees}(\mathcal{X})=$ $\mathcal{X} \rightarrow \operatorname{trees}(\mathcal{X})$. The nodes of the tree $T \in \operatorname{trees}(\mathcal{X})$ are $\operatorname{nodes}(T):=T \cup$ $\bigcup\{\operatorname{nodes}(R):(x, R) \in T\}$, and the elements are elements $(T):=\operatorname{dom}(\operatorname{nodes}(T))$. The paths of a tree paths $(T) \subset \mathcal{L}(\mathcal{X})$ is a set of lists. Given a set of lists $Q \subset \mathcal{L}(\mathcal{X})$ a tree can be constructed $\operatorname{tree}(Q) \in \operatorname{trees}(\mathcal{X})$.

### 2.2 Maximum Entropy

Let $X \subset \mathcal{X}$ be a finite set of micro-states, $0<|X|<\infty$. Consider a system of $n$ distinguishable particles, each in a micro-state. The set of states of the system is the set of micro-state functions of particle identifier, $\{1 \ldots n\}: \rightarrow X$. The cardinality of the set of states is $|X|^{n}$.

Each state implies a distribution of particles over micro-states,

$$
I=\left\{\left(R,\left\{(x,|C|):(x, C) \in R^{-1}\right\}\right): R \in\{1 \ldots n\}: \rightarrow X\right\}
$$

That is, a state $R \in\{1 \ldots n\}: \rightarrow X$ has a particle distribution $I(R) \in X \rightarrow$ $\{1 \ldots n\}$ such that $\operatorname{sum}(I(R))=n$.

The cardinality of states for each particle distribution, $I(R)$, is the multinomial coefficient,

$$
\begin{aligned}
W & =\left\{(N,|D|):(N, D) \in I^{-1}\right\} \\
& =\left\{\left(N, \frac{n!}{\prod_{(x, \cdot) \in N} N_{x}!}\right):(N, \cdot) \in I^{-1}\right\}
\end{aligned}
$$

That is, there are $W(I(R))$ states that have the same particle distribution, $I(R)$, as state $R$. The normalisation of the state distribution over particle distributions is a probability function, $\hat{W} \in\left((X \rightarrow\{1 \ldots n\}) \rightarrow \mathbf{Q}_{>0}\right) \cap \mathcal{P}$.

In the case where the number of particles is large, $n \gg \ln n$, the logarithm of the multinomial coefficient of a particle distribution $N \in X \rightarrow\{1 \ldots n\}$ approximates to the scaled entropy,

$$
\ln \frac{n!}{\prod_{(x,) \in N} N_{x}!} \approx n \times \operatorname{entropy}(N)
$$

so the probability of the particle distribution varies with its entropy, $\hat{W}(N) \sim$ entropy $(N)$.

The least probable particle distributions are singletons,

$$
\operatorname{mind}(W)=\{\{(x, n)\}: x \in X\}
$$

because they have only one state, $\forall x \in X(W(\{(x, n)\})=1)$. The entropy of a singleton distribution is zero, entropy $(\{(x, n)\})=0$.

In the case where the number of particles per micro-state is integral, $n /|X| \in$ $\mathbf{N}_{>0}$, the modal particle distribution is the uniform distribution,

$$
\operatorname{maxd}(W)=\{\{(x, n /|X|): x \in X\}\}
$$

The entropy of the uniform distribution is maximised, entropy $(\{(x, n /|X|)$ : $x \in X\})=\ln |X|$.

The normalisation of a particle distribution $N \in X \rightarrow\{1 \ldots n\}$ is a microstate probability function, $\hat{N} \in\left(X \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$, which is independent of the number of particles, $\operatorname{sum}(\hat{N})=1$.

So in the case where a problem domain is parameterised by an unknown micro-state probability function otherwise arbitrarily chosen from a known subset $Q \subseteq\left(X \rightarrow \mathrm{Q}_{\geq 0}\right) \cap \mathcal{P}$, where the number of particles is known to be large, the maximum likelihood estimate $\tilde{P} \in Q$ is the probability function with the greatest entropy, $\forall P \in Q$ (entropy $(\tilde{P}) \geq$ entropy $(P))$ or $\tilde{P} \in \operatorname{maxd}(\{(P, \operatorname{entropy}(P)): P \in Q\})$.

### 2.3 Histograms

### 2.3.1 States, histories and histograms

The set of all variables is $\mathcal{V}$. The set of all values is $\mathcal{W}$. A system $U \in \mathcal{V} \rightarrow \mathrm{P}(\mathcal{W})$ is a functional mapping between variables and non-empty sets of values, $\forall(v, W) \in U(|W|>0)$. The variables of a system is the domain, $\operatorname{vars}(U):=\operatorname{dom}(U)$.

In a system of finite variables, $\forall v \in \operatorname{vars}(U)\left(\left|U_{v}\right|<\infty\right)$, each variable has a set of discrete values. The values need not be ordered. The valency of a variable $v$ is the cardinality of its values, $\left|U_{v}\right|$. The volume of a set of variables in a system $V \subseteq \operatorname{vars}(U)$ is the product of the valencies, $\prod_{v \in V}\left|U_{v}\right| \geq 1$.

The set of states is the set of value valued functions of variable, $\mathcal{S}=$ $\mathcal{V} \rightarrow \mathcal{W}$. The variables of a state $S \in \mathcal{S}$ is the function domain, $\operatorname{vars}(S):=$ $\operatorname{dom}(S)$.

The state, $S$, is in a system $U$ if (i) the variables of the state are variables of the system, $\operatorname{vars}(S) \subseteq \operatorname{vars}(U)$, and (ii) the value of each variable in the state is in the system, $\forall v \in \operatorname{vars}(S)\left(S_{v} \in U_{v}\right)$.

Given a set of variables in a system $V \subseteq \operatorname{vars}(U)$, the cartesian set of all
possible states is $\prod_{v \in V}\left(\{v\} \times U_{v}\right)$, which has cardinality equal to the volume $\prod_{v \in V}\left|U_{v}\right|$.

The variables $V=\operatorname{vars}(S)$ of a state $S$ may be reduced to a given subset $K \subseteq V$ by taking the subset of the variable-value pairs,

$$
S \% K:=\{(v, u):(v, u) \in S, v \in K\}
$$

A set of states $Q \subset \mathcal{S}$ in the same variables $\forall S \in Q(\operatorname{vars}(S)=V)$ may be split into a subset of its variables $K \subseteq V$ and the complement $V \backslash K$,

$$
\operatorname{split}(K, Q)=\{(S \% K, S \%(V \backslash K)): S \in Q\}
$$

Two states $S, T \in \mathcal{S}$ are said to join if their union is also a state, $S \cup T \in \mathcal{S}$. That is, a join is functional,

$$
\begin{aligned}
S \cup T \in \mathcal{S} & \Longleftrightarrow|\operatorname{vars}(S) \cup \operatorname{vars}(T)|=|S \cup T| \\
& \Longleftrightarrow \forall v \in \operatorname{vars}(S) \cap \operatorname{vars}(T)\left(S_{v}=T_{v}\right)
\end{aligned}
$$

States in disjoint variables always join, $\forall S, T \in \mathcal{S}(\operatorname{vars}(S) \cap \operatorname{vars}(T)=$ $\emptyset \Longrightarrow S \cup T \in \mathcal{S})$. States in the same variables only join if they are equal, $\forall S, T \in \mathcal{S}(\operatorname{vars}(S)=\operatorname{vars}(T) \Longrightarrow(S \cup T \in \mathcal{S} \Longleftrightarrow S=T))$.

The set of event identifiers is the universal set $\mathcal{X}$. An event $(x, S)$ is a pair of an event identifier and a state, $(x, S) \in \mathcal{X} \times \mathcal{S}$. A history $H$ is a state valued function of event identifiers, $H \in \mathcal{X} \rightarrow \mathcal{S}$, such that all of the states of its events share the same set of variables, $\forall(x, S),(y, T) \in H(\operatorname{vars}(S)=$ $\operatorname{vars}(T))$. The set of histories is denoted $\mathcal{H} \subset \mathcal{X} \rightarrow \mathcal{S}$.

The set of variables of a history is the set of the variables of any of the events of the history, $\operatorname{vars}(H)=\operatorname{vars}(S)$ where $(x, S) \in H$.

The event identifiers of a history need not be ordered, so a history is not necessarily sequential or chronological.

The inverse of a history, $H^{-1}$, is called the classification. So a classification is an event identifier set valued function of state, $H^{-1} \in \mathcal{S} \rightarrow \mathrm{P}(\mathcal{X})$. The event identifier components are non-empty, $\forall(S, X) \in H^{-1}(X \neq \emptyset)$.

The reduction of a history is the reduction of its events, $H \% V:=\{(x, S \% V)$ : $(x, S) \in H\}$.

The addition operation of histories is defined as the disjoint union of the events if both histories have the same variables,

$$
H_{1}+H_{2}:=\left\{((x, \cdot), S):(x, S) \in H_{1}\right\} \cup\left\{((\cdot, y), T):(y, T) \in H_{2}\right\}
$$

where $\operatorname{vars}\left(H_{1}\right)=\operatorname{vars}\left(H_{2}\right)$. The size of the sum equals the sum of the sizes, $\left|H_{1}+H_{2}\right|=\left|H_{1}\right|+\left|H_{2}\right|$.

The multiplication operation of histories is defined as the product of the events where the states join,

$$
\begin{aligned}
H_{1} * H_{2}:=\{((x, y), S \cup T):(x, S) & \in H_{1},(y, T) \in H_{2}, \\
& \left.\forall v \in \operatorname{vars}(S) \cap \operatorname{vars}(T)\left(S_{v}=T_{v}\right)\right\}
\end{aligned}
$$

The size of the product equals the product of the sizes if the variables are disjoint, $\operatorname{vars}\left(H_{1}\right) \cap \operatorname{vars}\left(H_{2}\right)=\emptyset \quad \Longrightarrow \quad\left|H_{1} * H_{2}\right|=\left|H_{1}\right| \times\left|H_{2}\right|$. The variables of the product is the union of the variables if the size is non-zero, $H_{1} * H_{2} \neq \emptyset \Longrightarrow \operatorname{vars}\left(H_{1} * H_{2}\right)=\operatorname{vars}\left(H_{1}\right) \cup \operatorname{vars}\left(H_{2}\right)$.

The set of all histograms $\mathcal{A}$ is a subset of the positive rational valued functions of states, $\mathcal{A} \subset \mathcal{S} \rightarrow \mathbf{Q}_{\geq 0}$, such that each state of each histogram has the same set of variables, $\forall A \in \mathcal{A} \forall S, T \in \operatorname{dom}(A)(\operatorname{vars}(S)=\operatorname{vars}(T))$.

The set of variables of a histogram $A \in \mathcal{A}$ is the set of the variables of any of the elements of the histogram, $\operatorname{vars}(A)=\operatorname{vars}(S)$ where $(S, q) \in A$. The dimension of a histogram is the cardinality of its variables, $|\operatorname{vars}(A)|$. The counts of a histogram is the range. The states of a histogram is the domain. Define the shorthand $A^{\mathrm{S}}:=\operatorname{dom}(A)$. The size of a histogram is the sum of the counts, $\operatorname{size}(A):=\operatorname{sum}(A)$. The size is always positive, $\operatorname{size}(A) \geq 0$. If the size is non-zero the normalised histogram has a size of one, $\operatorname{size}(A)>0 \Longrightarrow \operatorname{size}(\hat{A})=1$. In this case the normalised histogram is a probability function, $\operatorname{size}(A)>0 \Longrightarrow \hat{A} \in \mathcal{P}$.

The volume of a histogram $A$ of variables $V$ in a system $U$ is the volume of the variables, $\prod_{v \in V}\left|U_{v}\right|$.

A histogram with no variables is called a scalar. The scalar of size $z$ is $\{(\emptyset, z)\}$. Define scalar $(z):=\{(\emptyset, z)\}$. A singleton is a histogram with only one state, $\{(S, z)\}$. A uniform histogram $A$ has unique non-zero count, $|\{c:(S, c) \in A, c>0\}|=1$.

The set of integral histograms is the subset of histograms which have integal counts $\mathcal{A}_{\mathrm{i}}=\mathcal{A} \cap(\mathcal{S} \rightarrow \mathbf{N})$. A unit histogram is a special case of an integral histogram in which all its counts equal one, $\operatorname{ran}(A)=\{1\}$. The size of a unit histogram equals its cardinality, $\operatorname{size}(A)=|A|$. A set of states $Q \subset \mathcal{S}$ in the same variables may be promoted to a unit histogram, $Q^{\mathrm{U}}:=Q \times\{1\} \in \mathcal{A}_{\mathrm{i}}$.

The unit effective histogram of a histogram is the unit histogram of the states where the count is non-zero. Define the shorthand $A^{F}:=\{(S, 1):(S, c) \in$ $A, c>0\} \in \mathcal{A}_{\mathrm{i}}$.

Given a system $U$ define the cartesian histogram of the set of variables $V$ as $V^{\mathrm{C}}:=\left(\prod_{v \in V}\left(\{v\} \times U_{v}\right)\right) \times\{1\} \in \mathcal{A}_{\mathrm{i}}$. The size of the cartesian histogram equals its cardinality which is the volume of the variables, $\operatorname{size}\left(V^{\mathrm{C}}\right)=\left|V^{\mathrm{C}}\right|=$ $\prod_{v \in V}\left|U_{v}\right|$. The unit effective histogram is a subset of the cartesian histogram of its variables, $A^{\mathrm{F}} \subseteq V^{\mathrm{C}}$, where $V=\operatorname{vars}(A)$. A complete histogram has the cartesian set of states, $A^{\mathrm{S}}=V^{\mathrm{CS}}$.

A partition $P$ is a partition of the cartesian states, $P \in \mathrm{~B}\left(V^{\mathrm{CS}}\right)$. The partition is a set of disjoint components, $\forall C, D \in P(C \neq D \Longrightarrow C \cap D=\emptyset)$, that union to equal the cartesian states, $\bigcup P=V^{\mathrm{CS}}$. The unary partition is $\left\{V^{\mathrm{CS}}\right\}$. The self partition is $V^{\mathrm{CS}\{ \}}=\left\{\{S\}: S \in V^{\mathrm{CS}}\right\}$. A partition variable $P \in \operatorname{vars}(U)$ in a system $U$ is such that its set of values equals its set of components, $U_{P}=P$. So the valency of a partition variable is the cardinality of the components, $\left|U_{P}\right|=|P|$.

A regular histogram $A$ of variables $V$ in system $U$ has unique valency of its variables, $\left|\left\{\left|U_{v}\right|: v \in V\right\}\right|=1$. The volume of a regular histogram is $d^{n}=\left|V^{\mathrm{C}}\right|=\prod_{v \in V}\left|U_{v}\right|$, where valency $d$ is such that $\{d\}=\left\{\left|U_{v}\right|: v \in V\right\}$ and dimension $n=|V|$.

The counts of the integral histogram $A \in \mathcal{A}_{\mathrm{i}}$ of a history $H \in \mathcal{H}$ are the cardinalities of the event identifier components of its classification, $A=$ $\operatorname{histogram}(H)$ where histogram $(H):=\left\{(S,|X|):(S, X) \in H^{-1}\right\}$. In this case the histogram is a distribution of events over states. If the history is bijective, $H \in \mathcal{X} \leftrightarrow \mathcal{S}$, then its histogram is a unit histogram, $A=\operatorname{ran}(H) \times\{1\}$.

A sub-histogram $A$ of a histogram $B$ is such that the effective states of $A$ are a subset of the effective states of $B$ and the counts of $A$ are less than or equal to those of $B, A \leq B:=A^{\mathrm{FS}} \subseteq B^{\mathrm{FS}} \wedge \forall S \in A^{\mathrm{FS}}\left(A_{S} \leq B_{S}\right)$. The histogram of a sub-history $G \subseteq H$ is a sub-histogram, histogram $(G) \leq \operatorname{histogram}(H)$.

The reduction of a histogram is the reduction of its states, adding the counts where two different states reduce to the same state,

$$
A \% V:=\left\{\left(R, \sum(c:(T, c) \in A, T \supseteq R)\right): R \in\left\{S \% V: S \in A^{\mathrm{S}}\right\}\right\}
$$

Reduction leaves the size of a histogram unchanged, $\operatorname{size}(A \% V)=\operatorname{size}(A)$, but the number of states may be fewer, $\left|(A \% V)^{\mathrm{S}}\right| \leq\left|A^{\mathrm{S}}\right|$. The reduction to the empty set is a scalar, $A \% \emptyset=\{(\emptyset, z)\}$, where $z=\operatorname{size}(A)$. The histogram of a reduction of a history equals the reduction of the histogram of the history,

$$
\operatorname{histogram}(H \% V)=\operatorname{histogram}(H) \% V
$$

The addition of histograms $A$ and $B$ is defined,

$$
\begin{aligned}
A+ & B:= \\
& \left\{(S, c):(S, c) \in A, S \notin B^{\mathrm{S}}\right\} \cup \\
& \{(S, c+d):(S, c) \in A,(T, d) \in B, S=T\} \cup \\
& \left\{(T, d):(T, d) \in B, T \notin A^{\mathrm{S}}\right\}
\end{aligned}
$$

where $\operatorname{vars}(A)=\operatorname{vars}(B)$. The sizes add, $\operatorname{size}(A+B)=\operatorname{size}(A)+\operatorname{size}(B)$. The histogram of an addition of histories equals the addition of the histograms of the histories,

$$
\operatorname{histogram}\left(H_{1}+H_{2}\right)=\operatorname{histogram}\left(H_{1}\right)+\operatorname{histogram}\left(H_{2}\right)
$$

The multiplication of histograms $A$ and $B$ is the product of the counts where the states join,
$A * B:=\left\{(S \cup T, c d):(S, c) \in A,(T, d) \in B, \forall v \in \operatorname{vars}(S) \cap \operatorname{vars}(T)\left(S_{v}=T_{v}\right)\right\}$
If the variables are disjoint, the sizes multiply, $\operatorname{vars}(A) \cap \operatorname{vars}(B)=\emptyset \Longrightarrow$ $\operatorname{size}(A * B)=\operatorname{size}(A) \times \operatorname{size}(B)$. Multiplication by a scalar scales the size, $\operatorname{size}(\operatorname{scalar}(z) * A)=z \times \operatorname{size}(A)$. The histogram of a multiplication of histories equals the multiplication of the histograms of the histories,

$$
\operatorname{histogram}\left(H_{1} * H_{2}\right)=\operatorname{histogram}\left(H_{1}\right) * \operatorname{histogram}\left(H_{2}\right)
$$

The reciprocal of a histogram is $1 / A:=\{(S, 1 / c):(S, c) \in A, c>0\}$. Define histogram division as $B / A:=B *(1 / A)$.

A histogram $A$ is causal in a subset of its variables $K \subset V$ if the reduction of the effective states to the subset, $K$, is functionally related to the reduction to the complement, $V \backslash K$,

$$
\left\{(S \% K, S \%(V \backslash K)): S \in A^{\mathrm{FS}}\right\} \in K^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}
$$

or

$$
\operatorname{split}\left(K, A^{\mathrm{FS}}\right) \in K^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}
$$

A histogram A is diagonalised if no pair of effective states shares any value, $\forall S, T \in A^{\mathrm{FS}}(S \neq T \Longrightarrow S \cap T=\emptyset)$. A diagonalised histogram $A$ is fully diagonalised if its effective cardinality equals the minimum valency of its variables, $\left|A^{\mathrm{F}}\right|=\operatorname{minr}\left(\left\{\left(v,\left|U_{v}\right|\right): v \in V\right\}\right)$. The cardinality of the effective states of a fully diagonalised regular histogram is the valency, $\left|A^{\mathrm{F}}\right|=d$, where $\{d\}=\left\{\left|U_{v}\right|: v \in V\right\}$. In a diagonalised histogram the causality is bijective or equational,

$$
\forall u, w \in V\left(\left\{(S \%\{u\}, S \%\{w\}): S \in A^{\mathrm{FS}}\right\} \in\{u\}^{\mathrm{CS}} \leftrightarrow\{w\}^{\mathrm{CS}}\right)
$$

Given some slice state $R \in K^{\mathrm{CS}}$, where $K \subset V$ and $V=\operatorname{vars}(A)$, the slice histogram, $A *\{R\}^{\mathrm{U}} \subset A$, is said to be contingent on the incident slice state. For example, if the slice histogram is diagonalised, diagonal $\left(A *\{R\}^{\mathrm{U}} \% ~(V \backslash\right.$ $K)$ ), then the histogram, $A$, is said to be contingently diagonalised.

The perimeters of a histogram $A \in \mathcal{A}$ is the set of its reductions to each of its variables, $\{A \%\{w\}: w \in V\}$, where $V=\operatorname{vars}(A)$. The independent of a histogram is the product of the normalised perimeters scaled to the size,

$$
A^{\mathrm{X}}:=Z * \prod_{w \in V} \hat{A} \%\{w\}
$$

where $z=\operatorname{size}(A)$ and $Z=\operatorname{scalar}(z)=A \% \emptyset$. The independent of a histogram is such that (i) the states are a superset, $A^{\mathrm{XS}} \supseteq A^{\mathrm{S}}$, (ii) the size is unchanged, $\operatorname{size}\left(A^{\mathrm{X}}\right)=\operatorname{size}(A)$, and (iii) the variables are unchanged, $\operatorname{vars}\left(A^{\mathrm{X}}\right)=\operatorname{vars}(A)$. A histogram is said to be independent if it equals its independent, $A=A^{\mathrm{X}}$. The independent of an independent histogram is the independent, $A^{\mathrm{XX}}=A^{\mathrm{X}}$. The scaled product of (i) any reduction of a normalised independent histogram to any subset of its variables $K \subseteq$ $V$, and (ii) the reduction to the complement, $V \backslash K$, is the independent, $Z *\left(\hat{A}^{\mathrm{X}} \% K\right) *\left(\hat{A}^{\mathrm{X}} \%(V \backslash K)\right)=A^{\mathrm{X}}$.

Scalar histograms are independent, $\{(\emptyset, z)\}=\{(\emptyset, z)\}^{X}$. Singleton histograms, $\left|A^{\mathrm{F}}\right|=1$, are independent, $\{(S, z)\}=\{(S, z)\}^{\mathrm{X}}$. If the histogram is monovariate, $|V|=1$, then it is independent $A=A \%\{w\}=A^{\mathrm{X}}$ where $\{w\}=V$. Uniform-cartesian histograms, which are scalar multiples of the cartesian, $A=V_{z}^{\mathrm{C}}$ where $V_{z}^{\mathrm{C}}=\operatorname{scalar}(z / v) * V^{\mathrm{C}}, z=\operatorname{size}(A)$ and $v=\left|V^{\mathrm{C}}\right|$, are independent, $V_{z}^{\mathrm{C}}=V_{z}^{\mathrm{CX}}$.

A completely effective pluri-variate independent histogram, $A^{\mathrm{XF}}=V^{\mathrm{C}}$ where $|V|>1$, for which all of the variables are pluri-valent, $\forall w \in V\left(\left|U_{w}\right|>1\right)$, must be non-causal,

$$
\begin{aligned}
& \forall K \subset V(K \notin\{\emptyset, V\} \Longrightarrow \\
& \left.\quad\left\{(S \% K, S \%(V \backslash K)): S \in A^{\mathrm{XFS}}\right\} \notin K^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}\right)
\end{aligned}
$$

The set of substrate histories $\mathcal{H}_{U, V, z}$ is the set of histories having event identifiers $\{1 \ldots z\}$, fixed size $z$ and fixed variables $V$,

$$
\begin{aligned}
\mathcal{H}_{U, V, z} & :=\{1 \ldots z\}: \rightarrow V^{\mathrm{CS}} \\
& =\left\{H: H \subseteq\{1 \ldots z\} \times V^{\mathrm{CS}}, \operatorname{dom}(H)=\{1 \ldots z\},|H|=z\right\}
\end{aligned}
$$

The cardinality of the substrate histories is $\left|\mathcal{H}_{U, V, z}\right|=v^{z}$ where $v=\left|V^{\mathrm{C}}\right|$. If the volume, $v$, is finite, the set of substrate histories is finite, $\left|\mathcal{H}_{U, V, z}\right|<\infty$.

The corresponding set of integral substrate histograms $\mathcal{A}_{U, \mathrm{i}, V, z}$ is the set of complete integral histograms in variables $V$ with size $z$,

$$
\begin{aligned}
\mathcal{A}_{U, \mathrm{i}, V, z} & :=\left\{\operatorname{histogram}(H): H \in \mathcal{H}_{U, V, z}\right\} \\
& =\left\{A: A \in V^{\mathrm{CS}}: \rightarrow\{0 \ldots z\}, \operatorname{size}(A)=z\right\}
\end{aligned}
$$

Note that the histogram function is redefined here to return complete histograms, histogram $(H):=\left\{(S,|X|):(S, X) \in H^{-1}\right\}+V^{\mathrm{CS}} \times\{0\}$.

The cardinality of integral substrate histograms is the cardinality of weak compositions,

$$
\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right|=\frac{(z+v-1)!}{z!(v-1)!}
$$

If the volume, $v$, is finite, the set of integral substrate histograms is finite, $\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right|<\infty$.

### 2.3.2 Entropy and alignment

The entropy of a non-zero histogram $A \in \mathcal{A}$ is defined as the expected negative logarithm of the normalised counts,

$$
\operatorname{entropy}(A):=-\sum_{S \in A^{\mathrm{FS}}} \hat{A}_{S} \ln \hat{A}_{S}
$$

(Note that in conventional terminology the entropy would be written $H[V]$.) The sized entropy is $z \times \operatorname{entropy}(A)$ where $z=\operatorname{size}(A)$. The entropy of a singleton is zero, $z \times \operatorname{entropy}(\{(\cdot, z)\})=0$. Entropy is highest in cartesian histograms, which are uniform and have maximum effective volume. The maximum sized entropy is $z \times \operatorname{entropy}\left(V_{z}^{\mathrm{C}}\right)=z \ln v$ where $v=\left|V^{\mathrm{C}}\right|$.

Given a histogram $A$ and a set of query variables $K \subset V$, the scaled label entropy is the degree to which the histogram is ambiguous or non-causal in the query variables, $K$. It is the sum of the sized entropies of the contingent slices reduced to the label variables, $V \backslash K$,

$$
\sum_{R \in(A \% K)^{\mathrm{FS}}}(A \% K)_{R} \times \operatorname{entropy}\left(A *\{R\}^{\mathrm{U}} \%(V \backslash K)\right)
$$

The scaled label entropy is also known as the scaled query conditional entropy,

$$
\begin{aligned}
& \sum_{R \in(A \% K)^{\mathrm{FS}}}(A \% K)_{R} \times \operatorname{entropy}\left(A *\{R\}^{\mathrm{U}} \%(V \backslash K)\right) \\
= & -\sum_{S \in A^{\mathrm{FS}}} A_{S} \ln \frac{A_{S}}{\left(A \% K * V^{\mathrm{C}}\right)_{S}} \\
= & -\sum_{S \in A^{\mathrm{FS}}} A_{S} \ln (A /(A \% K))_{S} \\
= & z \times \operatorname{entropy}(A)-z \times \operatorname{entropy}(A \% K)
\end{aligned}
$$

The query conditional entropy is a special case of negative relative entropy, $\operatorname{entropy}(A)-\operatorname{entropy}(A \% K)=-$ entropyRelative $(A, A \% K)$. See appendix 'Entropy and Gibbs' inequality'. (Note that in conventional terminology the query conditional entropy would be written $H[V \backslash K \mid K]=H[V]-H[K]$. See the discussion of Bayes' theorem in section 'Transforms and probability', below.)

When the histogram, $A$, is causal in the query variables, $\operatorname{split}\left(K, A^{\mathrm{FS}}\right) \in$ $K^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}$, the label entropy is zero because each slice is an effective singleton, $\forall R \in(A \% K)^{\mathrm{FS}}\left(\left|A^{\mathrm{F}} *\{R\}^{\mathrm{U}}\right|=1\right)$. In this case the label state is unique for every effective query state. By contrast, when the label variables are independent of the query variables, $A=Z * \hat{A} \% K * \hat{A} \%(V \backslash K)$, the label entropy is maximised.

The multinomial coefficient of a non-zero integral histogram $A \in \mathcal{A}_{\mathrm{i}}$ is

$$
\frac{z!}{\prod_{S \in A^{S}} A_{S}!} \in \mathbf{N}_{>0}
$$

where $z=\operatorname{size}(A)>0$. In the case where the histogram is non-integral the multinomial coefficient is defined by the unit-translated gamma function,

$$
\frac{\Gamma_{!} z}{\prod_{S \in A^{S}} \Gamma_{!} A_{S}}
$$

Given an arbitrary substrate history $H \in \mathcal{H}_{U, V, z}$ and its histogram $A=$ histogram $(H)$, the cardinality of histories having the same histogram, $A$, is the multinomial coefficient,

$$
\left|\left\{G: G \in \mathcal{H}_{U, V, z}, \operatorname{histogram}(G)=A\right\}\right|=\frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!}
$$

In the case where the counts are not small, $z \gg \ln z$, the logarithm of the multinomial coefficient approximates to the sized entropy,

$$
\ln \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \approx z \times \operatorname{entropy}(A)
$$

so the entropy, entropy $(A)$, is a measure of the probability of the histogram of a randomly chosen history. Singleton histograms are least probable and uniform histograms are most probable.

The sized relative entropy between a histogram and its independent is the sized mutual entropy,

$$
\sum_{S \in A^{\mathrm{FS}}} A_{S} \ln \frac{A_{S}}{A_{S}^{\mathrm{X}}}
$$

It can be shown that the size scaled expected logarithm of the independent with respect to the histogram equals the size scaled expected logarithm of the independent with respect to the independent,

$$
\sum_{S \in A^{\mathrm{FS}}} A_{S} \ln A_{S}^{\mathrm{X}}=\sum_{S \in A^{\mathrm{xFS}}} A_{S}^{\mathrm{X}} \ln A_{S}^{\mathrm{X}}
$$

so the sized mutual entropy is the difference between the sized independent entropy and the sized histogram entropy,

$$
\sum_{S \in A^{\mathrm{FS}}} A_{S} \ln \frac{A_{S}}{A_{S}^{\mathrm{X}}}=z \times \operatorname{entropy}\left(A^{\mathrm{X}}\right)-z \times \operatorname{entropy}(A)
$$

The sized mutual entropy can be viewed as a measure of the probability of the independent, $A^{\mathrm{X}}$, relative to the histogram, $A$, given arbitrary substrate history. Equivalently, sized mutual entropy can be viewed as a measure of
the surprisal of the histogram, $A$, relative to the independent, $A^{\mathrm{X}}$. That is, sized mutual entropy is a measure of the dependency between the variables in the histogram, $A$.

The sized mutual entropy is the sized relative entropy so it is always positive,

$$
z \times \operatorname{entropy}\left(A^{\mathrm{X}}\right)-z \times \operatorname{entropy}(A) \geq 0
$$

and so the independent entropy is always greater than or equal to the histogram entropy

$$
\operatorname{entropy}\left(A^{\mathrm{X}}\right) \geq \operatorname{entropy}(A)
$$

That is, histograms of substrate histories arbitrarily chosen from a uniform distribution are probably independent or nearly independent. The expected sized mutual entropy is low.

An example of a dependency between variables is where a histogram $A$ is causal in a subset of its variables $K \subset V$. In this case the histogram cannot be independent, $A \neq A^{\mathrm{X}}$, and so the sized mutual entropy must be greater than zero,

$$
\begin{aligned}
&\left\{(S \% K, S \%(V \backslash K)): S \in A^{\mathrm{FS}}\right\} \in K^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}} \Longrightarrow \\
& z \times \operatorname{entropy}\left(A^{\mathrm{X}}\right)-z \times \operatorname{entropy}(A)>0
\end{aligned}
$$

The alignment of a histogram $A \in \mathcal{A}$ is defined

$$
\operatorname{algn}(A):=\sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}-\sum_{S \in A^{\mathrm{xS}}} \ln \Gamma_{!} A_{S}^{\mathrm{X}}
$$

where $\Gamma_{!}$is the unit-translated gamma function.
In the case where both the histogram and its independent are integral, $A, A^{\mathrm{X}} \in$ $\mathcal{A}_{\mathrm{i}}$, then the alignment is the difference between the sum log-factorial counts of the histogram and its independent,

$$
\operatorname{algn}(A)=\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!-\sum_{S \in A^{\mathrm{XS}}} \ln A_{S}^{\mathrm{X}}!
$$

Alignment is the logarithm of the ratio of the independent multinomial coefficient to the multinomial coefficient,

$$
\operatorname{algn}(A)=\ln \left(\frac{z!}{\prod_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}}!} / \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!}\right)
$$

so alignment is the logarithm of the probability of the independent, $A^{\mathrm{X}}$, relative to the histogram, $A$. Equivalently, alignment is the logarithm of the surprisal of the histogram, $A$, relative to the independent, $A^{\mathrm{X}}$. Alignment is a measure of the dependency between the variables in the histogram, $A$.

Alignment is approximately equal to the sized mutual entropy,

$$
\begin{aligned}
\operatorname{algn}(A) & \approx z \times \operatorname{entropy}\left(A^{\mathrm{X}}\right)-z \times \operatorname{entropy}(A) \\
& =\sum_{S \in A^{\mathrm{FS}}} A_{S} \ln \frac{A_{S}}{A_{S}^{\mathrm{X}}}
\end{aligned}
$$

so the histogram of an arbitrary history usually has low alignment. Note that, because sized entropy is only an approximation to the logarithm of the multinomial coefficient, especially at low sizes, alignment is the better measure of the surprisal of the histogram, $A$, relative to the independent, $A^{\mathrm{X}}$, than sized mutual entropy.

The alignment of an independent histogram, $A=A^{\mathrm{X}}$, is zero. In particular, scalar histograms, $V=\emptyset$, mono-variate histograms, $|V|=1$, uniform cartesian histograms, $A=V_{z}^{\mathrm{C}}$, and effective singleton histograms, $\left|A^{\mathrm{F}}\right|=1$, all have zero alignment.

The maximum alignment of a histogram $A$ occurs when the histogram is both uniform and fully diagonalised. No pair of effective states shares any value, $\forall S, T \in A^{\mathrm{FS}}(S \neq T \Longrightarrow S \cap T=\emptyset)$, and all counts are equal along the diagonal, $\forall S, T \in A^{\mathrm{FS}}\left(A_{S}=A_{T}\right)$. The maximum alignment of a regular histogram with dimension $n=|V|$ and valency $d$ is

$$
d \ln \Gamma!\frac{z}{d}-d^{n} \ln \Gamma!\frac{z}{d^{n}}
$$

The maximum alignment is approximately $z \ln d^{n-1}=z \ln v / d$, where $v=d^{n}$. It can be compared to the maximum sized entropy of the 'co-histogram' reduced by one variable along the diagonal.

Although alignment varies against sized entropy, $\operatorname{algn}(A) \sim-z \times \operatorname{entropy}(A)$, the maximum alignment does not occur when the entropy is minimised. At minimum entropy the histogram is a singleton, but the alignment is zero because singletons are independent.

An example of an aligned histogram $A$ is where the histogram is causal in a
subset of its variables $K \subset V$. In this case the histogram cannot be independent, $A \neq A^{\mathrm{X}}$, and so the alignment must be greater than zero,

$$
\left\{(S \% K, S \%(V \backslash K)): S \in A^{\mathrm{FS}}\right\} \in K^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}} \quad \Longrightarrow \quad \operatorname{algn}(A)>0
$$

At maximum alignment the histogram is fully diagonalised, so all pairs of variables are necessarily bijectively causal or equational,

$$
\forall u, w \in V\left(\left\{(S \%\{u\}, S \%\{w\}): S \in A^{\mathrm{FS}}\right\} \in\{u\}^{\mathrm{CS}} \leftrightarrow\{w\}^{\mathrm{CS}}\right)
$$

The alignment is approximately equal to the scaled mutual entropy, so the alignment varies against the scaled label entropy or scaled query conditional entropy,

$$
\begin{aligned}
\operatorname{algn}(A) & \approx z \times \operatorname{entropy}\left(A^{\mathrm{X}}\right)-z \times \operatorname{entropy}(A) \\
& \sim z \times \operatorname{entropy}(A \% K)+z \times \operatorname{entropy}(A \%(V \backslash K))-z \times \operatorname{entropy}(A) \\
& \sim-(z \times \operatorname{entropy}(A)-z \times \operatorname{entropy}(A \% K)) \\
& =-\sum_{R \in(A \% K)^{\mathrm{FS}}}(A \% K)_{R} \times \operatorname{entropy}\left(A *\{R\}^{\mathrm{U}} \%(V \backslash K)\right)
\end{aligned}
$$

The conditional entropy is directed from the query variables to the label variables, whereas the alignment is symmetrical with respect to the variables.

### 2.3.3 Encoding and compression

A substrate history probability function $P \in\left(\mathcal{H}_{U, V, z}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$ is a normalised distribution over substrate histories, $\sum\left(P_{H}: H \in \mathcal{H}_{U, V, z}\right)=1$. The entropy of the probability function is entropy $(P)$. Note that history probability function entropy is not to be confused with histogram entropy. A history probability function is a distribution over histories, $\mathcal{H}_{U, V, z} \rightarrow \mathbf{Q}_{\geq 0}$, whereas a histogram is a distribution of events over states, $V^{\mathrm{CS}} \rightarrow \mathbf{Q}_{\geq 0}$.

History coders define the conversion of lists of histories, $\mathcal{L}(\mathcal{H})$, to and from the natural numbers, $\mathbf{N}$. A substrate history coder $C \in \operatorname{coders}\left(\mathcal{H}_{U, V, z}\right)$ defines an encode function of any list of substrate histories into a positive integer, encode $(C) \in \mathcal{L}\left(\mathcal{H}_{U, V, z}\right): \rightarrow \mathbf{N}$, and the corresponding decode function of the integer back into the list of histories, $\operatorname{decode}(C) \in \mathbf{N} \times \mathbf{N} \rightarrow: \mathcal{L}\left(\mathcal{H}_{U, V, z}\right)$, given the length of the list.

A third function is the space function, space $(C) \in \mathcal{H}_{U, V, z}: \rightarrow \ln \mathbf{N}_{>0}$, which defines the logarithm of the cardinality of the encoding states of a substrate
history. The encoding integer of a single history is always less than this cardinality, $\forall H \in \mathcal{H}_{U, V, z}(\operatorname{encode}(C)(\{(1, H)\})<\exp (\operatorname{space}(C)(H)))$. The space of an encoded list of histories is the sum of the spaces of the histories. The space function is also denoted $C^{\text {s }}=\operatorname{space}(C)$.

Given a substrate history probability function $P \in\left(\mathcal{H}_{U, V, z}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$, the expected substrate history space is $\sum\left(P_{H} C^{\mathrm{s}}(H): H \in \mathcal{H}_{U, V, z}\right)$. The expected space is always greater than or equal to the probability function entropy (or Shannon entropy in nats), $\sum\left(P_{H} C^{\mathrm{s}}(H): H \in \mathcal{H}_{U, V, z}\right) \geq \operatorname{entropy}(P)$.

A minimal history coder $C_{\mathrm{m}, U, V, z} \in \operatorname{coders}\left(\mathcal{H}_{U, V, z}\right)$ encodes the history by encoding the index of an enumeration of the entire set of substrate histories, encode $\left(C_{\mathrm{m}, U, V, z}\right)(\{(1, H)\}) \in\left\{0 \ldots v^{z}-1\right\}$. The space is fixed, $C_{\mathrm{m}, U, V, z}^{\mathrm{s}}(H)=$ $\ln \left|\mathcal{H}_{U, V, z}\right|=z \ln v$. In the case where the probability function is uniform, $P=\mathcal{H}_{U, V, z} \times\left\{1 / v^{z}\right\}$, the expected space equals the probability function entropy, $\sum\left(P_{H} C_{\mathrm{m}, U, V, z}^{\mathrm{s}}(H): H \in \mathcal{H}_{U, V, z}\right)=\operatorname{entropy}(P)=z \ln v$. In other words, when the history is arbitrary then the minimal history coder has the least expected space.

There are two canonical history coders, the index history coder $C_{\mathrm{H}}$ and the classification coder $C_{\mathrm{G}}$. The index substrate history coder $C_{\mathrm{H}, U, V, z} \in$ $\operatorname{coders}\left(\mathcal{H}_{U, V, z}\right)$ is the simpler of the two. It encodes each history by indexing the volume for each event. The space of an index into a volume $v=\left|V^{\mathrm{CS}}\right|$ is $\ln v$. So the total space of any substrate history $H \in \mathcal{H}_{U, V, z}$ is

$$
C_{\mathrm{H}, U, V, z}^{\mathrm{s}}(H)=z \ln v
$$

The space is fixed because it does not depend on the histogram, $A$. The index history space equals the minimal history space, $C_{\mathrm{H}, U, V, z}^{\mathrm{s}}(H)=C_{\mathrm{m}, U, V, z}^{\mathrm{s}}(H)=$ $z \ln v$, but the encode functions are different. In the case of an arbitrary history, or uniform history probability function, the index history coder also has least expected space.

The classification substrate history coder $C_{\mathrm{G}, U, V, z} \in \operatorname{coders}\left(\mathcal{H}_{U, V, z}\right)$ encodes each history in two steps. First the histogram is encoded by choosing one of the integral substrate histograms, $\mathcal{A}_{U, \mathrm{i}, V, z}$. The choice has fixed space

$$
\ln \left|\mathcal{A}_{U, \mathrm{i}, V, z}\right|=\ln \frac{(z+v-1)!}{z!(v-1)!}
$$

Given the histogram, $A$, the cardinality of classifications equals the multinomial coefficient. Now the choice of the classification, $H^{-1}$, is encoded in a
space equal to the logarithm of the multinomial coefficient,

$$
\ln \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!}
$$

The total space to encode the history in the classification substrate history coder is

$$
C_{\mathrm{G}, U, V, z}^{\mathrm{s}}(H)=\ln \frac{(z+v-1)!}{z!(v-1)!}+\ln \frac{z!}{\prod_{S \in A^{\mathrm{s}}} A_{S}!}
$$

The space is not fixed because it depends on the histogram, $A$.
The classification space may be approximated in terms of sized entropy,

$$
C_{\mathrm{G}, U, V, z}^{\mathrm{s}}(H) \approx(z+v) \ln (z+v)-z \ln z-v \ln v+z \times \operatorname{entropy}(A)
$$

The maximum sized entropy, $z \times$ entropy $(A)$, is $z \ln v$, so when the entropy is high the classification space is greater than the index space, $C_{\mathrm{G}, U, V, z}^{\mathrm{s}}(H)>$ $C_{\mathrm{H}, U, V, z}^{\mathrm{s}}(H)$, but when the entropy is low the classification space is less than the index space, $C_{\mathrm{G}, U, V, z}^{\mathrm{s}}(H)<C_{\mathrm{H}, U, V, z}^{\mathrm{s}}(H)$. The break-even sized entropy is approximately

$$
z \times \operatorname{entropy}(A) \approx z \ln v-((z+v) \ln (z+v)-z \ln z-v \ln v)
$$

In the case where the size is much less than the volume, $z \ll v$, the break-even sized entropy is approximately $z \times \operatorname{entropy}(A) \approx z \ln z$.

### 2.4 Induction without model

Induction may be defined as the determination of the likely properties of unknown history probability functions.

Let $P$ be a substrate history probability function, $P \in\left(\mathcal{H}_{U, V, z}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$. Let the domain of the probability function, $\operatorname{dom}(P)=\mathcal{H}_{U, V, z}$, be known. The simplest case of induction is that nothing else is known about the probability function, $P$. If the probability function is assumed to be the normalisation of the distribution of a finite history valued function of undefined particle, $\mathcal{X} \rightarrow \mathcal{H}$, and this particle function is assumed to be chosen arbitrarily, then the maximum likelihood estimate $\tilde{P}$ for the probability function, $P$, maximises the entropy, entropy $(\tilde{P})$, at the mode. So the likely history probability function, $\tilde{P}$, is the uniform distribution,

$$
\tilde{P}=\mathcal{H}_{U, V, z} \times\left\{1 / v^{z}\right\}
$$

That is, the likely substrate histories are arbitrary or random.

The next case is where a history $H \in \mathcal{H}_{U, V, z}$ is known to be necessary, $P(H)=1$. In this case the probability function, $P$, is,

$$
\begin{aligned}
P= & \{(H, 1)\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \neq H\right\}
\end{aligned}
$$

If the history, $H$, is known, then the probability function, $P$, is known. The maximum likelihood estimate equals the probability function, $\tilde{P}=P$. The entropy is zero, entropy $(\tilde{P})=0$.

### 2.4.1 Classical induction

In classical induction the history probability functions are constrained by histogram.

Let his $=$ histogram. Now consider the case where the histogram $A \in \mathcal{A}_{U, \mathrm{i}, V, z}$ is known to be necessary, $\sum\left(P(H): H \in \mathcal{H}_{U, V, z}, \operatorname{his}(H)=A\right)=1$. The maximum likelihood estimate which maximises the entropy, entropy $(\tilde{P})$, is

$$
\begin{aligned}
\tilde{P}= & \left\{(H, 1): H \in \mathcal{H}_{U, V, z}, \operatorname{his}(H)=A\right\}^{\wedge} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, \operatorname{his}(G) \neq A\right\} \\
= & \left\{\left(H, 1 / \frac{z!}{\left.\left.\overline{\prod_{S \in A^{\mathrm{S}}} A_{S}!}\right): H \in \mathcal{H}_{U, V, z}, \operatorname{his}(H)=A\right\}}\right.\right. \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, \operatorname{his}(G) \neq A\right\}
\end{aligned}
$$

where ()$^{\wedge}=$ normalise. That is, the maximum likelihood estimate, $\tilde{P}$, is such that all histories with the histogram, his $(H)=A$, are uniformly probable and all other histories, $\operatorname{his}(G) \neq A$, are impossible, $\tilde{P}(G)=0$. If the histogram, $A$, is known, then the likely probability function, $\tilde{P}$, is known. Note that the likely history probability function entropy varies with the histogram entropy, $\operatorname{entropy}(\tilde{P}) \sim \operatorname{entropy}(A)$.

Next consider the case where either histogram $A$ or histogram $B$ are known to be necessary, $\sum\left(P(H): H \in \mathcal{H}_{U, V, z},(\operatorname{his}(H)=A \vee \operatorname{his}(H)=B)\right)=1$. The maximum likelihood estimate which maximises the entropy, entropy $(\tilde{P})$,
is

$$
\begin{aligned}
\tilde{P}= & \left\{(H, 1): H \in \mathcal{H}_{U, V, z},(\operatorname{his}(H)=A \vee \operatorname{his}(H)=B)\right\}^{\wedge} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, \operatorname{his}(G) \neq A, \operatorname{his}(G) \neq B\right\} \\
= & \left\{\left(H, 1 /\left(\frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!}+\frac{z!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}\right)\right):\right. \\
& \left.H \in \mathcal{H}_{U, V, z},(\operatorname{his}(H)=A \vee \operatorname{his}(H)=B)\right\} \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, \operatorname{his}(G) \neq A, \operatorname{his}(G) \neq B\right\}
\end{aligned}
$$

That is, the maximum likelihood estimate, $\tilde{P}$, is such that all histories with either histogram, $A$ or $B$, are uniformly probable and all other histories, $\operatorname{his}(G) \neq A$ and $\operatorname{his}(G) \neq B$, are impossible, $\tilde{P}(G)=0$. If the histograms, $A$ and $B$, are known, then the likely probability function, $\tilde{P}$, is known.

Given a history $H_{E} \in \mathcal{H}_{U, V, z_{E}}$, of size $z_{E}=\left|H_{E}\right|$, consider the case where its subsets of size $z$ are known to be necessary, $\sum\left(P(H): H \subseteq H_{E},|H|=\right.$ $z)=1$. The given history, $H_{E}$, is called the distribution history. A subset $H \subseteq H_{E}$ is a sample history drawn from the distribution history, $H_{E}$. The maximum likelihood estimate which maximises the entropy, entropy $(\tilde{P})$, is

$$
\begin{aligned}
\tilde{P}= & \left\{(H, 1): H \subseteq H_{E},|H|=z\right\}^{\wedge} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z},|G| \neq z\right\} \\
= & \left\{\left(H, 1 /\binom{z_{E}}{z}\right): H \subseteq H_{E},|H|=z\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z},|G| \neq z\right\}
\end{aligned}
$$

That is, the maximum likelihood estimate, $\tilde{P}$, is such that all drawn histories $H \subseteq H_{E}$ of size $|H|=z$ are uniformly probable and all other histories, $G \nsubseteq H_{E}$ or $|G| \neq z$, are impossible, $\tilde{P}(G)=0$. If the distribution histogram, $H_{E}$, is known, then the likely probability function, $\tilde{P}$, is known.

Now consider the case where the drawn histogram $A$ is known to be necessary, $\sum\left(P(H): H \subseteq H_{E}, \operatorname{his}(H)=A\right)=1$. The maximum likelihood
estimate which maximises the entropy, entropy $(\tilde{P})$, is

$$
\begin{aligned}
\tilde{P}= & \left\{(H, 1): H \subseteq H_{E}, \operatorname{his}(H)=A\right\}^{\wedge} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, \operatorname{his}(G) \neq A\right\} \\
= & \left\{\left(H, 1 / \prod_{S \in A^{\mathrm{S}}}\binom{E_{S}}{A_{S}}\right): H \subseteq H_{E}, \operatorname{his}(H)=A\right\} \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, \operatorname{his}(G) \neq A\right\}
\end{aligned}
$$

where the distribution histogram $E=\operatorname{his}\left(H_{E}\right)$.
That is, the maximum likelihood estimate, $\tilde{P}$, is such that all drawn histories $H \subseteq H_{E}$ with the histogram, $\operatorname{his}(H)=A$, are uniformly probable and all other histories, $G \nsubseteq H_{E}$ or $\operatorname{his}(G) \neq A$, are impossible, $\tilde{P}(G)=0$. If the histogram, $A$, is known and the distribution histogram, $H_{E}$, is known, then the likely probability function, $\tilde{P}$, is known.

The historical distribution $Q_{\mathrm{h}, U}$ is defined

$$
Q_{\mathrm{h}, U}(E, z)(A):=\prod_{S \in A^{\mathrm{S}}}\binom{E_{S}}{A_{S}}=\prod_{S \in A^{\mathrm{S}}} \frac{E_{S}!}{A_{S}!\left(E_{S}-A_{S}\right)!}
$$

where $A \leq E$. The frequency of histogram $A$ in the historical distribution, $Q_{\mathrm{h}, U}$, parameterised by draw $(E, z)$, is the cardinality of histories drawn without replacement having histogram $A$,

$$
Q_{\mathrm{h}, U}(E, z)(A)=\left|\left\{H: H \subseteq H_{E}, \operatorname{his}(H)=A\right\}\right|
$$

The historical probability distribution is normalised,

$$
\hat{Q}_{\mathrm{h}, U}(E, z)(A):=1 /\binom{z_{E}}{z} \times Q_{\mathrm{h}, U}(E, z)(A)
$$

The likely history probability function, $\tilde{P}$, can be re-written in terms of the historical distribution,

$$
\begin{aligned}
\tilde{P}= & \left\{\left(H, 1 / Q_{\mathrm{h}, U}(E, z)(A)\right): H \subseteq H_{E}, \operatorname{his}(H)=A\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, \operatorname{his}(G) \neq A\right\}
\end{aligned}
$$

So the likely history probability function entropy, entropy $(\tilde{P})$, is maximised when the historical distribution frequency, $Q_{\mathrm{h}, U}(E, z)(A)$, is maximised.

Consider the case where the histogram, $A$, is known, but the distribution histogram, $E$, is unknown and hence the likely history probability function, $\tilde{P}$, is unknown. The historical probability distribution is a probability function, $\hat{Q}_{\mathrm{h}, U}(E, z) \in \mathcal{P}$, parameterised by the distribution histogram, $E$, so there is a corresponding likelihood function $L_{\mathrm{h}, U}(A) \in \mathcal{A}_{U, \mathrm{i}, V, z_{E}} \rightarrow \mathbf{Q}_{\geq 0}$ such that $L_{\mathrm{h}, U}(A)(E)=\hat{Q}_{\mathrm{h}, U}(E, z)(A)$. The maximum likelihood estimate $\tilde{E}$ for the distribution histogram, $E$, is a modal value of this likelihood function,

$$
\begin{aligned}
\tilde{E} & \in \operatorname{maxd}\left(L_{\mathrm{h}, U}(A)\right) \\
& =\operatorname{maxd}\left(\left\{\left(D, Q_{\mathrm{h}, U}(D, z)(A)\right): D \in \mathcal{A}_{U, \mathrm{i}, V, z_{E}}\right\}\right)
\end{aligned}
$$

The likely distribution histogram, $\tilde{E}$, is known if the distribution histogram size, $z_{E}$, is known and the histogram, $A$, is known. If it is assumed that the distribution histogram equals the likely distribution histogram, $E=\tilde{E}$, then the likely history probability is known, $\tilde{P}(H)=1 / Q_{\mathrm{h}, U}(\tilde{E}, z)(A)$ where $\operatorname{his}(H)=A$.

The multinomial distribution $Q_{\mathrm{m}, U}$ is defined

$$
Q_{\mathrm{m}, U}(E, z)(A):=\frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}} E_{S}^{A_{S}}
$$

where $A^{\mathrm{F}} \leq E^{\mathrm{F}}$. The frequency of histogram $A$ in the multinomial distribution, $Q_{\mathrm{m}, U}$, parameterised by draw $(E, z)$, is the cardinality of histories drawn with replacement having histogram $A$,

$$
Q_{\mathrm{m}, U}(E, z)(A)=\left|\left\{L: L \in H_{E}^{z}, \operatorname{his}(\{((i, x), S):(i,(x, S)) \in L\})=A\right\}\right|
$$

where $H_{E}^{z} \in \mathcal{L}\left(H_{E}\right)$ is the set of lists of the distribution history events of length $z$.

The multinomial probability distribution is normalised,

$$
\begin{aligned}
\hat{Q}_{\mathrm{m}, U}(E, z)(A) & :=\frac{1}{z_{E}^{z}} \times Q_{\mathrm{m}, U}(E, z)(A) \\
& =\frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}} \hat{E}_{S}^{A_{S}}
\end{aligned}
$$

so the multinomial probability, $\hat{Q}_{\mathrm{m}, U}(E, z)(A)=\hat{Q}_{\mathrm{m}, U}(\hat{E}, z)(A)$, does not depend on the distribution histogram size, $z_{E}$.

As the distribution histogram size, $z_{E}$, tends to infinity, the historical probability tends to the multinomial probability. That is, for large distribution histogram size, $z_{E} \gg z$, the historical probability may be approximated by the multinomial probability, $\hat{Q}_{\mathrm{h}, U}(E, z)(A) \approx \hat{Q}_{\mathrm{m}, U}(E, z)(A)$.

In the case where the distribution histogram is known to be cartesian, $E=$ $V_{z_{E}}^{\mathrm{C}}$, but the distribution histogram size, $z_{E}$, is unknown, except that it is known to be large, $z_{E} \gg z$, then the case where the drawn histogram, $A$, is known to be necessary, $\sum\left(P(H): H \subseteq H_{E}, \operatorname{his}(H)=A\right)=1$, approximates to the case where the substrate histogram, $A$, is known to be necessary, $\sum\left(P(H): H \in \mathcal{H}_{U, V, z}, \operatorname{his}(H)=A\right)=1$. That is,

$$
\begin{aligned}
\tilde{P}= & \left\{\left(H, 1 / \prod_{S \in A^{\mathrm{S}}}\binom{V_{z_{E}}^{\mathrm{C}}(S)}{A(S)}\right): H \subseteq H_{E}, \operatorname{his}(H)=A\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, \operatorname{his}(G) \neq A\right\} \\
\approx & \left\{\left(H, 1 / \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!}\right): H \in \mathcal{H}_{U, V, z}, \operatorname{his}(H)=A\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, \operatorname{his}(G) \neq A\right\}
\end{aligned}
$$

In this case, the likely history probability function entropy varies with the histogram entropy, entropy $(\tilde{P}) \sim \operatorname{entropy}(A)$.

In the case where the distribution histogram, $E$, is unknown, and the distribution histogram size, $z_{E}$, is also unknown, except that it is known to be large, $z_{E} \gg z$, then the maximum likelihood estimate $\tilde{E}$ for the distribution probability histogram, $\hat{E}$, may be approximated by a modal value of a likelihood function which depends on the multinomial distribution instead,

$$
\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, Q_{\mathrm{m}, U}(D, z)(A)\right): D \in \mathcal{A}_{U, V, 1}\right\}\right)
$$

The mean of the multinomial probability distribution is the sized distribution histogram,

$$
\operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)=\operatorname{scalar}(z) * \hat{E}
$$

so the maximum likelihood estimate, $\tilde{E}$, for the distribution probability histogram, $\hat{E}$, is the sample probability histogram, $\hat{A}$,

$$
\tilde{E}=\hat{A}
$$

If it is assumed that the distribution probability histogram equals the likely distribution probability histogram, $\hat{E}=\tilde{E}=\hat{A}$, then the likely history probability varies against the sample-distributed multinomial probability, $\tilde{P}(H) \sim$ $1 / \hat{Q}_{\mathrm{m}, U}(\hat{A}, z)(A)$.

The sample-distributed multinomial log-likelihood is

$$
\ln \hat{Q}_{\mathrm{m}, U}(A, z)(A)=\ln z!-z \ln z-\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!+\sum_{S \in A^{\mathrm{FS}}} A_{S} \ln A_{S}
$$

which varies against the sum of the logarithms of the counts

$$
\ln \hat{Q}_{\mathrm{m}, U}(A, z)(A) \sim-\sum_{S \in A^{\mathrm{FS}}} \ln A_{S}
$$

So the log-likelihood varies weakly against the histogram entropy,

$$
\ln \hat{Q}_{\mathrm{m}, U}(A, z)(A) \sim-\operatorname{entropy}(A)
$$

If it is assumed that the distribution probability histogram equals the likely distribution probability histogram, $\hat{E}=\tilde{E}=\hat{A}$, then the likely history probability function entropy varies against the histogram entropy, entropy $(\tilde{P}) \sim$ - entropy $(A)$, in contrast to the case where the distribution histogram is cartesian.

The Fisher information of a probability function varies with the negative curvature of the likelihood function near the maximum likelihood estimate of the parameter. So the Fisher information is a measure of the sensitivity of the likelihood function with respect to the maximum likelihood estimate. The Fisher information of the multinomial probability distribution, $\hat{Q}_{\mathrm{m}, U}(E, z)$, is the sum sensitivity

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right)=\sum_{S \in V^{\mathrm{CS}}} \frac{z}{\hat{E}_{S}\left(1-\hat{E}_{S}\right)}
$$

The sum sensitivity varies against the sized entropy,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right) \sim-z \times \operatorname{entropy}(E)
$$

So, in the case of sample-distributed multinomial probability distribution, $\hat{Q}_{\mathrm{m}, U}(A, z)$, the sum sensitivity varies weakly with the log-likelihood,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(A, z)\right)\right) & \sim-z \times \operatorname{entropy}(A) \\
& \sim \ln \hat{Q}_{\mathrm{m}, U}(A, z)(A)
\end{aligned}
$$

If it is assumed that the distribution probability histogram equals the likely distribution probability histogram, $\hat{E}=\tilde{E}=\hat{A}$, then, as the likely history probability function entropy, entropy $(\tilde{P})$, increases, the sensitivity to the distribution histogram, $\tilde{E}$, increases.

The lower the entropy of the sample the more likely the normalised sample histogram, $\hat{A}$, equals the normalised distribution histogram, $\hat{E}$, but the larger the likely difference between them if they are not equal.

Now consider the case where either the drawn histogram $A$ or the drawn histogram $B$ are known to be necessary, $\sum\left(P(H): H \subseteq H_{E}\right.$, $(\operatorname{his}(H)=$ $A \vee \operatorname{his}(H)=B))=1$. The maximum likelihood estimate which maximises the entropy, entropy $(\tilde{P})$, is

$$
\begin{aligned}
\tilde{P}= & \left\{(H, 1): H \subseteq H_{E},(\operatorname{his}(H)=A \vee \operatorname{his}(H)=B)\right\}^{\wedge} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, \operatorname{his}(G) \neq A, \operatorname{his}(G) \neq B\right\} \\
= & \left\{\left(H, 1 /\left(Q_{\mathrm{h}, U}(E, z)(A)+Q_{\mathrm{h}, U}(E, z)(B)\right)\right):\right. \\
& \left.H \subseteq H_{E},(\operatorname{his}(H)=A \vee \operatorname{his}(H)=B)\right\}\llcorner \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, \operatorname{his}(G) \neq A, \operatorname{his}(G) \neq B\right\}
\end{aligned}
$$

That is, the maximum likelihood estimate, $\tilde{P}$, is such that all drawn histories $H \subseteq H_{E}$ with either histogram, $A$ or $B$, are uniformly probable and all other histories, $G \nsubseteq H_{E}$ or $\operatorname{his}(G) \neq A$ and $\operatorname{his}(G) \neq B$, are impossible, $\tilde{P}(G)=0$. If the histograms, $A$ and $B$, are known and the distribution histogram, $H_{E}$, is known, then the likely probability function, $\tilde{P}$, is known.

The likely probability of drawing histogram $A$ from necessary drawn histograms $A$ or $B$ is

$$
\sum\left(\tilde{P}(H): H \in \mathcal{H}_{U, V, z}, \operatorname{his}(H)=A\right)=\frac{Q_{\mathrm{h}, U}(E, z)(A)}{Q_{\mathrm{h}, U}(E, z)(A)+Q_{\mathrm{h}, U}(E, z)(B)}
$$

The likely history probability function entropy, entropy $(\tilde{P})$, is maximised when the sum of the historical frequencies, $Q_{\mathrm{h}, U}(E, z)(A)+Q_{\mathrm{h}, U}(E, z)(B)$, is maximised.

Consider the case where the drawn histograms, $A$ and $B$, are known, but the distribution histogram, $E$, is unknown and hence the likely history probability function, $\tilde{P}$, is unknown. The maximum likelihood estimate $\tilde{E}$ for the
distribution histogram, $E$, is a modal value of the likelihood function,

$$
\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, Q_{\mathrm{h}, U}(D, z)(A)+Q_{\mathrm{h}, U}(D, z)(B)\right): D \in \mathcal{A}_{U, \mathrm{i}, V, z_{E}}\right\}\right)
$$

The likely distribution histogram, $\tilde{E}$, is known if the distribution histogram size, $z_{E}$, is known and the drawn histograms, $A$ and $B$, are known. If it is assumed that the distribution histogram equals the likely distribution histogram $_{\tilde{\tilde{}}} E=\tilde{E}$, then the likely history probability is known, $\tilde{P}(H)=$ $1 /\left(Q_{\mathrm{h}, U}(\tilde{E}, z)(A)+Q_{\mathrm{h}, U}(\tilde{E}, z)(B)\right)$ where $\operatorname{his}(H)=A$ or $\operatorname{his}(H)=B$.

In the case where the distribution histogram, $E$, is unknown, and the distribution histogram size, $z_{E}$, is also unknown, except that it is known to be large, $z_{E} \gg z$, then the maximum likelihood estimate $\tilde{E}$ for the distribution probability histogram, $\hat{E}$, may be approximated by a modal value of a likelihood function which depends on the multinomial distribution instead,

$$
\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, Q_{\mathrm{m}, U}(D, z)(A)+Q_{\mathrm{m}, U}(D, z)(B)\right): D \in \mathcal{A}_{U, V, 1}\right\}\right)
$$

Now the likely distribution histogram, $\tilde{E}$, is known if there is a computable solution and the drawn histograms, $A$ and $B$, are known.

Consider the case where the histogram is uniformly possible. Instead of assuming the substrate history probability function $P \in\left(\mathcal{H}_{U, V, z}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$ to be the distribution of an arbitrary history valued function of undefined particle, $\mathcal{X} \rightarrow \mathcal{H}$, assume that it is the distribution of an arbitrary history valued function, $\mathcal{X} \rightarrow \mathcal{H}$, given an arbitrary histogram valued function, $\mathcal{X} \rightarrow$ $\mathcal{A}$. In this case, the history valued function is chosen arbitrarily from the constrained subset

$$
\begin{aligned}
& \{G: F \in \mathcal{X} \rightarrow(\mathcal{A} \times(\mathcal{X} \rightarrow \mathcal{H})), \\
& \quad(\cdot,(A, G)) \in F, \forall(\cdot, H) \in G(\operatorname{his}(H)=A)\} \subset \mathcal{X} \rightarrow \mathcal{H}
\end{aligned}
$$

In the case where there is no distribution history, the maximum likelihood estimate which maximises the entropy, entropy $(\tilde{P})$, is

$$
\begin{aligned}
\tilde{P} & =\left(\bigcup\left\{\left\{(H, 1): H \in \mathcal{H}_{U, V, z}, \operatorname{his}(H)=A\right\}^{\wedge}: A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right)^{\wedge} \\
& =\left\{\left(H, 1 /\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right| \times 1 / \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!}\right): H \in \mathcal{H}_{U, V, z}, A=\operatorname{his}(H)\right\}
\end{aligned}
$$

That is, the maximum likelihood estimate, $\tilde{P}$, is such that all histograms are uniformly probable, $\forall A \in \mathcal{A}_{U, \mathrm{i}, V, z}\left(\sum\left(\tilde{P}(H): H \in \mathcal{H}_{U, V, z}, \operatorname{his}(H)=A\right)=\right.$
$\left.1 /\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right|\right)$, and then all histories with the same $\operatorname{histogram}, \operatorname{his}(H)=A$, are uniformly probable. The likely probability function, $\tilde{P}$, is known.

In the case where there is a distribution history $H_{E}$, the maximum likelihood estimate which maximises the entropy, entropy $(\tilde{P})$, is

$$
\begin{aligned}
\tilde{P}= & \left(\bigcup\left\{\left\{(H, 1): H \subseteq H_{E}, \operatorname{his}(H)=A\right\}^{\wedge}: A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right)^{\wedge} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\} \\
= & \left(\bigcup \left\{\left\{\left(H, 1 / Q_{\mathrm{h}, U}(E, z)(A)\right): H \subseteq H_{E}, \operatorname{his}(H)=A\right\}:\right.\right. \\
& \left.\left.A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right)^{\wedge} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\}
\end{aligned}
$$

That is, the maximum likelihood estimate, $\tilde{P}$, is such that all drawn histograms, $A \leq E$, are uniformly probable, and then all drawn histories $H \subseteq$ $H_{E}$ with the same histogram, his $(H)=A$, are uniformly probable. If the distribution histogram, $H_{E}$, is known, then the likely probability function, $\tilde{P}$, is known.

Consider the case where a drawn sample $A$ is known, but the distribution histogram, $E$, is unknown and hence the likely history probability function, $\tilde{P}$, is unknown. The maximum likelihood estimate $\tilde{E}$ for the distribution histogram, $E$, is the same as for necessary histogram,

$$
\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, Q_{\mathrm{h}, U}(D, z)(A)\right): D \in \mathcal{A}_{U, \mathrm{i}, V, z_{E}}\right\}\right)
$$

The likely distribution histogram, $\tilde{E}$, is known if the distribution histogram size, $z_{E}$, is known and the histogram, $A$, is known. If it is assumed that the distribution histogram equals the likely distribution histogram, $E=\tilde{E}$, then the likely history probability is known, $\tilde{P}(H)=1 / \mid\left\{B: B \in \mathcal{A}_{U, \mathbf{i}, V, z}, B \leq\right.$ $\tilde{E}\} \mid \times 1 / Q_{\mathrm{h}, U}(\tilde{E}, z)(A)$ where $\operatorname{his}(H)=A$.

In the case where the distribution histogram, $E$, is unknown, and the distribution histogram size, $z_{E}$, is also unknown, except that it is known to be large, $z_{E} \gg z$, then the maximum likelihood estimate $\tilde{E}$ for the distribution probability histogram, $\hat{E}$, may be approximated by a modal value of a likelihood function which depends on the multinomial distribution instead,

$$
\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, Q_{\mathrm{m}, U}(D, z)(A)\right): D \in \mathcal{A}_{U, V, 1}\right\}\right)
$$

Again, the maximum likelihood estimate, $\tilde{E}$, for the distribution probability histogram, $\hat{E}$, is the sample probability histogram, $\hat{A}$,

$$
\tilde{E}=\hat{A}
$$

If it is assumed that the distribution probability histogram equals the likely distribution probability histogram, $\hat{E}=\tilde{E}=\hat{A}$, then the likely history probability varies against the sample-distributed multinomial probability, $\tilde{P}(H) \sim$ $1 /\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right| \times 1 / \hat{Q}_{\mathrm{m}, U}(\hat{A}, z)(A)$.

So the properties of uniform possible histogram are similar to necessary histogram except that more histories are possible but less probable.

### 2.4.2 Aligned induction

In aligned induction the history probability functions are constrained by independent histogram.

The independent histogram valued function of integral substrate histograms $Y_{U, i, V, z}$ is defined

$$
Y_{U, \mathrm{i}, V, z}:=\left\{\left(A, A^{\mathrm{X}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
$$

The finite set of iso-independents of independent histogram $A^{\mathrm{X}}$ is

$$
Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{x}}=A^{\mathrm{x}}\right\}
$$

Given any subset of the integral substrate histograms $I \subseteq \mathcal{A}_{U, \mathbf{i}, V, z}$ that contains the histogram, $A \in I$, the degree to which the subset is said to be aligned-like is called the iso-independence. The iso-independence is defined as the ratio of (i) the cardinality of the intersection between the integral substrate histograms subset and the set of integral iso-independents, and (ii) the cardinality of the union,

$$
\frac{1}{\left|\mathcal{A}_{U, i, V, z}\right|} \leq \frac{\left|I \cap Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|I \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|} \leq 1
$$

Consider the case where the independent $A^{\mathrm{X}}$ of drawn histories is known to be necessary, $\sum\left(P(H): H \subseteq H_{E}\right.$, $\left.\operatorname{his}(H)^{\mathrm{X}}=A^{\mathrm{X}}\right)=1$. The maximum
likelihood estimate which maximises the entropy, entropy $(\tilde{P})$, is

$$
\begin{aligned}
\tilde{P}= & \left\{(H, 1): H \subseteq H_{E}, \operatorname{his}(H)^{\mathrm{X}}=A^{\mathrm{X}}\right\}^{\wedge} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, \operatorname{his}(G)^{\mathrm{X}} \neq A^{\mathrm{X}}\right\} \\
= & \left\{\left(H, 1 / \sum\left(Q_{\mathrm{h}, U}(E, z)(B): B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right)\right):\right. \\
& \left.H \subseteq H_{E}, \operatorname{his}(H)^{\mathrm{X}}=A^{\mathrm{X}}\right\} \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, \operatorname{his}(G)^{\mathrm{X}} \neq A^{\mathrm{X}}\right\}
\end{aligned}
$$

That is, the maximum likelihood estimate, $\tilde{P}$, is such that all drawn histories $H \subseteq H_{E}$ with the independent, his $(H)^{\mathrm{X}}=A^{\mathrm{X}}$, are uniformly probable and all other histories, $G \nsubseteq H_{E}$ or $\operatorname{his}(G)^{\mathrm{X}} \neq A^{\mathrm{X}}$, are impossible, $\tilde{P}(G)=0$. If the independent, $A^{\mathrm{X}}$, is known and the distribution histogram, $H_{E}$, is known, then the likely probability function, $\tilde{P}$, is known.

The likely probability of drawing histogram $A$ from necessary drawn independent $A^{\mathrm{X}}$ is

$$
\begin{aligned}
\sum\left(\tilde{P}(H): H \in \mathcal{H}_{U, V, z}, \operatorname{his}(H)=\right. & A)= \\
& \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum Q_{\mathrm{h}, U}(E, z)(B): B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)}
\end{aligned}
$$

The likely history probability function entropy, entropy $(\tilde{P})$, is maximised when the sum of the iso-independent historical frequencies, $\sum Q_{\mathrm{h}, U}(E, z)(B)$ : $B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, is maximised.

Consider the case where the independent, $A^{\mathrm{X}}$, is known, but the distribution histogram, $E$, is unknown and hence the likely history probability function, $\tilde{P}$, is unknown. The maximum likelihood estimate $\tilde{E}$ for the distribution histogram, $E$, is a modal value of the likelihood function,

$$
\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{h}, U}(D, z)(B): B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right)\right): D \in \mathcal{A}_{U, \mathrm{i}, V, z_{E}}\right\}\right)
$$

The likely distribution histogram, $\tilde{E}$, is known if the distribution histogram size, $z_{E}$, is known and the independent, $A^{\mathrm{X}}$, is known. If it is assumed that the distribution histogram equals the likely distribution histogram, $E=\tilde{E}$, then the likely history probability is known, $\tilde{P}(H)=1 / \sum\left(Q_{\mathrm{h}, U}(\tilde{E}, z)(B)\right.$ : $\left.B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right)$ where his $(H)^{\mathrm{X}}=A^{\mathrm{X}}$.

In the case where the distribution histogram, $E$, is unknown, and the distribution histogram size, $z_{E}$, is also unknown, except that it is known to be large, $z_{E} \gg z$, then the maximum likelihood estimate $\tilde{E}$ for the distribution probability histogram, $\hat{E}$, may be approximated by a modal value of a likelihood function which depends on the multinomial distribution instead,

$$
\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right)\right): D \in \mathcal{A}_{U, V, 1}\right\}\right)
$$

which has a solution $\tilde{E}=\hat{A}^{\mathrm{X}}$. So the maximum likelihood estimate, $\tilde{E}$, for the distribution probability histogram, $\hat{E}$, is the independent probability histogram, $\hat{A}^{\mathrm{X}}$,

$$
\tilde{E}=\hat{A}^{\mathrm{X}}
$$

In the case where the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, the sum of the isoindependent independent-distributed multinomial probabilities varies with the independent independent-distributed multinomial probability,

$$
\sum\left(Q_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(B): B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right) \sim Q_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)
$$

So, if it is assumed that the distribution probability histogram equals the likely distribution probability histogram, $\hat{E}=\tilde{E}=\hat{A}^{\mathrm{X}}$, then the likely history probability varies against the independent-distributed multinomial probability of the independent, $\tilde{P}(H) \sim 1 / \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)$.

In this case, the likely probability of drawing histogram $A$ from necessary drawn independent $A^{\mathrm{X}}$ is approximately

$$
\begin{aligned}
\sum\left(\tilde{P}(H): H \in \mathcal{H}_{U, V, z},\right. & \operatorname{his}(H)=A) \\
& \approx \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B): B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} \\
& \sim \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(A)}{Q_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A^{\mathrm{x}}\right)}
\end{aligned}
$$

The negative logarithm of the ratio of the histogram independent-distributed multinomial probability to the independent independent-distributed multinomial probability equals the alignment,

$$
-\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A)}{Q_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}=\operatorname{algn}(A)
$$

So the logarithm of the likely probability of drawing histogram $A$ from necessary drawn independent $A^{\mathrm{X}}$ varies against the alignment,

$$
\ln \sum\left(\tilde{P}(H): H \in \mathcal{H}_{U, V, z}, \operatorname{his}(H)=A\right) \sim-\operatorname{algn}(A)
$$

The independent, $A^{\mathrm{X}}$, which has zero alignment, $\operatorname{algn}\left(A^{\mathrm{X}}\right)=0$, is the most probable histogram, $\forall B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\left(Q_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right) \geq Q_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(B)\right)$. As the alignment increases, algn $(A)>0$, the likely histogram probability, $Q_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A) / \sum\left(Q_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(B): B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right)$, decreases.

The likely history probability function entropy varies with the independent entropy, entropy $(\tilde{P}) \sim \operatorname{entropy}\left(A^{\mathrm{X}}\right)$.

Define the dependent histogram $A^{Y} \in \mathcal{A}_{U, V, z}$ as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram $A$ conditional that it is an iso-independent,

$$
\left\{A^{\mathrm{Y}}\right\}=\operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

Note that the dependent, $A^{\mathrm{Y}}$, is not always computable, but an approximation to any accuracy can be made to it. In the case where the histogram is independent, the dependent equals the independent, $A=A^{\mathrm{X}} \Longrightarrow A^{\mathrm{Y}}=$ $A=A^{\mathrm{X}}$. The dependent alignment is greater than or equal to the histogram alignment, $\operatorname{algn}\left(A^{\mathrm{Y}}\right) \geq \operatorname{algn}(A) \geq \operatorname{algn}\left(A^{\mathrm{X}}\right)=0$. In the case where the histogram is uniformly diagonalised, the histogram alignment, $\operatorname{algn}(A)$, is at the maximum, and the dependent equals the histogram, $A^{\mathrm{Y}}=A$.

Now consider the case where, given necessary drawn independent $A^{\mathrm{X}}$, it is known, in addition, that the sample histogram $A$ is the most probable histogram, regardless of its alignment. That is, the likely probability of drawing histogram $A$ from necessary drawn independent $A^{\mathrm{X}}$,

$$
\begin{aligned}
\sum\left(\tilde{P}(H): H \in \mathcal{H}_{U, V, z}, \operatorname{his}(H)=\right. & A)= \\
& \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum Q_{\mathrm{h}, U}(E, z)(B): B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)}
\end{aligned}
$$

is maximised.
In the case where the sample, $A$, is known, but the distribution histogram,
$E$, is unknown, the maximum likelihood estimate $\tilde{E}$ for the distribution histogram, $E$, is a modal value of the likelihood function,

$$
\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{h}, U}(D, z)(A)}{\sum Q_{\mathrm{h}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)}\right): D \in \mathcal{A}_{U, \mathrm{i}, V, z_{E}}\right\}\right)
$$

The likely distribution histogram, $\tilde{E}$, is known if the distribution histogram size, $z_{E}$, is known and the sample, $A$, is known. If it is assumed that the distribution histogram equals the likely distribution histogram, $E=\tilde{E}$, then the likely history probability is known, $\tilde{P}(H)=1 / \sum\left(Q_{\mathrm{h}, U}(\tilde{E}, z)(B): B \in\right.$ $\left.Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right)$ where $\operatorname{his}(H)^{\mathrm{X}}=A^{\mathrm{X}}$.

If the histogram is independent, $A=A^{\mathrm{X}}$, then the additional constraint of probable sample makes no change to the maximum likelihood estimate, $\tilde{E}$,

$$
\begin{aligned}
A= & A^{\mathrm{X}} \Longrightarrow \\
& \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{h}, U}(D, z)(A)}{\sum Q_{\mathrm{h}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)}\right): D \in \mathcal{A}_{U, \mathrm{i}, V, z_{E}}\right\}\right) \\
= & \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{h}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right)\right): D \in \mathcal{A}_{U, \mathrm{i}, V, z_{E}}\right\}\right)
\end{aligned}
$$

If the histogram is not independent, $\operatorname{algn}(A) \geq 0$, however, then the likely history probability function entropy, entropy $(\tilde{P})$, is lower than it is in the case of necessary independent unconstrained by probable sample.

In the case where the distribution histogram, $E$, is unknown, and the distribution histogram size, $z_{E}$, is also unknown, except that it is known to be large, $z_{E} \gg z$, then the maximum likelihood estimate $\tilde{E}$ for the distribution probability histogram, $\hat{E}$, is now approximated by a modal value of the conditional likelihood function,

$$
\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)}\right): D \in \mathcal{A}_{U, V, 1}\right\}\right)
$$

The solution to this is the normalised dependent, $\tilde{E}=\hat{A}^{\mathrm{Y}}$. The maximum likelihood estimate is near the sample, $\tilde{E} \sim \hat{A}$, only in as much as it is far from the independent, $\tilde{E} \nsim \hat{A}^{\mathrm{X}}$. This may be compared to the case unconstrained by probable sample where the maximum likelihood estimate equals the independent, $\tilde{E}=\hat{A}^{\mathrm{X}}$. In the probable sample case the sized maximum likelihood estimate is aligned, $\operatorname{algn}\left(A^{\mathrm{Y}}\right)>0$, so there are fewer ways to draw the isoindependents and the likely history probability function entropy, entropy $(\tilde{P})$, is lower. At maximum alignment, where the histogram is uniformly diagonalised, the dependent equals the histogram, $A^{\mathrm{Y}}=A$, and the likely history
probability function entropy, entropy $(\tilde{P})$, is least.
The iso-independent conditional multinomial probability distribution is defined,

$$
\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z)(A):=\frac{1}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)\right|} \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum Q_{\mathrm{m}, U}(E, z)(B): B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)}
$$

So the optimisation can be rewritten,

$$
\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, \hat{Q}_{\mathrm{m}, \mathrm{y}, U}(D, z)(A)\right): D \in \mathcal{A}_{U, V, 1}\right\}\right)
$$

The logarithm of the independent-distributed iso-independent conditional multinomial probability varies against the alignment,

$$
\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B): B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)} \sim-\operatorname{algn}(A)
$$

Conversely, the logarithm of the dependent-distributed iso-independent conditional multinomial probability varies with the alignment,

$$
\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}}, z\right)(B): B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \sim \operatorname{algn}(A)
$$

That is, the log-likelihood varies with the sample alignment,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{y}, U}\left(A^{\mathrm{Y}}, z\right)(A) \sim \operatorname{algn}(A)
$$

In the case where the alignment is low the sum sensitivity varies with the alignment

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{y}, U}\left(A^{\mathrm{Y}}, z\right)\right)\right) \sim \operatorname{algn}(A)
$$

and in the case where the alignment is high the sum sensitivity varies against the alignment

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{y}, U}\left(A^{\mathrm{Y}}, z\right)\right)\right) \sim-\operatorname{algn}(A)
$$

At intermediate alignments the sum sensitivity is independent of the alignment.

So, in the probable sample case, if it is assumed that the distribution probability histogram equals the likely distribution probability histogram, $\hat{E}=\tilde{E}=$ $\hat{A}^{\mathrm{Y}}$, then the likely history probability function entropy varies against the
alignment, $\operatorname{entropy}(\tilde{P}) \sim-\operatorname{algn}(A)$.
As the alignment, $\operatorname{algn}(A)$, increases towards its maximum, the likely distribution probability histogram tends to the histogram, $\tilde{E}=\hat{A}^{\mathrm{Y}} \sim \hat{A}$, and the log-likelihood, $\ln \hat{Q}_{\mathrm{m}, \mathrm{y}, U}\left(A^{\mathrm{Y}}, z\right)(A)$, increases, but the sensitivity to distribution histogram, $E$, decreases. In other words, the more aligned the sample the more likely the normalised sample histogram, $\hat{A}$, equals the normalised distribution histogram, $\hat{E}$, and the smaller the likely difference between them if they are not equal.

Consider the case where the independent is uniformly possible. Assume that the substrate history probability function $P \in\left(\mathcal{H}_{U, V, z}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$ is the distribution of an arbitrary history valued function, $\mathcal{X} \rightarrow \mathcal{H}$, given an arbitrary independent valued function, $\mathcal{X} \rightarrow \mathcal{A}$. In this case, the history valued function is chosen arbitrarily from the constrained subset

$$
\begin{aligned}
& \{G: F \in \mathcal{X} \rightarrow(\mathcal{A} \times(\mathcal{X} \rightarrow \mathcal{H})), \\
& \left.\quad(\cdot,(A, G)) \in F, \forall(\cdot, H) \in G\left(\operatorname{his}(H)^{\mathrm{x}}=A\right)\right\} \subset \mathcal{X} \rightarrow \mathcal{H}
\end{aligned}
$$

Uniformly possible independent is a weaker constraint than uniformly possible histogram, so the subset of history valued functions is larger.

In the case where there is a distribution history $H_{E}$, the maximum likelihood estimate which maximises the entropy, entropy $(\tilde{P})$, is

$$
\begin{aligned}
\tilde{P}= & \left(\bigcup\left\{\left\{(H, 1): H \subseteq H_{E}, \operatorname{his}(H)^{\mathrm{x}}=A\right\}^{\wedge}: A \in \operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)\right\}\right)^{\wedge} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\} \\
= & \left(\bigcup \left\{\left\{\left(H, 1 / \sum\left(Q_{\mathrm{h}, U}(E, z)(B): B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right)\right):\right.\right.\right. \\
& \left.\left.\left.H \subseteq H_{E}, \operatorname{his}(H)^{\mathrm{x}}=A\right\}: A \in \operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)\right\}\right)^{\wedge} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\}
\end{aligned}
$$

That is, the maximum likelihood estimate, $\tilde{P}$, is such that all drawn independents are uniformly probable, and then all drawn histories $H \subseteq H_{E}$ with the same independent, $\operatorname{his}(H)^{\mathrm{X}}=A$, are uniformly probable. If the distribution histogram, $H_{E}$, is known, then the likely probability function, $\tilde{P}$, is known.

The properties of uniformly possible independent are the same as for necessary independent, except that the probabilities are scaled. So, in the case
where the distribution histogram, $E$, is unknown, and the distribution histogram size, $z_{E}$, is also unknown, except that it is known to be large, $z_{E} \gg z$, then the likely history probability varies against the independent-distributed multinomial probability of the independent,

$$
\tilde{P}(H) \sim 1 /\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)\right| \times 1 / \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)
$$

That is, more histories are possible but less probable.

### 2.5 Models

### 2.5.1 Transforms

Transforms are the simplest models. All models can be converted to transforms.

Given a histogram $X \in \mathcal{A}$ and a subset of its variables $W \subseteq \operatorname{vars}(X)$, the pair $T=(X, W)$ forms a transform. The variables, $W$, are the derived variables. The complement $V=\operatorname{vars}(X) \backslash W$ are the underlying variables. The set of all transforms is

$$
\mathcal{T}:=\{(X, W): X \in \mathcal{A}, W \subseteq \operatorname{vars}(X)\}
$$

The transform histogram is $X=\operatorname{his}(T)$. The transform derived is $W=$ $\operatorname{der}(T)$. The transform underlying is $V=\operatorname{und}(T)$. The set of underlying variables of a transform is also called the substrate.

The null transform is $(X, \emptyset)$. The full transform is $(X, \operatorname{vars}(X))$.
Given a histogram $A \in \mathcal{A}$, the multiplication of the histogram, $A$, by the transform $T \in \mathcal{T}$ equals the multiplication of the histogram, $A$, by the transform histogram $X=\operatorname{his}(T)$ followed by the reduction to the derived variables $W=\operatorname{der}(T)$,

$$
A * T=A *(X, W):=A * X \% W
$$

If the histogram variables are a superset of the underlying variables, $\operatorname{vars}(A) \supseteq$ $\operatorname{und}(T)$, then the histogram, $A$, is called the underlying histogram and the multiplication, $A * T$, is called the derived histogram. The derived histogram variables equals the derived variables, $\operatorname{vars}(A * T)=\operatorname{der}(T)$.

The application of the null transform of the cartesian is the scalar, $A *$ $\left(V^{\mathrm{C}}, \emptyset\right)=A \% \emptyset=\operatorname{scalar}(\operatorname{size}(A))$, where $V=\operatorname{vars}(A)$. The application of the full transform of the cartesian is the histogram, $A *\left(V^{\mathrm{C}}, V\right)=A \% V=A$.

Given a histogram $A \in \mathcal{A}$ and a transform $T \in \mathcal{T}$, the formal histogram is defined as the independent derived, $A^{\mathrm{x}} * T$. The abstract histogram is defined as the derived independent, $(A * T)^{\mathrm{X}}$.

In the case where the formal and abstract are equal, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{x}}$, the abstract equals the independent abstract, $(A * T)^{\mathrm{X}}=A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, and so only depends on the independent, $A^{\mathrm{X}}$, not on the histogram, $A$. The formal equals the formal independent, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, and so is itself independent.

A transform $T \in \mathcal{T}$ is functional if there is a causal relation between the underlying variables $V=\operatorname{und}(T)$ and the derived variables $W=\operatorname{der}(T)$,

$$
\operatorname{split}\left(V, X^{\mathrm{FS}}\right) \in V^{\mathrm{CS}} \rightarrow W^{\mathrm{CS}}
$$

where $X=\operatorname{his}(T)$. The set of functional transforms $\mathcal{T}_{\mathrm{f}} \subset \mathcal{T}$ is the subset of all transforms that are causal.

A functional transform $T \in \mathcal{T}_{\mathrm{f}}$ has an inverse,

$$
T^{-1}:=\{((S \% V, c), S \% W):(S, c) \in X\}^{-1}
$$

A transform $T$ is one functional in system $U$ if the reduction of the transform histogram to the underlying variables equals the cartesian histogram, $X \% V=$ $V^{\mathrm{C}}$. So the causal relation is a derived state valued left total function of underlying state, $\operatorname{split}\left(V, X^{\mathrm{S}}\right) \in V^{\mathrm{CS}}: \rightarrow W^{\mathrm{CS}}$. The set of one functional transforms $\mathcal{T}_{U, \mathrm{f}, 1} \subset \mathcal{T}_{\mathrm{f}}$ is

$$
\begin{aligned}
\mathcal{T}_{U, \mathrm{f}, 1}= & \{(\{(S \cup R, 1):(S, R) \in Q\}, W): \\
& \left.V, W \subseteq \operatorname{vars}(U), V \cap W=\emptyset, Q \in V^{\mathrm{CS}}: \rightarrow W^{\mathrm{CS}}\right\}
\end{aligned}
$$

The application of a one functional transform to an underlying histogram preserves the size, $\operatorname{size}(A * T)=\operatorname{size}(A)$.

The one functional transform inverse is a unit component valued function of derived state, $T^{-1} \in W^{\mathrm{CS}} \rightarrow \mathrm{P}\left(V^{\mathrm{C}}\right)$. That is, the range of the inverse corresponds to a partition of the cartesian states into components, $\operatorname{ran}\left(T^{-1}\right) \in \mathrm{B}\left(V^{\mathrm{C}}\right)$.

The application of a one functional transform $T$ to its underlying cartesian $V^{\mathrm{C}}$ is the component cardinality histogram, $V^{\mathrm{C}} * T=\{(R,|C|):(R, C) \in$ $\left.T^{-1}\right\}$. The effective cartesian derived volume is less than or equal to the derived volume, $\left|\left(V^{\mathrm{C}} * T\right)^{\mathrm{F}}\right|=\left|T^{-1}\right| \leq\left|W^{\mathrm{C}}\right|$.

A one functional transform $T \in \mathcal{T}_{U, f, 1}$ may be applied to a history $H \in \mathcal{H}$ in the underlying variables of the transform, $\operatorname{vars}(H)=\operatorname{und}(T)$, to construct a derived history,

$$
H * T:=\left\{(x, R):(x, S) \in H,\{R\}=\left(\{S\}^{\mathrm{U}} * T\right)^{\mathrm{FS}}\right\}
$$

The size is unchanged, $|H * T|=|H|$, and the event identifiers are conserved, $\operatorname{dom}(H * T)=\operatorname{dom}(H)$.

Given a partition $P \in \mathrm{~B}\left(V^{\mathrm{CS}}\right)$ of the cartesian states of variables $V$, a one functional transform can be constructed. The partition transform is

$$
P^{\mathrm{T}}:=(\{(S \cup\{(P, C)\}, 1): C \in P, S \in C\},\{P\})
$$

The set of derived variables of the partition transform is a singleton of the partition variable, $\operatorname{der}\left(P^{\mathrm{T}}\right)=\{P\}$. The derived volume is the component cardinality, $\left|\{P\}^{\mathrm{C}}\right|=|P|$. The underlying variables are the given variables, $\operatorname{und}\left(P^{\mathrm{T}}\right)=V$.

The unary partition transform is $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$. The self partition transform is $T_{\mathrm{s}}=V^{\mathrm{CS}\{ \} \mathrm{T}}$.

Given a one functional transform $T \in \mathcal{T}_{U, f, 1}$, the natural converse is

$$
T^{\dagger}:=(X /(X \% W), V)
$$

where $(X, W)=T$ and $V=\operatorname{und}(T)$. The natural converse may be expressed in terms of components,

$$
T^{\dagger}:=\left(\sum_{(R, C) \in T^{-1}}\{R\}^{\mathrm{U}} * \hat{C}, V\right)
$$

Given a histogram $A \in \mathcal{A}$ in the underlying variables, $\operatorname{vars}(A)=V$, the naturalisation is the application of the natural converse transform to the derived histogram, $A * T * T^{\dagger}$. The naturalisation can be rewritten $A *$ $X \% W * X /(X \% W) \% V$. The naturalisation is in the underlying variables, $\operatorname{vars}\left(A * T * T^{\dagger}\right)=V$. The size is conserved, $\operatorname{size}\left(A * T * T^{\dagger}\right)=\operatorname{size}(A)$. The naturalisation derived equals the derived, $A * T * T^{\dagger} * T=A * T$.

The naturalisation equals the sum of the scaled components, $A * T * T^{\dagger}=$ $\sum \operatorname{scalar}\left((A * T)_{R}\right) * \hat{C}:(R, C) \in T^{-1}$. So each component is uniform, $\forall(R, C) \in T^{-1}\left(\left|\operatorname{ran}\left(A * T * T^{\dagger} * C\right)\right|=1\right)$.

The naturalisation of the unary partition transform, $T_{u}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$, is the sized cartesian, $A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger}=V_{z}^{\mathrm{C}}$, where $z=\operatorname{size}(A)$. The naturalisation of the self partition transform, $T_{\mathrm{s}}=V^{\mathrm{CS}\{ \} \mathrm{T}}$, is the histogram, $A * T_{\mathrm{s}} * T_{\mathrm{s}}^{\dagger}=A$.

A histogram is natural when it equals its naturalisation, $A=A * T * T^{\dagger}$. The cartesian is natural, $V^{\mathrm{C}}=V^{\mathrm{C}} * T * T^{\dagger}$.

Given a one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ with underlying variables $V=\operatorname{und}(T)$, and a histogram $A \in \mathcal{A}$ in the same variables, $\operatorname{vars}(A)=V$, the sample converse is

$$
(\hat{A} * X, V)
$$

where $X=\operatorname{his}(T)$.
Related to the sample converse, the actual converse is defined as the summed normalised application of the components to the sample histogram,

$$
T^{\odot A}:=\left(\sum_{(R, C) \in T^{-1}}\{R\}^{\mathrm{U}} *(A * C)^{\wedge}, V\right)
$$

The application of the actual converse transform to the derived histogram equals the histogram, $A * T * T^{\odot A}=A$.

Given a one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ with underlying variables $V=\operatorname{und}(T)$, and a histogram $A \in \mathcal{A}$ in the same variables, $\operatorname{vars}(A)=V$, the independent converse is defined as the summed normalised independent application of the components to the sample histogram,

$$
T^{\dagger A}:=\left(\sum_{(R, C) \in T^{-1}}\{R\}^{\mathrm{U}} *(A * C)^{\wedge \mathrm{X}}, V\right)
$$

The idealisation is the application of the independent converse transform to the derived histogram, $A * T * T^{\dagger A}$. The idealisation is in the underlying variables, $\operatorname{vars}\left(A * T * T^{\dagger A}\right)=V$. The size is conserved, $\operatorname{size}\left(A * T * T^{\dagger A}\right)=\operatorname{size}(A)$. The idealisation derived equals the derived, $A * T * T^{\dagger A} * T=A * T$.

The idealisation equals the sum of the independent components, $A * T *$ $T^{\dagger A}=\sum(A * C)^{\mathrm{X}}:(R, C) \in T^{-1}$. So each component is independent, $\forall(R, C) \in T^{-1}\left(A * T * T^{\dagger A} * C=\left(A * T * T^{\dagger A} * C\right)^{\mathrm{X}}=(A * C)^{\mathrm{X}}\right)$.

The idealisation of the unary partition transform, $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$, is the sized cartesian, $A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger A}=V_{z}^{\mathrm{C}}$. The idealisation of the self partition transform, $T_{\mathrm{s}}=V^{\mathrm{CS}\{ \} \mathrm{T}}$, is the histogram, $A * T_{\mathrm{s}} * T_{\mathrm{s}}^{\dagger A}=A$.

The idealisation independent equals the independent, $\left(A * T * T^{\dagger A}\right)^{\mathrm{X}}=A^{\mathrm{X}}$. The idealisation formal equals the formal, $\left(A * T * T^{\dagger A}\right)^{\mathrm{X}} * T=A^{\mathrm{X}} * T$. The idealisation abstract equals the abstract, $\left(A * T * T^{\dagger A} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$.

A histogram is ideal when it equals its idealisation, $A=A * T * T^{\dagger A}$.
The sense in which a transform is a simple model can be seen by considering queries on a sample histogram. Let histogram $A$ have a set of variables $V=\operatorname{vars}(A)$ which is partitioned into query variables $K \subset V$ and label variables $V \backslash K$. Let $T=(X, W)$ be a one functional transform having underlying variables equal to the query variables, $\operatorname{und}(T)=K$. Given a query state $Q \in K^{\mathrm{CS}}$ that is ineffective in the sample, $Q \notin(A \% K)^{\mathrm{FS}}$, but is effective in the sample derived, $R \in(A * T)^{\mathrm{FS}}$ where $\{R\}=\left(\{Q\}^{\mathrm{U}} * T\right)^{\mathrm{FS}}$, the probability histogram for the label is

$$
\left(\{Q\}^{\mathrm{U}} * T *(\hat{A} * X, V)\right)^{\wedge} \%(V \backslash K) \in \mathcal{A} \cap \mathcal{P}
$$

where the sample converse transform is $(\hat{A} * X, V)$. This can be expressed more simply in terms of the actual converse,

$$
\{Q\}^{\mathrm{U}} * T * T^{\odot A} \%(V \backslash K) \in \mathcal{A} \cap \mathcal{P}
$$

The query of the sample via model can also be written without the transforms, $\left(\{Q\}^{\mathrm{U}} * X \% W * X * A\right)^{\wedge} \%(V \backslash K)$. The query state, $Q$, in the query variables, $K$, is raised to the query derived state, $R$, in the derived variables, $W$, then lowered to effective sample states, in the sample variables, $V$, and finally reduced to label states, in the label variables, $V \backslash K$. Even though the sample itself does not contain the query, $\{Q\}^{\mathrm{U}} * \hat{A}=\emptyset$, the sample derived does contain the query derived, $\{R\}^{\mathrm{U}} *(\hat{A} * T) \neq \emptyset$, and so the resultant labels are those of the corresponding effective component, $(A * C)^{\wedge} \%(V \backslash K)$, where $(R, C) \in T^{-1}$.

The set of substrate histories $\mathcal{H}_{U, V, z}$ is defined above as the set of histories having event identifiers $\{1 \ldots z\}$, fixed size $z$ and fixed variables $V$,

$$
\mathcal{H}_{U, V, z}:=\{1 \ldots z\}: \rightarrow V^{\mathrm{CS}}
$$

The corresponding set of integral substrate histograms $\mathcal{A}_{U, \mathrm{i}, V, z}$ is the set of complete integral histograms in variables $V$ with size $z$,

$$
\mathcal{A}_{U, \mathrm{i}, V, z}:=\left\{A: A \in V^{\mathrm{CS}}: \rightarrow\{0 \ldots z\}, \operatorname{size}(A)=z\right\}
$$

The set of substrate transforms $\mathcal{T}_{U, V}$ is the subset of one functional transforms, $\mathcal{T}_{U, V} \subset \mathcal{T}_{U, f, 1}$, that have underlying variables $V$ and derived variables which are partitions,

$$
\mathcal{T}_{U, V}=\left\{\left(\prod_{(X, \cdot) \in F} X, \bigcup_{(\cdot, W) \in F} W\right): F \subseteq\left\{P^{\mathrm{T}}: P \in \mathrm{~B}\left(V^{\mathrm{CS}}\right)\right\}\right\}
$$

Let $v$ be the volume of the substrate, $v=\left|V^{\mathrm{C}}\right|$. The cardinality of the substrate transforms set is $\left|\mathcal{T}_{U, V}\right|=2^{\operatorname{bell}(v)}$, where bell $(n)$ is Bell's number, which has factorial computation complexity. If the volume, $v$, is finite, the set of substrate transforms is finite, $\left|\mathcal{T}_{U, V}\right|<\infty$.

### 2.5.2 Transform entropy

Let $T$ be a one functional transform, $T \in \mathcal{T}_{U, \mathrm{f}, 1}$, having underlying variables $V=\operatorname{und}(T)$. Let $A$ be a histogram, $A \in \mathcal{A}$, in the underlying variables, $\operatorname{vars}(A)=V$, having size $z=\operatorname{size}(A)>0$. The underlying volume is $v=\left|V^{\mathrm{C}}\right|$. The derived volume is $w=\left|T^{-1}\right|$.

The derived entropy or component size entropy is

$$
\operatorname{entropy}(A * T):=-\sum_{(R, \cdot) \in T^{-1}}(\hat{A} * T)_{R} \times \ln (\hat{A} * T)_{R}
$$

The derived entropy is positive and less than or equal to the logarithm of the derived volume, $0 \leq \operatorname{entropy}(A * T) \leq \ln w$.

Complementary to the derived entropy is the expected component entropy,

$$
\begin{aligned}
\text { entropyComponent }(A, T) & :=\sum_{(R, C) \in T^{-1}}(\hat{A} * T)_{R} \times \operatorname{entropy}(A * C) \\
& =\sum_{(R, \cdot) \in T^{-1}}(\hat{A} * T)_{R} \times \operatorname{entropy}\left(\{R\}^{\mathrm{U}} * T^{\odot A}\right)
\end{aligned}
$$

The cartesian derived entropy or component cardinality entropy is

$$
\operatorname{entropy}\left(V^{\mathrm{C}} * T\right):=-\sum_{(R, \cdot) \in T^{-1}}\left(\hat{V}^{\mathrm{C}} * T\right)_{R} \times \ln \left(\hat{V}^{\mathrm{C}} * T\right)_{R}
$$

The cartesian derived entropy is positive and less than or equal to the logarithm of the derived volume, $0 \leq \operatorname{entropy}\left(V^{\mathrm{C}} * T\right) \leq \ln w$.

The cartesian derived derived sum entropy or component size cardinality sum entropy is

$$
\operatorname{entropy}(A * T)+\operatorname{entropy}\left(V^{\mathrm{C}} * T\right)
$$

The component size cardinality cross entropy is the negative derived histogram expected normalised cartesian derived count logarithm,

$$
\text { entropy } \operatorname{Cross}\left(A * T, V^{\mathrm{C}} * T\right):=-\sum_{(R, \cdot) \in T^{-1}}(\hat{A} * T)_{R} \times \ln \left(\hat{V}^{\mathrm{C}} * T\right)_{R}
$$

The component size cardinality cross entropy is greater than or equal to the derived entropy, entropy $\operatorname{Cross}\left(A * T, V^{\mathrm{C}} * T\right) \geq \operatorname{entropy}(A * T)$.

The component cardinality size cross entropy is the negative cartesian derived expected normalised derived histogram count logarithm,

$$
\text { entropy } \operatorname{Cross}\left(V^{\mathrm{C}} * T, A * T\right):=-\sum_{(R, \cdot) \in T^{-1}}\left(\hat{V}^{\mathrm{C}} * T\right)_{R} \times \ln (\hat{A} * T)_{R}
$$

The component cardinality size cross entropy is greater than or equal to the cartesian derived entropy, entropyCross $\left(V^{\mathrm{C}} * T, A * T\right) \geq$ entropy $\left(V^{\mathrm{C}} * T\right)$.

The component size cardinality sum cross entropy is,

$$
\operatorname{entropy}\left(A * T+V^{\mathrm{C}} * T\right)
$$

The component size cardinality sum cross entropy is positive and less than or equal to the logarithm of the derived volume, $0 \leq \operatorname{entropy}\left(A * T+V^{\mathrm{C}} * T\right) \leq$ $\ln w$.

In all cases the cross entropy is maximised when high size components are low cardinality components, $(\hat{A} * T)_{R} \gg\left(\hat{V}^{\mathrm{C}} * T\right)_{R}$ or $\operatorname{size}(A * C) / z \gg|C| / v$, and low size components are high cardinality components, $(\hat{A} * T)_{R} \ll\left(\hat{V}^{\mathrm{C}} * T\right)_{R}$ or $\operatorname{size}(A * C) / z \ll|C| / v$, where $(R, C) \in T^{-1}$.

The cross entropy is minimised when the normalised derived histogram equals the normalised cartesian derived, $\hat{A} * T=\hat{V}^{\mathrm{C}} * T$ or $\forall(R, C) \in T^{-1}$ (size $(A *$ $C) / z=|C| / v)$. In this case the cross entropy equals the corresponding component entropy.

The component size cardinality relative entropy is the component size cardinality cross entropy minus the component size entropy,

$$
\begin{aligned}
& \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right) \\
&\left.:=\sum_{(R, \cdot) \in T^{-1}}(\hat{A} * T)_{R} \times \ln \frac{(\hat{A} * T)_{R}}{(\hat{V} \mathrm{C}} * T\right)_{R} \\
&=\text { entropyCross }\left(A * T, V^{\mathrm{C}} * T\right)-\operatorname{entropy}(A * T)
\end{aligned}
$$

The component size cardinality relative entropy is positive, entropyRelative $(A *$ $\left.T, V^{\mathrm{C}} * T\right) \geq 0$.

The component cardinality size relative entropy is the component cardinality size cross entropy minus the component cardinality entropy,

$$
\begin{aligned}
\text { entropyRelative } & \left(V^{\mathrm{C}} * T, A * T\right) \\
& :=\sum_{(R, \cdot) \in T^{-1}}\left(\hat{V}^{\mathrm{C}} * T\right)_{R} \times \ln \frac{\left(\hat{V}^{\mathrm{C}} * T\right)_{R}}{(\hat{A} * T)_{R}} \\
& =\text { entropy } \operatorname{Cross}\left(V^{\mathrm{C}} * T, A * T\right)-\operatorname{entropy}\left(V^{\mathrm{C}} * T\right)
\end{aligned}
$$

The component cardinality size relative entropy is positive, entropyRelative $\left(V^{\mathrm{C}} *\right.$ $T, A * T) \geq 0$.

The size-volume scaled component size cardinality sum relative entropy is the size-volume scaled component size cardinality sum cross entropy minus the size-volume scaled component size cardinality sum entropy,

$$
\begin{aligned}
(z+v) \times \operatorname{entropy}(A * T+ & \left.V^{\mathrm{C}} * T\right) \\
& -z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)
\end{aligned}
$$

The size-volume scaled component size cardinality sum relative entropy is positive, $(z+v) \times \operatorname{entropy}\left(A * T+V^{\mathrm{C}} * T\right)-z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} *\right.$ $T) \geq 0$. The size-volume scaled component size cardinality sum relative entropy is less than the size-volume scaled logarithm of the derived volume, $(z+v) \times \operatorname{entropy}\left(A * T+V^{\mathrm{C}} * T\right)-z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)<$ $(z+v) \ln w$.

In all cases the relative entropy is maximised when (a) the cross entropy is maximised and (b) the component entropy is minimised. That is, the relative entropy is maximised when both (i) the component size entropy,
entropy $(A * T)$, and (ii) the component cardinality entropy, entropy $\left(V^{\mathrm{C}} * T\right)$, are low, but low in different ways so that the component size cardinality sum cross entropy, entropy $\left(A * T+V^{\mathrm{C}} * T\right)$, is high.

Let histogram $A$ have a set of variables $V=\operatorname{vars}(A)$ which is partitioned into query variables $K \subset V$ and label variables $V \backslash K$. Let $T \in \mathcal{T}_{U, f, 1}$ be a one functional transform having underlying variables equal to the query variables, und $(T)=K$. As shown above, given a query state $Q \in K^{\mathrm{CS}}$ that is effective in the sample derived, $R \in(A * T)^{\mathrm{FS}}$ where $\{R\}=\left(\{Q\}^{\mathrm{U}} * T\right)^{\mathrm{FS}}$, the probability histogram for the label is

$$
\{Q\}^{\mathrm{U}} * T * T^{\odot A} \%(V \backslash K) \in \mathcal{A} \cap \mathcal{P}
$$

If the normalised histogram, $\hat{A} \in \mathcal{A} \cap \mathcal{P}$, is treated as a probability function of a single-state query, the scaled expected entropy of the modelled transformed conditional product, or scaled label entropy, is

$$
\begin{aligned}
& \sum_{(R, C) \in T^{-1}}(A * T)_{R} \times \operatorname{entropy}(A * C \%(V \backslash K)) \\
= & \sum_{(R, \cdot) \in T^{-1}}(A * T)_{R} \times \operatorname{entropy}\left(\{R\}^{\mathrm{U}} * T^{\odot A} \%(V \backslash K)\right)
\end{aligned}
$$

This is similar to the definition of the scaled expected component entropy, above,

$$
\begin{aligned}
z \times \text { entropyComponent }(A, T): & =\sum_{(R, C) \in T^{-1}}(A * T)_{R} \times \operatorname{entropy}(A * C) \\
& =\sum_{(R, \cdot) \in T^{-1}}(A * T)_{R} \times \operatorname{entropy}\left(\{R\}^{\mathrm{U}} * T^{\odot A}\right)
\end{aligned}
$$

but now the component is reduced to the label variables, $V \backslash K$.
The label entropy, may be contrasted with the alignment between the derived variables, $W$, and the label variables, $V \backslash K$,

$$
\operatorname{algn}(A * \operatorname{his}(T) \%(W \cup V \backslash K))
$$

The alignment varies against the scaled label entropy or scaled query conditional entropy. Let $B=A * \operatorname{his}(T) \%(W \cup V \backslash K)$,

$$
\begin{aligned}
& \operatorname{algn}(A * \operatorname{his}(T) \%(W \cup V \backslash K)) \\
& =\operatorname{algn}(B) \\
& \approx z \times \operatorname{entropy}\left(B^{\mathrm{X}}\right)-z \times \operatorname{entropy}(B) \\
& \sim z \times \operatorname{entropy}(B \% W)+z \times \operatorname{entropy}(B \%(V \backslash K))-z \times \operatorname{entropy}(B) \\
& \sim-(z \times \operatorname{entropy}(B)-z \times \operatorname{entropy}(B \% W)) \\
& =-\sum_{R \in(B \% W)^{\mathrm{FS}}}(B \% W)_{R} \times \operatorname{entropy}\left(B *\{R\}^{\mathrm{U}} \%(V \backslash K)\right) \\
& =-\sum_{(R, C) \in T^{-1}}(A * T)_{R} \times \operatorname{entropy}(A * C \%(V \backslash K))
\end{aligned}
$$

The label entropy, may also be compared to the slice entropy, which is the sum of the sized entropies of the contingent slices reduced to the label variables, $V \backslash K$,

$$
\sum_{R \in(A \% K)^{\mathrm{FS}}}(A \% K)_{R} \times \operatorname{entropy}\left(A *\{R\}^{\mathrm{U}} \%(V \backslash K)\right)
$$

In the case where the relation between the derived variables and the label variables is functional or causal,

$$
\operatorname{split}\left(W,(A * \operatorname{his}(T) \%(W \cup V \backslash K))^{\mathrm{FS}}\right) \in W^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}
$$

the label entropy is zero,

$$
\sum_{(R, C) \in T^{-1}}(A * T)_{R} \times \operatorname{entropy}(A * C \%(V \backslash K))=0
$$

So label entropy is a measure of the ambiguity in the relation between the derived variables and the label variables. Negative label entropy may be viewed as the degree to which the derived variables of the model predict the label variables. In the cases of low label entropy, or high causality, the derived variables and the label variables are correlated and therefore aligned, $\operatorname{algn}(A * \operatorname{his}(T) \%(W \cup V \backslash K))>0$. In these cases the derived histogram tends to the diagonal, $\operatorname{algn}(A * T)>0$.

### 2.5.3 Functional definition sets

This section may be skipped until section 'Artificial neural networks'.

A functional definition set $F \in \mathcal{F}$ is a set of unit functional transforms, $\forall T \in F\left(T \in \mathcal{T}_{\mathrm{f}}\right)$. Functional definition sets are also called fuds. Fuds are constrained such that derived variables can appear in only one transform. That is, the sets of derived variables are disjoint,

$$
\forall F \in \mathcal{F} \forall T_{1}, T_{2} \in F\left(T_{1} \neq T_{2} \Longrightarrow \operatorname{der}\left(T_{1}\right) \cap \operatorname{der}\left(T_{2}\right)=\emptyset\right)
$$

The set of fud histograms is $\operatorname{his}(F):=\{\operatorname{his}(T): T \in F\}$. The set of fud variables is $\operatorname{vars}(F):=\bigcup\{\operatorname{vars}(X): X \in \operatorname{his}(F)\}$. The fud derived is $\operatorname{der}(F):=\bigcup_{T \in F} \operatorname{der}(T) \backslash \bigcup_{T \in F} \operatorname{und}(T)$. The fud underlying is und $(F):=$ $\bigcup_{T \in F} \operatorname{und}(T) \backslash \bigcup_{T \in F} \operatorname{der}(T)$. The set of underlying variables of a fud is also called the substrate.

A functional definition set is a model, so it can be converted to a functional transform,

$$
F^{\mathrm{T}}:=\left(\prod \operatorname{his}(F) \%(\operatorname{der}(F) \cup \operatorname{und}(F)), \operatorname{der}(F)\right)
$$

The resultant transform has the same derived and underlying variables as the $f u d, \operatorname{der}\left(F^{\mathrm{T}}\right)=\operatorname{der}(F)$ and $\operatorname{und}\left(F^{\mathrm{T}}\right)=\operatorname{und}(F)$.

The set of one functional definition sets $\mathcal{F}_{U, 1}$ in system $U$ is the subset of the functional definition sets, $\mathcal{F}_{U, 1} \subset \mathcal{F}$, such that all transforms are one functional and the fuds are not circular. The transform of a one functional definition set is a one functional transform, $\forall F \in \mathcal{F}_{U, 1}\left(F^{\mathrm{T}} \in \mathcal{T}_{U, f, 1}\right)$.

A dependent variable of a one functional definition set $F \in \mathcal{F}_{U, 1}$ is any variable that is not a fud underlying variable, $\operatorname{vars}(F) \backslash \operatorname{und}(F)$. Each dependent variable depends on an underlying subset of the fud, depends $\in \mathcal{F} \times \mathrm{P}(\mathcal{V}) \rightarrow$ $\mathcal{F}$ where $\forall w \in \operatorname{vars}(F) \backslash \operatorname{und}(F)$ (depends $(F,\{w\}) \subseteq F)$.

Each dependent variable is in a layer. The layer is the length of the longest path of underlying transforms to the dependent variable. Given fud $F \in \mathcal{F}_{U, 1}$, let $l$ be the highest layer, $l=\operatorname{layer}(F, \operatorname{der}(F))$, where layer $\in \mathcal{F} \times \mathrm{P}(\mathcal{V}) \rightarrow \mathbf{N}$ is defined in terms of depends $\in \mathcal{F} \times \mathrm{P}(\mathcal{V}) \rightarrow \mathcal{F}$. Let $F_{i}$ be the subset of the fud in a particular layer, $F_{i}=\{T: T \in F$, layer $(F, \operatorname{der}(T))=i\}$. Then $F=\bigcup_{i \in\{1 \ldots l\}} F_{i}$.

A one functional definition set $F \in \mathcal{F}_{U, 1}$ is non-overlapping if the sets of variables of the underlying transforms of each of the fud derived variables are disjoint, $\forall v, w \in \operatorname{der}(F)(v \neq w \wedge \operatorname{vars}(\operatorname{depends}(F,\{v\})) \cap$
$\operatorname{vars}(\operatorname{depends}(F,\{w\}))=\emptyset)$. A one functional transform $T \in \mathcal{T}_{U, f, 1}$ is nonoverlapping if it is equal to the transform of a non-overlapping fud, $T=F^{\mathrm{T}}$. If the transform, $T$, is non-overlapping, then its formal is always independent, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, where $A$ is any underlying histogram, $\operatorname{vars}(A) \supseteq \operatorname{und}(T)$.

Given a set of substrate variables $V$, the set of substrate functional definition sets $\mathcal{F}_{U, V}$ is the subset of one functional definition sets, $\mathcal{F}_{U, V} \subset \mathcal{F}_{U, 1}$, that (i) have underlying variables which are subsets of the substrate, $\forall F \in$ $\mathcal{F}_{U, V}(\operatorname{und}(F) \subseteq V)$, and (ii) consist of partition transforms, $\forall F \in \mathcal{F}_{U, V} \forall T \in$ $F \exists P \in \mathrm{~B}\left(\operatorname{und}(T)^{\mathrm{CS}}\right)\left(T=P^{\mathrm{T}}\right)$. In addition, partition circularities are excluded by ensuring that the partitions are unique in the fud when flattened to substrate.

Let $v$ be the volume of the substrate, $v=\left|V^{\mathrm{C}}\right|$. If the volume, $v$, is finite, the set of substrate fuds is finite, $\left|\mathcal{F}_{U, V}\right|<\infty$.

Avoiding partition circularities is computationally expensive. The infinitelayer substrate functional definition sets $\mathcal{F}_{\infty, U, V}$ is the superset of the substrate functional definition sets, $\mathcal{F}_{\infty, U, V} \supset \mathcal{F}_{U, V}$, that drop the exclusion of partition circularities. The infinite-layer substrate fud set is defined recursively,

$$
\mathcal{F}_{\infty, U, V}=\{F: F \subseteq \operatorname{powinf}(U, V)(\emptyset), \quad \operatorname{und}(F) \subseteq V\}
$$

where

$$
\begin{aligned}
& \operatorname{powinf}(U, V)(F):=F \cup G \cup \operatorname{powinf}(U, V)(F \cup G): \\
& G=\left\{P^{\mathrm{T}}: K \subseteq \operatorname{vars}(F) \cup V, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}
\end{aligned}
$$

The cardinality of the infinite-layer substrate fud set is infinite, $\left|\mathcal{F}_{\infty, U, V}\right|=\infty$.

### 2.5.4 Decompositions

This section may be skipped until section "Tractable and practicable aligned induction'.

A functional definition set decomposition is a model that consists of a tree of fuds that are contingent on components.

The set of functional definition set decompositions $\mathcal{D}_{\mathrm{F}}$ is a subset of the trees of pairs of (i) states, $\mathcal{S}$, and (ii) functional definition sets, $\mathcal{F}$

$$
\mathcal{D}_{\mathrm{F}} \subset \operatorname{trees}(\mathcal{S} \times \mathcal{F})
$$

Let $D$ be a fud decomposition, $D \in \mathcal{D}_{\mathrm{F}}$. The set of $f u d s$ is $\operatorname{fuds}(D):=$ $\{F:((\cdot, F), \cdot) \in \operatorname{nodes}(D)\}$. The underlying is $\operatorname{und}(D):=\bigcup\{\operatorname{und}(F): F \in$ fuds $(D)\}$. The set of underlying variables of a decomposition is also called the substrate.

Fud decompositions are constrained such that each of the states in child pairs are states in the derived variables of the parent fud,

$$
\forall D \in \mathcal{D}_{\mathrm{F}} \forall((\cdot, F), E) \in \operatorname{nodes}(D) \forall((S, \cdot), \cdot) \in E\left(S \in \operatorname{dom}\left(\left(F^{\mathrm{T}}\right)^{-1}\right)\right)
$$

The root nodes have no parent and so their states are constrained to be null, $\forall D \in \mathcal{D}_{\mathrm{F}} \forall((S, \cdot), \cdot) \in D(S=\emptyset)$. Given a fud decomposition $D \in \mathcal{D}_{\mathrm{F}}$ having underlying variables $V=\operatorname{und}(D)$, each fud $F \in$ fuds $(D)$ is contingent on the component $C \in \mathrm{~B}\left(V^{\mathrm{C}}\right)$ implied by the union of the ancestor derived states in the derived variables of the union of the ancestor fuds. Let $L$ be a path in the fud decomposition, $L \in \operatorname{paths}(D)$. Then for each child fud $(\cdot, F)=L_{i}$, where $i \in\{2 \ldots|L|\}$, the union of the ancestor derived states is $R=\bigcup\left\{S: j \in\{2 \ldots i\},(S, \cdot)=L_{j}\right\}$, the union of the ancestor fuds is $G=\bigcup\left\{H: j \in\{1 \ldots i-1\},(\cdot, H)=L_{j}\right\}$, and so the contingent component is $\left(G^{\mathrm{T}}\right)^{-1}(R)$. In the case where the underlying of the ancestor $f u d, G$, is the whole substrate, $\operatorname{und}(G)=V$, then the component is $C=\left(G^{\mathrm{T}}\right)^{-1}(R) \subseteq V^{\mathrm{C}}$.

The function cont $\in \mathcal{D}_{\mathrm{F}} \rightarrow \mathrm{P}(\mathcal{A} \times \mathcal{F})$ returns the set of component-fud pairs of the fud decomposition. When the fud decomposition, $D$, is applied to a histogram $A \in \mathcal{A}$ in variables $\operatorname{vars}(A)=V$, each fud transform is applied to the contingent slice, $A * C * F^{\mathrm{T}}$ where $(C, F) \in \operatorname{cont}(D)$. Two fuds on the same path $\left(\cdot, F_{1}\right) \in L_{j}$ and $\left(\cdot, F_{2}\right) \in L_{i}$ where $L \in \operatorname{paths}(D)$ and $j<i$, are such that the fud $\left(C_{1}, F_{1}\right) \in \operatorname{cont}(D)$ nearer the root has a component which is a superset of the component of the fud $\left(C_{2}, F_{2}\right) \in \operatorname{cont}(D)$ nearer the leaves, $C_{1} \supset C_{2}$. So the slice nearer the root is greater than or equal to the slice nearer the leaves, $A * C_{1} \geq A * C_{2}$. That is, the fuds are more and more selectively contingent along the fud decomposition's paths, and so are applied to smaller and smaller slices.

In the case where each of the slice derived are diagonalised, $\forall(C, F) \in$ cont $(D)$ (diagonal $\left(A * C * F^{\mathrm{T}}\right)$ ), the fud decomposition, $D$, is a contingent, layered, redundant model of the sample histogram, $A$.

A fud decomposition is a model, so it can be converted to a functional transform, $D^{\mathrm{T}} \in \mathcal{T}_{\mathrm{f}}$. The partition of the fud decomposition transform is equal to the set of components corresponding to those fud derived states that
are not parent derived states in the decomposition tree, $\bigcup\left\{\operatorname{dom}\left(\left(F^{\mathrm{T}}\right)^{-1}\right) \backslash\{S\right.$ : $((S, \cdot), \cdot) \in E\}:((\cdot, F), E) \in \operatorname{nodes}(D)\}$. The resultant transform has the same underlying variables as the fud decomposition, $\operatorname{und}\left(D^{\mathrm{T}}\right)=\operatorname{und}(D)$.

The tree of a fud decomposition is sometimes unwieldy, so consider the fud decomposition fud, $D^{\mathrm{F}} \in \mathcal{F}$, which is the intermediate fud used in the construction of the fud decomposition transform, $D^{\mathrm{T}}$. The decomposition fud is defined as the union of the decomposition fuds and the nullable fud, $D^{\mathrm{F}}:=\bigcup$ fuds $(D) \cup$ nullable $(U)\left(D^{\mathrm{D}}\right)$. The nullable fud, nullable $(U)\left(D^{\mathrm{D}}\right)$, is defined in section 'Decompositions', below. It consists of a layer of transforms which is added on top of the union of the decomposition fuds, $\bigcup$ fuds $(D)$. Each derived variable in the fud union, $w \in \operatorname{der}(F)$ where $F \in \operatorname{fuds}(D)$, is in the underlying of a corresponding transform, $w \in \operatorname{und}\left(T_{w}\right)$, in the nullable layer. The transform derived consists of a nullable variable $\left\{w^{\prime}\right\}=\operatorname{der}\left(T_{w}\right)$. This nullable variable, $w^{\prime}$, has the same values as its underlying variable, $w$, but with an additional null value, $U_{w^{\prime}}=U_{w} \cup\{$ null $\}$. If the fud, $F$, is not the root fud, there is also a contingent variable $c$ with values corresponding to the fud's in-slice and out-slice states, $U_{c}=\{$ in, out $\}$. That is, given contingent state $S \in C^{\mathrm{S}}$, where $(C, F) \in \operatorname{cont}(D)$, the derived state, $R$, is such that $(c$, in $) \in R$. Similarly, if $S \in V^{\mathrm{CS}} \backslash C^{\mathrm{S}}$, then $(c$, out $) \in R$. The underlying of nullable variable's transform will also contain the contingent variable, $\{c, w\}=\operatorname{und}\left(T_{w}\right)$. The nullable variable, $w^{\prime}$, is constrained by the transform, $T_{w}$, to be in the null value whenever the contingent variable, $c$, is in the out value, and to be in the value of the underlying variable, $w$, otherwise. That is, ( $c$, out $) \in R \Longrightarrow\left(w^{\prime}\right.$, null $) \in R$, and $(c$, in $) \in R \Longrightarrow\left(w^{\prime}, R_{w}\right) \in R$. In this way, there is no need to navigate the slices of the decomposition. The fud decomposition fud, $D^{\mathrm{F}}$, can be analysed by examining the effective states of reductions to its nullable derived variables, $\operatorname{der}\left(D^{\mathrm{F}}\right)$.

Given a set of substrate variables $V$, the set of substrate fud decompositions $\mathcal{D}_{\mathrm{F}, U, V}$ is a subset of fud decompositions, $\mathcal{D}_{\mathrm{F}, U, V} \subset \mathcal{D}_{\mathrm{F}}$, that contain only substrate fuds, $\forall D \in \mathcal{D}_{\mathrm{F}, U, V} \forall F \in \operatorname{fuds}(D)\left(F \in \mathcal{F}_{U, V}\right)$. In addition, each fud is unique in a path, $\forall D \in \mathcal{D}_{\mathrm{F}, U, V} \forall L \in \operatorname{paths}(D)(|\{F:(\cdot,(\cdot, F)) \in L\}|=|L|)$.

Let $v$ be the volume of the substrate, $v=\left|V^{\mathrm{C}}\right|$. If the volume, $v$, is finite, the set of substrate fud decompositions is finite, $\left|\mathcal{D}_{\mathrm{F}, U, V}\right|<\infty$.

Similarly, the infinite-layer substrate fud decompositions $\mathcal{D}_{\mathrm{F}, \infty, U, V}$ is the superset of the substrate fud decompositions, $\mathcal{D}_{\mathrm{F}, \infty, U, V} \supset \mathcal{D}_{\mathrm{F}, U, V}$, that contain only infinite-layer substrate fuds, $\forall D \in \mathcal{D}_{\mathrm{F}, \infty, U, V} \forall F \in \operatorname{fuds}(D)\left(F \in \mathcal{F}_{\infty, U, V}\right)$.

The cardinality of the infinite-layer substrate fud decomposition set is infinite, $\left|\mathcal{D}_{\mathrm{F}, \infty, U, V}\right|=\infty$.

### 2.6 Induction with model

### 2.6.1 Classical induction

Given substrate transform $T \in \mathcal{T}_{U, V}$, the derived histogram valued integral substrate histograms function $D_{U, \mathbf{i}, T, z}$ is defined

$$
D_{U, \mathbf{i}, T, z}:=\left\{(A, A * T): A \in \mathcal{A}_{U, i, V, z}\right\}
$$

The finite set of iso-deriveds of derived histogram $A * T$ is

$$
D_{U, \mathbf{i}, T, z}^{-1}(A * T)=\left\{B: B \in \mathcal{A}_{U, i, V, z}, B * T=A * T\right\}
$$

The degree to which an integral iso-set $I \subseteq \mathcal{A}_{U, \mathrm{i}, V, z}$ that contains the histogram, $A \in I$, is said to be law-like is called the iso-derivedence. The iso-derivedence is defined as the ratio of (i) the cardinality of the intersection between the integral iso-set and the set of integral iso-deriveds, and (ii) the cardinality of the union,

$$
\frac{1}{\left|\mathcal{A}_{U, i, V, z}\right|} \leq \frac{\left|I \cap D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right|}{\left|I \cup D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right|} \leq 1
$$

In classical modelled induction the history probability functions are constrained by derived histogram.

Let $P$ be a substrate history probability function, $P \in\left(\mathcal{H}_{U, V, z}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$. Given a history $H_{E} \in \mathcal{H}_{U, V, z_{E}}$, of size $z_{E}=\left|H_{E}\right|$, consider the case where the derived histogram $A * T$ of drawn histories is known to be necessary, $\sum\left(P(H): H \subseteq H_{E}, \operatorname{his}(H) * T=A * T\right)=1$. The maximum likelihood estimate which maximises the entropy, entropy $(\tilde{P})$, is

$$
\begin{aligned}
\tilde{P}= & \left\{(H, 1): H \subseteq H_{E}, \operatorname{his}(H) * T=A * T\right\}^{\wedge} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, \operatorname{his}(G) * T \neq A * T\right\} \\
= & \left\{\left(H, 1 / \sum\left(Q_{\mathrm{h}, U}(E, z)(B): B \in D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right)\right):\right. \\
& \left.H \subseteq H_{E}, \operatorname{his}(H) * T=A * T\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, \operatorname{his}(G) * T \neq A * T\right\}
\end{aligned}
$$

That is, the maximum likelihood estimate, $\tilde{P}$, is such that all drawn histories $H \subseteq H_{E}$ with the derived, $\operatorname{his}(H) * T=A * T$, are uniformly probable and all other histories, $G \nsubseteq H_{E}$ or $\operatorname{his}(G) * T \neq A * T$, are impossible, $\tilde{P}(G)=0$. If (i) the transform, $T$, is known, (ii) the derived, $A * T$, is known and (iii) the distribution histogram, $H_{E}$, is known, then the likely probability function, $\tilde{P}$, is known.

The likely probability of drawing histogram A from necessary drawn derived $A * T$ is

$$
\begin{aligned}
\sum\left(\tilde{P}(H): H \in \mathcal{H}_{U, V, z}, \operatorname{his}(H)=\right. & A)= \\
& \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum Q_{\mathrm{h}, U}(E, z)(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)}
\end{aligned}
$$

The likely history probability function entropy, entropy $(\tilde{P})$, is maximised when the sum of the iso-derived historical frequencies, $\sum Q_{\mathrm{h}, U}(E, z)(B)$ : $B \in D_{U, i, T, z}^{-1}(A * T)$, is maximised.

Consider the case where the transform, $T$, is known and the derived, $A * T$, is known, but the distribution histogram, $E$, is unknown and hence the likely history probability function, $\tilde{P}$, is unknown. The maximum likelihood estimate $\tilde{E}$ for the distribution histogram, $E$, is a modal value of the likelihood function,
$\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{h}, U}(D, z)(B): B \in D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right)\right): D \in \mathcal{A}_{U, \mathrm{i}, V, z_{E}}\right\}\right)$
The likely distribution histogram, $\tilde{E}$, is known if the distribution histogram size, $z_{E}$, is known, the transform, $T$, is known and the derived, $A * T$, is known. If it is assumed that the distribution histogram equals the likely distribution histogram, $E=\tilde{E}$, then the likely history probability is known, $\tilde{P}(H)=1 / \sum\left(Q_{\mathrm{h}, U}(\tilde{E}, z)(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right)$ where his $(H) * T=A * T$.

In the case where the distribution histogram, $E$, is unknown, and the distribution histogram size, $z_{E}$, is also unknown, except that it is known to be large, $z_{E} \gg z$, then the maximum likelihood estimate $\tilde{E}$ for the distribution probability histogram, $\hat{E}$, may be approximated by a modal value of a likelihood function which depends on the multinomial distribution instead,
$\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right)\right): D \in \mathcal{A}_{U, V, 1}\right\}\right)$
The normalised naturalisation, $\hat{A} * T * T^{\dagger}$, is a solution. The naturalisation, $A * T * T^{\dagger}$, is the independent analogue of the iso-deriveds. So the maximum
likelihood estimate, $\tilde{E}$, for the distribution probability histogram, $\hat{E}$, is the naturalisation probability histogram, $\hat{A} * T * T^{\dagger}$,

$$
\tilde{E}=\hat{A} * T * T^{\dagger}
$$

In the case where the naturalisation is integral, $A * T * T^{\dagger} \in \mathcal{A}_{\mathrm{i}}$, the sum of the iso-derived naturalisation-distributed multinomial probabilities varies with the naturalisation naturalisation-distributed multinomial probability,

$$
\begin{aligned}
& \sum Q_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)(B): B \in D_{U, \mathbf{i}, T, z}^{-1}(A * T) \sim \\
& Q_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right)
\end{aligned}
$$

So, if it is assumed that the distribution probability histogram equals the likely distribution probability histogram, $\hat{E}=\tilde{E}=\hat{A} * T * T^{\dagger}$, then the likely history probability varies against the naturalisation-distributed multinomial probability of the naturalisation, $\tilde{P}(H) \sim 1 / \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right)$.

The cardinality of the set of integral iso-deriveds may be stated explicitly as the product of the weak compositions of the components,

$$
\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|=\prod_{(R, C) \in T^{-1}} \frac{\left((A * T)_{R}+|C|-1\right)!}{(A * T)_{R}!(|C|-1)!}
$$

So the integral iso-deriveds log-cardinality varies against the size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
& \ln \left|D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right| \sim \\
& \quad-\left((z+v) \times \operatorname{entropy}\left(A * T+V^{\mathrm{C}} * T\right)\right. \\
& \left.\quad-z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)\right)
\end{aligned}
$$

where size $z=\operatorname{size}(A)=\operatorname{size}(A * T)$ and volume $v=\left|V^{\mathrm{C}}\right|$. In the domain where the size is less than or equal to the volume, $z \leq v$, the integral iso-deriveds log-cardinality varies against the size scaled component size cardinality relative entropy,

$$
\ln \left|D_{U, i, T, z}^{-1}(A * T)\right| \sim-z \times \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)
$$

So the logarithm of the likely probability of drawing histogram $A$ from necessary drawn derived $A * T$ varies with the relative entropy,

$$
\begin{aligned}
\ln \sum\left(\tilde{P}(H): H \in \mathcal{H}_{U, V, z}, \operatorname{his}(H)=A\right) & \sim \\
& z \times \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)
\end{aligned}
$$

The naturalisation, $A * T * T^{\dagger}$, is the most probable histogram, $\forall B \in D_{U,, T, z}^{-1}(A *$ T) $\left(Q_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right) \geq Q_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)(B)\right)$. In the case where the histogram is natural, $A=A * T * T^{\dagger}$, then, as the relative entropy, entropyRelative $\left(A * T, V^{\mathrm{C}} * T\right)$, increases, the likely histogram probability, $Q_{\mathrm{m}, U}(A, z)(A) / \sum\left(Q_{\mathrm{m}, U}(A, z)(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right)$, increases.

The likely history probability function entropy varies with the naturalisation entropy, entropy $(\tilde{P}) \sim \operatorname{entropy}\left(A * T * T^{\dagger}\right)$, and against the relative entropy, entropy $(\tilde{P}) \sim-$ entropyRelative $\left(A * T, V^{\mathrm{C}} * T\right)$.

Consider the case where a drawn histogram $A$ is known, but neither the distribution histogram, $E$, is known nor the transform, $T$, is known, and hence the likely history probability function, $\tilde{P}$, is unknown. The maximum likelihood estimate $(\tilde{E}, \tilde{T})$ for the pair of the distribution histogram, $E$, and the transform, $T$, is a modal value of the likelihood function,

$$
\begin{align*}
& \operatorname{maxd}\left(\left\{\left((D, M), \sum\left(Q_{\mathrm{h}, U}(D, z)(B): B \in D_{U, \mathrm{i}, M, z}^{-1}(A * M)\right)\right):\right.\right.  \tag{E}\\
&\left.\left.D \in \mathcal{A}_{U, \mathrm{i}, V, z_{E}}, M \in \mathcal{T}_{U, V}\right\}\right)
\end{align*}
$$

All solutions are such that the transform maximum likelihood estimate is unary, $\tilde{T}=T_{\mathrm{u}}$ where $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$. This is the trivial case where the set of iso-derived histograms is the entire set of substrate histograms, $D_{U, \mathrm{i}, T_{\mathrm{u}}, z}^{-1}(A *$ $\left.T_{\mathrm{u}}\right)=\mathcal{A}_{U, \mathrm{i}, V, z}$. In this case necessary derived, $H \subseteq H_{E}$ and $\operatorname{his}(H) * T_{\mathrm{u}}=$ $A * T_{\mathrm{u}}$, reduces to drawn history, $H \subseteq H_{E}$. If it is assumed that the transform equals the likely transform, $T=\tilde{T}=T_{\mathrm{u}}$, then the likely history probability function which maximises the entropy, entropy $(\tilde{P})$, is

$$
\begin{aligned}
\tilde{P}= & \left\{\left(H, 1 /\binom{z_{E}}{z}\right): H \subseteq H_{E},|H|=z\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\}
\end{aligned}
$$

That is, in the case of unknown transform, the maximum likelihood estimate, $\tilde{P}$, is such that all drawn histories $H \subseteq H_{E}$ of size $|H|=z$ are uniformly probable and all other histories, $G \nsubseteq H_{E}$, are impossible, $\tilde{P}(G)=0$.

Define the derived-dependent $A^{\mathrm{D}(T)} \in \mathcal{A}_{U, V, z}$ as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the
histogram, $A$, conditional that it is an iso-derived,

$$
\begin{aligned}
& \left\{A^{\mathrm{D}(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in D_{U, i, T, z}^{-1}(A * T)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The derived-dependent, $A^{\mathrm{D}(T)}$, is the dependent analogue of the iso-deriveds. Note that the derived-dependent, $A^{\mathrm{D}(T)}$, is not always computable, but an approximation to any accuracy can be made to it. In the case where the histogram is natural, the derived-dependent equals the naturalisation, $A=$ $A * T * T^{\dagger} \Longrightarrow A^{\mathrm{D}(T)}=A=A * T * T^{\dagger}$.

Now consider the case where, given necessary drawn derived $A * T$, it is known, in addition, that the sample histogram $A$ is the most probable histogram of the iso-derived. That is, the likely probability of drawing histogram $A$ from necessary drawn derived $A * T$,

$$
\begin{aligned}
\sum\left(\tilde{P}(H): H \in \mathcal{H}_{U, V, z}, \operatorname{his}(H)=\right. & A)= \\
& \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum Q_{\mathrm{h}, U}(E, z)(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)}
\end{aligned}
$$

is maximised.
In the case where the transform, $T$, is known and the sample, $A$, is known, but the distribution histogram, $E$, is unknown, the maximum likelihood estimate $\tilde{E}$ for the distribution histogram, $E$, is a modal value of the likelihood function,

$$
\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{h}, U}(D, z)(A)}{\sum Q_{\mathrm{h}, U}(D, z)(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)}\right): D \in \mathcal{A}_{U, \mathrm{i}, V, z_{E}}\right\}\right)
$$

The likely distribution histogram, $\tilde{E}$, is known if the distribution histogram size, $z_{E}$, is known, the transform, $T$, is known and the sample, $A$, is known. If it is assumed that the distribution histogram equals the likely distribution histogram, $E=\tilde{E}$, then the likely history probability is known, $\tilde{P}(H)=$ $1 / \sum\left(Q_{\mathrm{h}, U}(\tilde{E}, z)(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right)$ where $\operatorname{his}(H) * T=A * T$.

If the histogram is natural, $A=A * T * T^{\dagger}$, then the additional constraint of
probable sample makes no change to the maximum likelihood estimate, $\tilde{E}$,

$$
\begin{aligned}
A= & A * T * T^{\dagger} \Longrightarrow \\
& \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{h}, U}(D, z)(A)}{\sum Q_{\mathrm{h}, U}(D, z)(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)}\right): D \in \mathcal{A}_{U, \mathrm{i}, V, z_{E}}\right\}\right) \\
= & \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{h}, U}(D, z)(B): B \in D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right)\right): D \in \mathcal{A}_{U, \mathrm{i}, V, z_{E}}\right\}\right)
\end{aligned}
$$

If the histogram is not natural, $A \neq A * T * T^{\dagger}$, however, then the likely history probability function entropy, entropy $(\tilde{P})$, is lower than it is in the case of necessary derived unconstrained by probable sample.

In the case where the distribution histogram, $E$, is unknown, and the distribution histogram size, $z_{E}$, is also unknown, except that it is known to be large, $z_{E} \gg z$, then the maximum likelihood estimate $\tilde{E}$ for the distribution probability histogram, $\hat{E}$, is now approximated by a modal value of the conditional likelihood function,

$$
\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)}\right): D \in \mathcal{A}_{U, V, 1}\right\}\right)
$$

The solution to this is the normalised derived-dependent, $\tilde{E}=\hat{A}^{\mathrm{D}(T)}$. The maximum likelihood estimate is near the sample, $\tilde{E} \sim \hat{A}$, only in as much as it is far from the naturalisation, $\tilde{E} \nsim \hat{A} * T * T^{\dagger}$.

The iso-derived conditional multinomial probability distribution is defined
$\hat{Q}_{\mathrm{m}, \mathrm{d}, T, U}(E, z)(A):=\frac{1}{\left|\operatorname{ran}\left(D_{U, \mathrm{i}, T, z}\right)\right|} \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum Q_{\mathrm{m}, U}(E, z)(B): B \in D_{U, \mathbf{i}, T, z}^{-1}(A * T)}$
So the optimisation can be rewritten,

$$
\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(D, z)(A)\right): D \in \mathcal{A}_{U, V, 1}\right\}\right)
$$

In the case where the histogram is natural, $A=A * T * T^{\dagger}$, the log likelihood varies against the iso-derived log-cardinality,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) & \propto \ln \frac{Q_{\mathrm{m}, U}(A, z)(A)}{\sum Q_{\mathrm{m}, U}(A, z)(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)} \\
& \sim-\ln \left|D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|
\end{aligned}
$$

So the log likelihood varies with the size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \sim \\
& \quad \begin{aligned}
(z+v) \times \operatorname{entropy}(A * T & \left.+V^{\mathrm{C}} * T\right) \\
& -z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)
\end{aligned}
\end{aligned}
$$

In the domain where the size is less than or equal to the volume, $z \leq v$, the log likelihood varies with the size scaled component size cardinality relative entropy,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \sim z \times \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)
$$

In other words, the log likelihood is maximised where (i) the derived entropy, entropy $(A * T)$, is minimised, and (ii) the cross entropy, entropyCross $(A *$ $T, V^{\mathrm{C}} * T$ ), is maximised, so that high counts are in low cardinality components and high cardinality components have low counts.

If the histogram is natural, $A=A * T * T^{\dagger}$, and the component size cardinality relative entropy is high, entropyCross $\left(A * T, V^{\mathrm{C}} * T\right)>\ln \left|T^{-1}\right|$, it can also be shown that the log likelihood varies against the derived multinomial probability,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \sim-\ln \hat{Q}_{\mathrm{m}, U}(A * T, z)(A * T)
$$

In this case the sum sensitivity of the iso-derived conditional multinomial probability distribution varies with the underlying-derived multinomial probability distribution sum sensitivity difference,

```
sum(sensitivity}(U)(\mp@subsup{\hat{Q}}{\textrm{m},\textrm{d},T,U}{}(A,z)))
    sum(sensitivity}(U)(\mp@subsup{\hat{Q}}{\textrm{m},U}{}(A,z)))-\operatorname{sum}(\operatorname{sensitivity}(U)(\mp@subsup{\hat{Q}}{\textrm{m},U}{}(A*T,z))
```

and so is less than or equal to the sum sensitivity of the multinomial probability distribution,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)\right)\right) \leq \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(A, z)\right)\right)
$$

Furthermore, the sum sensitivity varies against the log-likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)\right)\right) \sim-\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A)
$$

That is, in the high relative entropy natural case, the maximisation of the log-likelihood also tends to minimise the sum sensitivity to the maximum likelihood estimate. This is opposite to the relationship between the sum sensitivity and the log-likelihood in classical non-modelled induction, which was found to be weakly positively correlated.

As the relative entropy, entropyRelative $\left(A * T, V^{\mathrm{C}} * T\right)$, increases, the loglikelihood, $\ln \hat{Q}_{\mathrm{m}, \mathrm{d}, T, U}(A, z)(A)$, increases, but the sensitivity to distribution histogram, $E$, decreases. In other words, the higher the sample relative entropy the more likely the normalised sample histogram, $\hat{A}$, equals the normalised distribution histogram, $\hat{E}$, and the smaller the likely difference between them if they are not equal.

Given necessary derived and probable sample, consider the case where a drawn histogram $A$ is known, but neither the distribution histogram, $E$, is known nor the transform, $T$, is known, and hence the likely history probability function, $\tilde{P}$, is unknown. The maximum likelihood estimate $(\tilde{E}, \tilde{T})$ for the pair of the distribution histogram, $E$, and the transform, $T$, is a modal value of the likelihood function,

$$
\begin{aligned}
& (\tilde{E}, \tilde{T}) \in \\
& \quad \operatorname{maxd}\left(\left\{\left((D, M), \frac{Q_{\mathrm{h}, U}(D, z)(A)}{\sum Q_{\mathrm{h}, U}(D, z)(B): B \in D_{U, \mathrm{i}, M, z}^{-1}(A * M)}\right)\right.\right. \\
& \left.\left.\quad D \in \mathcal{A}_{U, \mathrm{i}, V, z_{E}}, M \in \mathcal{T}_{U, V}\right\}\right)
\end{aligned}
$$

All solutions are such that the transform maximum likelihood estimate is self, $\tilde{T}=T_{\mathrm{s}}$ where $T_{\mathrm{s}}=V^{\mathrm{CS}\{ \} \mathrm{T}}$. This is the trivial case where the set of iso-derived histograms is just the sample, $D_{U, i, T \mathrm{~s}, z}^{-1}\left(A * T_{\mathrm{s}}\right)=\{A\}$. In this case necessary derived, $\operatorname{his}(H) * T_{\mathrm{s}}=A * T_{\mathrm{s}}$, reduces to necessary histogram, $\operatorname{his}(H)=A$. If it is assumed that the transform equals the likely transform, $T=\tilde{T}=T_{\mathrm{s}}$, then the likely history probability function which maximises the entropy, entropy $(\tilde{P})$, is

$$
\begin{aligned}
\tilde{P}= & \left\{\left(H, 1 / Q_{\mathrm{h}, U}(E, z)(A)\right): H \subseteq H_{E}, \operatorname{his}(H)=A\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, \operatorname{his}(G) \neq A\right\}
\end{aligned}
$$

That is, in the case of unknown transform, the maximum likelihood estimate, $\tilde{P}$, is such that all drawn histories $H \subseteq H_{E}$ with the histogram, his $(H)=A$, are uniformly probable and all other histories, $G \nsubseteq H_{E}$ or $\operatorname{his}(G) \neq A$, are impossible, $\tilde{P}(G)=0$.

In this case the maximum likelihood estimate, $\tilde{E}$, for the distribution probability histogram, $\hat{E}$, is the sample probability histogram, $\hat{A}$,

$$
\tilde{E}=\hat{A}=\hat{A} * T_{\mathrm{s}} * T_{\mathrm{s}}^{\dagger}
$$

Consider the case where the derived is uniformly possible. Given substrate transform $T \in \mathcal{T}_{U, V}$, assume that the substrate history probability function $P \in\left(\mathcal{H}_{U, V, z}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$ is the distribution of an arbitrary history valued function, $\mathcal{X} \rightarrow \mathcal{H}$, given an arbitrary derived valued function, $\mathcal{X} \rightarrow \mathcal{A}$. In this case, the history valued function is chosen arbitrarily from the constrained subset

$$
\begin{aligned}
\{G: F \in \mathcal{X} \rightarrow & (\mathcal{A} \times(\mathcal{X} \rightarrow \mathcal{H})), \\
& \left.\left(\cdot,\left(A^{\prime}, G\right)\right) \in F, \forall(\cdot, H) \in G\left(\operatorname{his}(H) * T=A^{\prime}\right)\right\} \subset \mathcal{X} \rightarrow \mathcal{H}
\end{aligned}
$$

Uniformly possible derived is a weaker constraint than uniformly possible histogram, so the subset of history valued functions is larger.

This subset of the substrate history probability functions can be generalised for all substrate transforms as the subset derived from

$$
\bigcup_{T \in \mathcal{T}_{\mathrm{f}}}\left(\mathcal{X} \rightarrow\left(\mathcal{A} \times_{T}(\mathcal{X} \rightarrow \mathcal{H})\right)\right)
$$

where $\mathcal{T}_{\mathrm{f}}$ is the set of all functional transforms, and the fibre product $\times_{T}$ is defined

$$
\begin{aligned}
& \mathcal{A} \times_{T}(\mathcal{X} \rightarrow \mathcal{H}): \\
& \quad\left\{\left(A^{\prime}, G\right):\left(A^{\prime}, G\right) \in \mathcal{A} \times(\mathcal{X} \rightarrow \mathcal{H}), \forall(\cdot, H) \in G\left(\operatorname{his}(H) * T=A^{\prime}\right)\right\}
\end{aligned}
$$

In the case where there is a distribution history $H_{E}$ and a substrate transform $T \in \mathcal{T}_{U, V}$, the maximum likelihood estimate which maximises the entropy, entropy $(\tilde{P})$, is

$$
\begin{aligned}
\tilde{P}= & \left(\bigcup\left\{\left\{(H, 1): H \subseteq H_{E}, \operatorname{his}(H) * T=A^{\prime}\right\}^{\wedge}: A^{\prime} \in \operatorname{ran}\left(D_{U, \mathbf{i}, T, z}\right)\right\}\right)^{\wedge} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\} \\
= & \left(\bigcup \left\{\left\{\left(H, 1 / \sum\left(Q_{\mathrm{h}, U}(E, z)(B): B \in D_{U, \mathbf{i}, T, z}^{-1}\left(A^{\prime}\right)\right)\right):\right.\right.\right. \\
& \left.\left.\left.H \subseteq H_{E}, \operatorname{his}(H) * T=A^{\prime}\right\}: A^{\prime} \in \operatorname{ran}\left(D_{U, \mathbf{i}, T, z}\right)\right\}\right)^{\wedge} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\}
\end{aligned}
$$

That is, the maximum likelihood estimate, $\tilde{P}$, is such that all drawn deriveds are uniformly probable, and then all drawn histories $H \subseteq H_{E}$ with the same derived, $\operatorname{his}(H) * T=A^{\prime}$, are uniformly probable. If the distribution histogram, $H_{E}$, is known and the substrate transform, $T$, is known, then the likely probability function, $\tilde{P}$, is known.

In the case where the distribution histogram is uniform, $\hat{E}=\hat{V}^{\mathrm{C}}$, so that all histories are substrate histories, $\left\{H: H \in \mathcal{H}_{U, V, z}, \operatorname{his}(H) * T=A^{\prime}\right\}$, the more probable histograms, $A \in \operatorname{maxd}\left(\left\{\left(B, \sum\left(\tilde{P}_{H}: H \in \mathcal{H}_{U, V, z}\right.\right.\right.\right.$, his $(H)=$ $\left.\left.B)): B \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right)$, tend to be such that they are uniform within the component, $\forall C \in T^{\mathrm{P}} \forall R, S \in C\left(A_{R} \approx A_{S}\right)$, or naturalised, $A \approx A * T * T^{\dagger}$.

The properties of uniformly possible derived are the same as for necessary derived, except that the probabilities are scaled. So, in the case where the distribution histogram, $E$, is unknown, and the distribution histogram size, $z_{E}$,
is also unknown, except that it is known to be large, $z_{E} \gg z$, then the likely history probability varies against the naturalisation-distributed multinomial probability of the naturalisation,

$$
\tilde{P}(H) \sim 1 /\left|\operatorname{ran}\left(D_{U, i, T, z}\right)\right| \times 1 / \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right)
$$

That is, more histories are possible but less probable.

Now consider the case where, given uniform possible derived, it is known, in addition, that the sample histogram $A$ is the most probable histogram of its iso-derived.

The iso-derived conditional multinomial probability distribution, is defined above as
$\hat{Q}_{\mathrm{m}, \mathrm{d}, T, U}(E, z)(A):=\frac{1}{\left|\operatorname{ran}\left(D_{U, \mathbf{i}, T, z}\right)\right|} \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum Q_{\mathrm{m}, U}(E, z)(B): B \in D_{U, \mathbf{i}, T, z}^{-1}(A * T)}$
The iso-derived conditional multinomial probability already includes the uniform possible scaling factor of $1 /\left|\operatorname{ran}\left(D_{U, i, T, z}\right)\right|$.

The cardinality of the derived, $\left|\operatorname{ran}\left(D_{U, \mathbf{i}, T, z}\right)\right|$, is equal to the cardinality of the derived substrate histograms,

$$
\left|\operatorname{ran}\left(D_{U, \mathrm{i}, T, z}\right)\right|=\frac{\left(z+w^{\prime}-1\right)!}{z!\left(w^{\prime}-1\right)!}
$$

where $w^{\prime}=\left|T^{-1}\right|$. So the additional term, $-\ln \left|\operatorname{ran}\left(D_{U, i, T, z}\right)\right|$, in the uniform possible log likelihood, $\ln \hat{Q}_{\mathrm{m}, \mathrm{d}, T, U}(E, z)(A)$, varies against the derived volume, $w^{\prime}$, where the derived volume is less than the size, $w^{\prime}<z$, otherwise against the size scaled $\log$ derived volume, $z \ln w^{\prime}$,

$$
-\ln \left|\operatorname{ran}\left(D_{U, \mathbf{i}, T, z}\right)\right| \sim-\left(\left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right)\right)
$$

In the case where the sample is natural, $A=A * T * T^{\dagger}$, the uniform possible log likelihood varies (i) against the derived volume, $w^{\prime}$, where the derived volume is less than the size, $w^{\prime}<z$, otherwise against the size scaled log derived volume, $z \ln w^{\prime}$, and (ii) with the size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \sim \\
& -\left(\left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right)\right) \\
& +(z+v) \times \operatorname{entropy}\left(A * T+V^{\mathrm{C}} * T\right) \\
& \quad-z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)
\end{aligned}
$$

In other words, the log likelihood is maximised where (i) the derived volume, $w^{\prime}$, is minimised, (ii) the derived entropy, entropy $(A * T)$, is minimised, and (iii) the cross entropy, entropy $\operatorname{Cross}\left(A * T, V^{\mathrm{C}} * T\right)$, is maximised, so that high counts are in low cardinality components and high cardinality components have low counts.

As in the case of necesary derived and probable sample, above, if the histogram is natural, $A=A * T * T^{\dagger}$, and the component size cardinality relative entropy is high, entropyCross $\left(A * T, V^{\mathrm{C}} * T\right)>\ln w^{\prime}$, the sum sensitivity of the iso-derived conditional multinomial probability distribution is less than or equal to the sum sensitivity of the multinomial probability distribution,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)\right)\right) \leq \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(A, z)\right)\right)
$$

and varies against the log-likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)\right)\right) \sim-\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A)
$$

Given uniform possible derived and probable sample, consider the case where a drawn histogram $A$ is known, but neither the distribution histogram, $E$, is known nor the transform, $T$, is known, and hence the likely history probability function, $\tilde{P}$, is unknown. In the case where the distribution histogram size, $z_{E}$, is also unknown, except that it is known to be large, $z_{E} \gg z$, then the maximum likelihood estimate $(\tilde{E}, \tilde{T})$ for the pair of the distribution histogram, $E$, and the transform, $T$, is approximated by a modal value of the conditional likelihood function,

$$
(\tilde{E}, \tilde{T}) \in \operatorname{maxd}\left(\left\{\left((D, M), \hat{Q}_{\mathrm{m}, \mathrm{~d}, M, U}(D, z)(A)\right): D \in \mathcal{A}_{U, V, 1}, M \in \mathcal{T}_{U, V}\right\}\right)
$$

If there is a unique maximum for the distribution probability histogram, $\tilde{E}$, this can be rewritten in terms of the derived-dependent,

$$
\tilde{T} \in \operatorname{maxd}\left(\left\{\left(M, \hat{Q}_{\mathrm{m}, \mathrm{~d}, M, U}\left(A^{\mathrm{D}(M)}, z\right)(A)\right): M \in \mathcal{T}_{U, V}\right\}\right)
$$

The derived-dependent, $A^{\mathrm{D}(T)}$, is not always computable, but an approximation to any accuracy can be made to it, so a computable approximation of the maximum likelihood estimate, $\tilde{T}$, can be made for the unknown transform, $T$. In some cases the likely transform, $\tilde{T}$, is not trivial, $\tilde{T} \neq T_{\mathrm{u}}$ and $\tilde{T} \neq T_{\mathrm{s}}$.

If it is also known that the sample is natural, the optimisation can be restricted to natural transforms, $A=A * T * T^{\dagger} \Longrightarrow A^{\mathrm{D}(T)}=A$. In this case the optimisation is

$$
\tilde{T} \in \operatorname{maxd}\left(\left\{\left(M, \hat{Q}_{\mathrm{m}, \mathrm{~d}, M, U}(A, z)(A)\right): M \in \mathcal{T}_{U, V}, A=A * M * M^{\dagger}\right\}\right)
$$

or

$$
\begin{array}{r}
\tilde{T} \in \operatorname{maxd}\left(\left\{\left(M, \frac{1}{\left|\operatorname{ran}\left(D_{U, \mathrm{i}, M, z}\right)\right|} \frac{Q_{\mathrm{m}, U}(A, z)(A)}{\sum Q_{\mathrm{m}, U}(A, z)(B): B \in D_{U, \mathbf{i}, M, z}^{-1}(A * M)}\right):\right.\right. \\
\left.\left.M \in \mathcal{T}_{U, V}, A=A * M * M^{\dagger}\right\}\right)
\end{array}
$$

The numerator is constant, so the optimisation can be simplified,

$$
\left.\left.\left.\begin{array}{r}
\tilde{T} \in \operatorname{mind}\left(\left\{\left(M,\left|\operatorname{ran}\left(D_{U, \mathrm{i}, M, z}\right)\right| \sum Q_{\mathrm{m}, U}(A, z)(B): B \in D_{U, \mathrm{i}, M, z}^{-1}(A * M)\right):\right.\right. \\
M
\end{array}\right) \mathcal{T}_{U, V}, A=A * M * M^{\dagger}\right\}\right) .
$$

In this case the maximum likelihood estimate, $\tilde{E}$, for the distribution probability histogram, $\hat{E}$, is the sample probability histogram, $\hat{A}$,

$$
\tilde{E}=\hat{A}=\hat{A} * \tilde{T} * \tilde{T}^{\dagger}
$$

Note that, although computable, this optimisation is intractable because the cardinality of the substrate transforms, $\left|\mathcal{T}_{U, V}\right|$, is factorial in the volume, $v$. Tractable optimisations require the computation to be at most polynomial.

Note, also, that, although the sensitivity to distribution, $E$, is defined above for uniform possible derived, the sensitivity to model, $T$, is not yet defined.

### 2.6.2 Specialising coder induction

It is shown above that there are two canonical history coders, the index history coder $C_{\mathrm{H}}$ and the classification coder $C_{\mathrm{G}}$. Given variables $V$ and size $z$, the index substrate history coder, $C_{\mathrm{H}, U, V, z}$, encodes each substrate history $H \in \mathcal{H}_{U, V, z}$ in a fixed space of $C_{\mathrm{H}, U, V, z}^{\mathrm{s}}(H)=z \ln v$, where volume $v=\left|V^{\mathrm{C}}\right|$. By contrast, the classification substrate history coder, $C_{\mathrm{G}, U, V, z}$, encodes each history in a space which depends on the histogram $A=\operatorname{his}(H)$,

$$
C_{\mathrm{G}, U, V, z}^{\mathrm{s}}(H)=\ln \frac{(z+v-1)!}{z!(v-1)!}+\ln \frac{z!}{\prod_{S \in A^{\mathrm{s}}} A_{S}!}
$$

When the histogram entropy, entropy $(A)$, is high the classification space is greater than the index space, $C_{\mathrm{G}, U, V, z}^{\mathrm{s}}(H)>C_{\mathrm{H}, U, V, z}^{\mathrm{s}}(H)$, but when the entropy is low the classification space is less than the index space, $C_{\mathrm{G}, U, V, z}^{\mathrm{s}}(H)<$ $C_{\mathrm{H}, U, V, z}^{\mathrm{s}}(H)$. In the case where the size is much less than the volume, $z \ll v$, the break-even sized entropy is approximately $z \times \operatorname{entropy}(A) \approx z \ln z$.

Given substrate transform $T \in \mathcal{T}_{U, V}$, the specialising derived substrate history coder, $C_{\mathrm{G}, \mathrm{H}, U, T, z}$, is intermediate between the classification coder, $C_{\mathrm{G}, U, V, z}$, and the index coder, $C_{\mathrm{H}, U, V, z}$. Given a substrate history $H \in \mathcal{H}_{U, V, z}$, the derived history, $H * T$, is encoded in a classification coder, $C_{\mathrm{G}, U, W, z}$, where derived variables $W=\operatorname{der}(T)$. Then each sub-history $H_{C}$, corresponding to a component of the partition, $H_{C} \subseteq H$, where $(R, C) \in T^{-1}$, is encoded in a index coder, $C_{\mathrm{H}, U, C, z_{C}}$, where $z_{C}=(A * T)_{R}$. The specialising space is

$$
\begin{aligned}
C_{\mathrm{G}, \mathrm{H}, U, T, z}^{\mathrm{s}}(H)= & \ln \frac{\left(z+w^{\prime}-1\right)!}{z!\left(w^{\prime}-1\right)!}+\ln \frac{z!}{\prod_{(R,) \in T^{-1}}(A * T)_{R}!}+ \\
& \sum_{(R, C) \in T^{-1}}(A * T)_{R} \ln |C|
\end{aligned}
$$

where $w^{\prime}=\left|T^{-1}\right|$.
In the case where the transform is self, $T=T_{\mathrm{s}}$ where $T_{\mathrm{s}}=V^{\mathrm{CS}\{ \} \mathrm{T}}$, then the specialising space equals the classification space, $C_{\mathrm{G}, H, U, T_{\mathrm{s}}, z}^{\mathrm{s}}(H)=C_{\mathrm{G}, U, V, z}^{\mathrm{s}}(H)$. In the case where the transform is unary, $T=T_{\mathrm{u}}$ where $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$, then the specialising space equals the index space, $C_{\mathrm{G}, \mathrm{H}, U, T_{\mathrm{u}}, z}^{\mathrm{s}}(H)=C_{\mathrm{H}, U, V, z}^{\mathrm{s}}(H)$.

The specialising space depends only on the transform, $T$, and the derived, $A * T$. Define the specialising space function $\operatorname{sp}(T)(A * T):=C_{\mathrm{G}, \mathrm{H}, U, T, z}^{\mathrm{s}}(H)$.

The specialising space varies (i) with the derived volume, $w^{\prime}$, where the derived volume is less than the size, $w^{\prime}<z$, otherwise with the size scaled log derived volume, $z \ln w^{\prime}$, and (ii) against the size scaled component size cardinality relative entropy,

$$
\begin{aligned}
C_{\mathrm{G}, \mathrm{H}, U, T, z}^{\mathrm{s}}(H) \sim & \left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right) \\
- & z \times \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)
\end{aligned}
$$

In general, the specialising space is less than either of the two canonical spaces where the derived entropy, entropy $(A * T)$, is low, but the expected component entropy, entropyComponent $(A, T)$, is high. So the specialising space is minimised when (a) the derived volume, $w^{\prime}$, is minimised, (b) the derived entropy, entropy $(A * T)$, is minimised, (c) high size components are low cardinality components and low size components are high cardinality components, and (d) the expected component entropy is maximised.

In specialising induction the history probability functions are constrained by specialising space which in turn depends on derived histogram.

In the discussion of 'Maximum Entropy', above, it was shown that, of a subset of the micro-state valued functions of distinguishable particle, the maximum likelihood estimate of the implied probability function is the probability function with the greatest entropy.

Consider a system of $r$ undefined particles where the micro-state is a substrate history, $H \in \mathcal{H}_{U, V, z}$. The set of substrate history valued functions having exactly $r$ particles with integer identifier is $\{1 \ldots r\}: \rightarrow \mathcal{H}_{U, V, z} \subset \mathcal{X} \rightarrow$ $\mathcal{H}$. Given substrate transform $T \in \mathcal{T}_{U, V}$, let the subset $S \subset\{1 \ldots r\}: \rightarrow$ $\mathcal{H}_{U, V, z}$ be such that the expected specialising space is a constant, $\forall R \in$ $S\left(\sum\left(C_{\mathrm{G}, \mathrm{H}, U, T, z}^{\mathrm{s}}(H) / r:(\cdot, H) \in R\right)=\epsilon\right)$. Of this subset, $S$, the implied probability function with the greatest entropy, $\tilde{P} \in \operatorname{maxd}(\{(N$, entropy $(N))$ : $\left.\left.R \in S, N=\left\{(H,|C| / r):(H, C) \in R^{-1}\right\}\right\}\right)$, approximates to a Boltzmann distribution.

Given substrate transform $T \in \mathcal{T}_{U, V}$, the maximum likelihood estimate $\tilde{P}$ of the substrate history probability function $P \in\left(\mathcal{H}_{U, V, z}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$, which maximises the entropy, entropy $(\tilde{P})$, is

$$
\begin{aligned}
\tilde{P} & =\left\{\left(H, \exp \left(-C_{\mathrm{G}, \mathrm{H}, U, T, z}^{\mathrm{s}}(H)\right)\right): H \in \mathcal{H}_{U, V, z}\right\}^{\wedge} \\
& =\left\{(H, \exp (-\operatorname{sp}(T)(\operatorname{his}(H) * T))): H \in \mathcal{H}_{U, V, z}\right\}^{\wedge} \\
& =\left\{\left(H, \frac{\exp (-\operatorname{sp}(T)(\operatorname{his}(H) * T))}{\sum \exp (-\operatorname{sp}(T)(\operatorname{his}(G) * T)): G \in \mathcal{H}_{U, V, z}}\right): H \in \mathcal{H}_{U, V, z}\right\}
\end{aligned}
$$

where exp is the exponential function. The likely probability of a history, $\tilde{P}(H)$, is inversely proportional to the bounding integer, for which the space is the logarithm, of the integer encoding of the history in the specialising coder. The maximum likelihood estimate, $\tilde{P}$, is such that all substrate histories $H \in \mathcal{H}_{U, V, z}$ with the same specialising space, $C_{\mathrm{G}, \mathrm{H}, U, T, z}^{\mathrm{s}}(H)$, are equally probable and all histories are possible, $\tilde{P}(H)>0$. If the transform, $T$, is known, then the likely probability function, $\tilde{P}$, is known and an approximation to the expected specialising space, $\epsilon$, is known.

The specialising space, $\operatorname{sp}(T)(\operatorname{his}(H) * T)=C_{\mathrm{G}, H, U, T, z}^{\mathrm{s}}(H)$, depends only on the transform, $T$, and the derived, his $(H) * T$, so all substrate histories with the same derived, his $(H) * T=A * T$, are equally probable. All histories are possible, $\tilde{P}(H)>0$, so specialising coder induction is similar to uniformly possible derived induction, above, except that the deriveds are not necesssarily equally probable.

The likely history probability function entropy, entropy $(\tilde{P})$, is maximised when the expected numerator, $\exp (-\operatorname{sp}(T)(\operatorname{his}(H) * T))$, is minimised. The expected specialising space is $\sum\left(\tilde{P}(H) \times \operatorname{sp}(T)(\operatorname{his}(H) * T): H \in \mathcal{H}_{U, V, z}\right) \approx \epsilon$, so the likely history probability function entropy varies with the expected specialising space, entropy $(\tilde{P}) \sim \epsilon$.

Now consider the case where, given specialising, it is known, in addition, that the sample histogram $A$ is the most probable histogram. That is, the likely probability of histogram A,

$$
\begin{aligned}
\sum(\tilde{P}(H): H & \left.\in \mathcal{H}_{U, V, z}, \operatorname{his}(H)=A\right)= \\
& \frac{z!}{\prod_{S \in A^{\mathrm{s}}} A_{S}!} \times \frac{\exp (-\operatorname{sp}(T)(A * T))}{\sum \exp (-\operatorname{sp}(T)(\operatorname{his}(G) * T)): G \in \mathcal{H}_{U, V, z}}
\end{aligned}
$$

is maximised.
The specialising probability distribution is defined

$$
\hat{Q}_{\mathrm{G}, \mathrm{H}, T, U}(z):=\left\{\left(A, \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \times \exp (-\operatorname{sp}(T)(A * T))\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}^{\wedge}
$$

The specialising log likelihood varies (i) with the size scaled underlying entropy (ii) against the derived volume, $w^{\prime}$, where the derived volume is less than the size, $w^{\prime}<z$, otherwise against the size scaled log derived volume, $z \ln w^{\prime}$, and (iii) with the size scaled component size cardinality relative entropy,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{G}, \mathrm{H}, T, U}(z)(A) \sim & z \times \operatorname{entropy}(A) \\
& -\left(\left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right)\right) \\
+ & z \times \operatorname{entropyRelative}\left(A * T, V^{\mathrm{C}} * T\right)
\end{aligned}
$$

In other words, the log likelihood is maximised where (i) the derived volume, $w^{\prime}$, is minimised, (ii) the derived entropy, entropy $(A * T)$, is minimised, (iii) the cross entropy, entropy $\operatorname{Cross}\left(A * T, V^{\mathrm{C}} * T\right)$, is maximised, so that high counts are in low cardinality components and high cardinality components have low counts, and (iv) the expected component entropy, entropyComponent $(A, T)$, is maximised.

In the case of probable sample, the likely history probability function entropy varies against the relative entropy, entropy $(\tilde{P}) \sim-\operatorname{entropyRelative}(A *$ $\left.T, V^{\mathrm{C}} * T\right)$. Similarly, the expected specialising space varies against the relative entropy, $\epsilon \sim-\operatorname{entropyRelative}\left(A * T, V^{\mathrm{C}} * T\right)$.

Given specialising and probable sample, consider the case where the histogram $A$ is known, but the transform, $T$, is unknown, and hence the likely history probability function, $\tilde{P}$, is unknown. The maximum likelihood estimate $\tilde{T}$ for the transform, $T$, is approximated by a modal value of the specialising likelihood,

$$
\tilde{T} \in \operatorname{maxd}\left(\left\{\left(M, \hat{Q}_{\mathrm{G}, \mathrm{H}, M, U}(z)(A)\right): M \in \mathcal{T}_{U, V}\right\}\right)
$$

Note that, as in the case of uniform possible derived induction, although computable, this optimisation is intractable because the cardinality of the substrate transforms, $\left|\mathcal{T}_{U, V}\right|$, is factorial in the volume, $v$.

Unlike uniform possible derived induction, in specialising induction there is no distribution history, $H_{E}$, and so no sensitivity to distribution, E. A sensitivity to model, $T$, can be defined, however, as the negative logarithm of the cardinality of the maximum likelihood estimate models,

$$
-\ln \left|\max \left(\left\{\left(M, \hat{Q}_{\mathrm{G}, \mathrm{H}, M, U}(z)(A)\right): M \in \mathcal{T}_{U, V}\right\}\right)\right|
$$

That is, as the cardinality of the modal models of the log likelihood function increases, the sensitivity to model decreases. It can be shown that the sensitivity to model varies against the size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
& -\ln \left|\max \left(\left\{\left(M, \hat{Q}_{\mathrm{G}, \mathrm{H}, M, U}(z)(A)\right): M \in \mathcal{T}_{U, V}\right\}\right)\right| \sim \\
& \quad-\left((z+v) \times \operatorname{entropy}\left(A * T+V^{\mathrm{C}} * T\right)\right. \\
& \left.\quad-z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)\right)
\end{aligned}
$$

So the sensitivity to model varies against the log likelihood,

$$
-\ln \left|\max \left(\left\{\left(M, \hat{Q}_{\mathrm{G}, \mathrm{H}, M, U}(z)(A)\right): M \in \mathcal{T}_{U, V}\right\}\right)\right| \quad \sim-\ln \hat{Q}_{\mathrm{G}, \mathrm{H}, T, U}(z)(A)
$$

As the relative entropy, entropyRelative $\left(A * T, V^{\mathrm{C}} * T\right)$, increases, the loglikelihood, $\ln \hat{Q}_{\mathrm{G}, \mathrm{H}, T, U}(z)(A)$, increases, but the sensitivity to model, $T$, decreases. In other words, the higher the sample relative entropy the more likely the maximum likelihood estimate, $\tilde{T}$, equals the model, $T$, and the smaller the likely difference between them if they are not equal.

It is shown above, in the case of uniform possible derived and natural sample, $A=A * T * T^{\dagger}$, that the log likelihood varies against the derived volume and with the size-volume scaled component size cardinality sum relative
entropy,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \sim \\
& \quad-\left(\left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right)\right) \\
& +(z+v) \times \operatorname{entropy}\left(A * T+V^{\mathrm{C}} * T\right) \\
& \quad-z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)
\end{aligned}
$$

so the iso-derived conditional log likelihood varies with the specialising log likelihood,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \sim \ln \hat{Q}_{\mathrm{G}, \mathrm{H}, T, U}(z)(A)
$$

and the iso-derived conditional model sensitivity varies against the iso-derived conditional log likelihood,

$$
\begin{aligned}
-\ln \mid \max \left(\left\{\left(M, \hat{Q}_{\mathrm{m}, \mathrm{~d}, M, U}(A, z)(A)\right): M \in \mathcal{T}_{U, V}, A=\right.\right. & \left.\left.A * M * M^{\dagger}\right\}\right) \mid \sim \\
& -\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A)
\end{aligned}
$$

The iso-derived conditional model sensitivity may be compared to the isoderived conditional distribution sensitivity which also varies against the isoderived conditional log likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)\right)\right) \sim-\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A)
$$

That is, in classical modelled induction, the log likelihood is maximised and the sensitivities to both distribution and model are minimised where (i) the derived volume is minimised, (ii) the derived entropy is minimised, (iii) the cross entropy is maximised, so that high counts are in low cardinality components and high cardinality components have low counts, and (iv) the expected component entropy is maximised.

### 2.6.3 Artificial neural networks

In the discussion of classical modelled induction, above, it is shown that, given uniform possible derived and probable sample $A \in \mathcal{A}_{U, V, z}$, where the sample is natural, $A=A * T * T^{\dagger}$, the maximum likelihood estimate $\tilde{T}$ for unknown transform $T \in \mathcal{T}_{U, V}$, is

$$
\tilde{T} \in \operatorname{maxd}\left(\left\{\left(M, \hat{Q}_{\mathrm{m}, \mathrm{~d}, M, U}(A, z)(A)\right): M \in \mathcal{T}_{U, V}, A=A * M * M^{\dagger}\right\}\right)
$$

Similarly, given specialising and probable sample, the maximum likelihood estimate, $\tilde{T}$, for the transform, $T$, is approximated by a modal value of the specialising likelihood,

$$
\tilde{T} \in \operatorname{maxd}\left(\left\{\left(M, \hat{Q}_{\mathrm{G}, \mathrm{H}, M, U}(z)(A)\right): M \in \mathcal{T}_{U, V}\right\}\right)
$$

In both cases, although computable, the optimisations are intractable because the cardinality of the substrate transforms, $\left|\mathcal{T}_{U, V}\right|$, is factorial in the volume, $v$. In order to make the optimisation tractable and then practicable, the search must be restricted to a subset of the models.

Artificial neural network induction is an example of practicable classical modelled induction. Here the models are artificial neural networks which correspond to functional definition sets of transforms representing the neurons. The optimisation consists of a sequence of these networks. The graph of the network remains constant, but the weights between neurons of successive networks are altered to decrease a loss function step by step. The weights of the initial network are chosen at random. The optimisation proceeds until the loss falls below a threshold. The fud of the terminating network is then the practicable model. The network graph is chosen depending on the given sample. In some cases of configuration the entropy properties of the resultant model are those of classical induction.

The one functional transforms, $\mathcal{T}_{U, f, 1}$, are derived state valued left total functions of underlying state,

$$
\forall T \in \mathcal{T}_{U, \mathrm{f}, 1}\left(\operatorname{split}\left(V, X^{\mathrm{S}}\right) \in V^{\mathrm{CS}}: \rightarrow W^{\mathrm{CS}}\right)
$$

where $(X, W)=T$ and $V=\operatorname{und}(T)$. In order to construct a coordinate from a state define ()$^{\rrbracket} \in \mathcal{S} \rightarrow \mathcal{L}(\mathcal{W})$ as

$$
S^{\mathbb{1}}:=\left\{(i, u):((v, u), i) \in \operatorname{order}\left(D_{\mathcal{V} \times \mathcal{W}}, S\right)\right\}
$$

where $D_{\mathcal{V} \times \mathcal{W}}$ is an order on the variables and values. The converse function to construct a state from a coordinate ()$^{V} \in \mathcal{L}(\mathcal{W}) \rightarrow \mathcal{S}$ is

$$
S^{V}:=\left\{\left(v, S_{i}\right):(v, i) \in \operatorname{order}\left(D_{\mathcal{V}}, V\right)\right\}
$$

Now one functional transforms may be represented as derived value coordinate valued left total functions of underlying value coordinate,

$$
\begin{aligned}
\left\{\left(S^{\square}, R^{\square}\right):(S, R) \in \operatorname{split}\left(V, X^{\mathrm{S}}\right)\right\} & \in\left\{S^{\square}: S \in V^{\mathrm{CS}}\right\}: \rightarrow\left\{R^{\square}: R \in W^{\mathrm{CS}}\right\} \\
& \subset \mathcal{W}^{n} \rightarrow \mathcal{W}^{m}
\end{aligned}
$$

where $n=|V|$ and $m=|W|$.
So an alternative definition for a one functional transform is a tuple of (i)
the underlying variables, $V$, (ii) the derived variables, $W$, and (iii) a derived value coordinate valued left total function of underlying value coordinate, $f$,

$$
\begin{aligned}
& \mathcal{T}_{U, f, 1}= \\
& \quad\{(V, W, f): V, W \in \mathrm{P}(\operatorname{vars}(U)), V \cap W=\emptyset \\
& \left.\quad f \in\left\{S^{\square}: S \in V^{\mathrm{CS}}\right\}: \rightarrow\left\{R^{\square}: R \in W^{\mathrm{CS}}\right\}\right\}
\end{aligned}
$$

The histogram of a function-defined one functional transform $T=(V, W, f) \in$ $\mathcal{T}_{U, f, 1}$ is

$$
\operatorname{histogram}(T):=\left\{S \cup f\left(S^{\square}\right)^{W}: S \in V^{\mathrm{CS}}\right\} \times\{1\}
$$

In the special case where the transform is mono-derived-variate, $T=(V,\{w\}, f)$, the function may be simplified to $f \in\left\{S^{\rrbracket}: S \in V^{\mathrm{CS}}\right\}: \rightarrow U_{w}$, and the histogram is

$$
\operatorname{histogram}(T):=\left\{S \cup\left\{\left(w, f\left(S^{\square}\right)\right)\right\}: S \in V^{\mathrm{CS}}\right\} \times\{1\}
$$

In the further special case of mono-derived-variate transform where its variables are real, $\forall v \in V\left(U_{v}=\mathbf{R}\right)$ and $U_{w}=\mathbf{R}$, then the function is a real valued left total function of a real coordinate, $f \in \mathbf{R}^{n}: \rightarrow \mathbf{R}$. Here the cartesian states are $V^{\mathrm{CS}}=\prod_{v \in V}(\{v\} \times \mathbf{R})$, so the histogram is

$$
\begin{aligned}
\operatorname{histogram}(T) & =\left\{S \cup\left\{\left(w, f\left(S^{\mathbb{D}}\right)\right)\right\}: S \in \prod_{v \in V}(\{v\} \times \mathbf{R})\right\} \times\{1\} \\
& =\left\{S^{V} \cup\{(w, f(S))\}: S \in \mathbf{R}^{n}\right\} \times\{1\}
\end{aligned}
$$

The cartesian volume is infinite, $\left|V^{\mathrm{C}}\right|=\left|\mathbf{R}^{n}\right|$, so the cardinality of the histogram is infinite, $|\operatorname{histogram}(T)|=\left|\mathbf{R}^{n}\right|$.

The reals form a metric space so a real valued function of real coordinates may be discretised given a finite subset of the reals $D \subset \mathbf{R}:|D|<\infty$. The discretised function is

$$
\operatorname{discrete}(D, n)(f):=\left\{(X, \operatorname{nearest}(D, f(X))): X \in D^{n}\right\} \in D^{n}: \rightarrow D
$$

where nearest $\in \mathrm{P}(\mathbf{R}) \times \mathbf{R} \rightarrow \mathbf{R}$ is defined

$$
\text { nearest }(D, r):=t:\{t\} \in \operatorname{mind}(\{(s,(|r-s|, s)): s \in D\})
$$

The cardinality of the discretised transform's histogram is finite,

$$
|\operatorname{histogram}((V,\{w\}, \operatorname{discrete}(D, n)(f)))|=\left|D^{n}\right|=|D|^{n}
$$

An example of a transform defined by a real valued function occurs in the function composition of artificial neural networks. Here a transform represents a model of a neuron called a perceptron, $T=\left(V, w, f_{\sigma}(Q)\right)$, where the dimension is $n=|V|$ and the function $f_{\sigma}(Q) \in \mathbf{R}^{n}: \rightarrow \mathbf{R}$ is parameterised by (i) some differentiable function $\sigma \in \mathbf{R}: \rightarrow \mathbf{R}$, called the activation function, and (ii) a vector of weights, $Q \in \mathbf{R}^{n+1}$, and is defined

$$
f_{\sigma}(Q)(S):=\sigma\left(\sum_{i \in\{1 \ldots n\}} Q_{i} S_{i}+Q_{n+1}\right)
$$

The function composition of artificial neural networks may be represented by fuds of these transforms. Define nets as a subset of the set of lists of tuples of the graph and real weights,

$$
\text { nets }:=\{G: G \in \mathcal{L}(\mathrm{P}(\mathcal{V}) \times \mathcal{V} \times \mathcal{L}(\mathbf{R})), \forall(\cdot,(V, \cdot, Q)) \in G(|Q|=|V|+1)\}
$$

Define the set of transforms, $\operatorname{fud}(\sigma) \in$ nets $\rightarrow \mathrm{P}\left(\mathcal{T}_{\mathrm{f}}\right)$ as

$$
\begin{aligned}
& \operatorname{fud}(\sigma)(G):= \\
& \qquad\left\{\left(\left\{S^{V} \cup\left\{\left(w, f_{\sigma}(Q)(S)\right)\right\}: S \in \mathbf{R}^{n}\right\} \times\{1\},\{w\}\right):\right. \\
& \quad(\cdot,(V, w, Q)) \in G, n=|V|\}
\end{aligned}
$$

The fud search is restricted to the neural net substrate fud set, $\mathcal{F}_{\infty, U, V, \sigma}=$ $\mathcal{F}_{\infty, U, V} \cap($ fud $(\sigma) \circ$ nets $)$.

An example of a neural net substrate fud $F \in \mathcal{F}_{\infty, U, V, \sigma}$ has $l=\operatorname{layer}(F, \operatorname{der}(F))$ layers of fixed breadth equal to the underlying dimension, $\forall i \in\{1 \ldots l\}\left(\left|F_{i}\right|=\right.$ $n$ ) where $n=|V|$ and $F_{i}=\{T: T \in F, \operatorname{layer}(F, \operatorname{der}(T))=i\}$, such that the underlying of each transform is the derived of the layer below, $\forall T \in F_{1}(\operatorname{und}(T)=V)$ and $\forall i \in\{2 \ldots l\} \forall T \in F_{i}\left(\operatorname{und}(T)=\operatorname{der}\left(F_{i-1}\right)\right)$.

The optimisation of artificial neural networks can be divided into unsupervised and supervised types. In the supervised case there is additional knowledge. First, there exists an unknown distribution histogram $E$ from which the known sample histogram, $A$, is drawn, $A<E$. Secondly, the substrate can be partitioned into query variables $K \subset V$ and label variables, $V \backslash K$, such that the distribution histogram, $E$, is causal between the query variables and the label variables,

$$
\operatorname{split}\left(K, E^{\mathrm{FS}}\right) \in K^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}
$$

and so the sample histogram, $A$, is also causal,

$$
\operatorname{split}\left(K, A^{\mathrm{FS}}\right) \in K^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}
$$

That is, in the supervised case, there is a functional relation such that there is exactly one label state for every effective query state. In an optimisation, a fud $F \in \mathcal{F}_{\infty, U, K, \sigma}$ has its underlying variables restricted to the query variables, $\operatorname{und}(F) \subseteq K$. The optimisation maximises the causality between the derived variables and the label variables by minimising the loss function. At the optimum there is no error and the relation is functional,

$$
\operatorname{split}\left(W_{F},\left(A * X_{F} \%\left(W_{F} \cup V \backslash K\right)\right)^{\mathrm{FS}}\right) \in W_{F}^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}
$$

where $X_{F}=\operatorname{histogram}\left(F^{\mathrm{T}}\right)$ and $W_{F}=\operatorname{der}(F)$. At zero loss the label state is implied for all query states that are effective in the sample derived,

$$
\operatorname{split}\left(K,\left(K^{\mathrm{C}} * F^{\mathrm{T}} *\left(A * X_{F}\right) \%(V \backslash K)\right)^{\mathrm{FS}}\right) \in K^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}
$$

That is, a query state $Q \in K^{\mathrm{CS}}$ that is effective in the sample derived $R \in\left(A * F^{\mathrm{T}}\right)^{\mathrm{FS}}$, where $\{R\}=\left(\{Q\}^{\mathrm{U}} * F^{\mathrm{T}}\right)^{\mathrm{FS}}$, but that is not necessarily effective in the sample itself, $Q \notin(A \% K)^{\mathrm{FS}}$, still has an implied label state, $\{L\}=\left(A * X_{F} *\{R\}^{\mathrm{U}} \%(V \backslash K)\right)^{\mathrm{FS}}$ where $L \in(V \backslash K)^{\mathrm{CS}}$.

In the case where the derived variables of the fud is a literal frame of the label variables, $W_{F}: \leftrightarrow:(V \backslash K)$ and $\forall v \in(V \backslash K)\left(U_{v} \subseteq \mathbf{R}\right)$, the least squares loss function lsq $\in \mathcal{A} \times \mathcal{F} \times \mathrm{P}(\mathcal{V}) \rightarrow \mathbf{R}$ is

$$
\operatorname{lsq}(A, F, K):=\sum_{(S, c) \in A * X_{F}}\left(c \times \sum_{i \in\{1 \ldots m\}}\left(\left(S \% W_{F}\right)_{i}^{\square}-(S \%(V \backslash K))_{i}^{\square}\right)^{2}\right)
$$

where $m=\left|W_{F}\right|=|(V \backslash K)|$. The loss function is a continuous real valued function and so its derivative with respect to each weight can be defined. In this case the optimisation is least squares gradient descent.

If the optimisation of artificial neural networks is of the unsupervised type, there is no knowledge of a causal label. Here the method of least squares gradient descent is still used but the label is simply a copy of the substrate, $V$, itself. Usually the network graph is constrained so that a middle layer $a \in\{2 \ldots l-1\}$ has narrower breadth than the substrate, $\left|F_{a}\right|<n$.

In the computations of alignment and entropy that follow, the derived variables are discretised to the values of the label variables, $D=\cup\left\{U_{v}: v \in\right.$ $(V \backslash K)\}$.

In some cases of sample and network optimisation configuration, the negative least squares loss (a) varies against the effective derived volume

$$
-\operatorname{lsq}\left(A, F_{D}, K\right) \sim-\left|\left(A * F_{D}^{\mathrm{T}}\right)^{\mathrm{F}}\right|
$$

(b) varies against the derived entropy of the fud transform,

$$
-\operatorname{lsq}\left(A, F_{D}, K\right) \sim-\operatorname{entropy}\left(A * F_{D}^{\mathrm{T}}\right)
$$

(c) varies with the component size cardinality relative entropy,

$$
-\operatorname{lsq}\left(A, F_{D}, K\right) \sim \text { entropyRelative }\left(A * F_{D}^{\mathrm{T}}, V^{\mathrm{C}} * F_{D}^{\mathrm{T}}\right)
$$

and (d) varies with the expected component entropy,

$$
-\operatorname{lsq}\left(A, F_{D}, K\right) \sim \text { entropyComponent }\left(A, F_{D}^{\mathrm{T}}\right)
$$

The initial $f u d F_{R}$ has arbitrary weights, so is likely to have a high least squares loss. That is, far from the derived variables and the label variables being causally related, $W_{D}^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}$, they are likely to be independent,

$$
\operatorname{algn}\left(A * X_{F_{R}} *\left\{W_{D}^{\mathrm{CS}\{ \} \mathrm{T}},(V \backslash K)^{\mathrm{CS}\{ \} \mathrm{T}}\right\}^{\mathrm{T}}\right) \approx 0
$$

where $\left\{W_{D}^{\mathrm{CS}\{ \} \mathrm{T}},(V \backslash K)^{\mathrm{CS}\{ \} \mathrm{T}}\right\}$ is the fud of the self transforms of the (i) discretised derived variables and (ii) label variables.

As the optimisation proceeds from the initial fud, $F_{R}$, to the optimal fud $F$, the loss decreases and the relation between the top layer and the label becomes more causal,

$$
\operatorname{algn}\left(A * X_{F} *\left\{W_{D}^{\mathrm{CS}\{ \} \mathrm{T}},(V \backslash K)^{\mathrm{CS}\{ \} \mathrm{T}}\right\}^{\mathrm{T}}\right)>0
$$

The negative least squares loss varies with the alignment of the self partition transforms, so varies against the derived entropy of the fud transform,

$$
\begin{aligned}
-\operatorname{lsq}\left(A, F_{D}, K\right) & \sim \operatorname{algn}\left(A * X_{F} *\left\{W_{D}^{\mathrm{CS}\{ \} \mathrm{T}},(V \backslash K)^{\mathrm{CS}\{ \} \mathrm{T}}\right\}^{\mathrm{T}}\right) \\
& \sim-z \times \operatorname{entropy}\left(A * F_{D}^{\mathrm{T}}\right)
\end{aligned}
$$

That is, as the loss, $\operatorname{lsq}\left(A, F_{D}, K\right)$, is minimised, the derived entropy, entropy $(A *$ $F_{D}^{\mathrm{T}}$ ), tends to be minimised. The minimisation of derived entropy is a property of classical induction.

The negative least squares loss only varies with the component size cardinality relative entropy, entropyRelative $\left(A * F_{D}^{\mathrm{T}}, V^{\mathrm{C}} * F_{D}^{\mathrm{T}}\right)$, in the case where the histogram, $A$, is clustered by the label variables. This requires alignment within the query variables, $\operatorname{algn}(A \% K)>0$. Clustering may be described as follows.

Consider the case of a multi-variate set of real valued query variables $K$, where $k=|K| \geq 2$ and $\forall x \in K\left(U_{x} \subseteq \mathbf{R}\right)$, and a neural net fud $F \in \mathcal{F}_{\infty, U, K, \sigma}$ consisting of two transforms, $F=\left\{T_{1}, T_{2}\right\}$, each having the query variables as the underlying, $\operatorname{und}\left(T_{1}\right)=\operatorname{und}\left(T_{2}\right)=K$. For a coordinate $S \in \mathbf{R}^{k}$ the weights of the transforms form a pair of hyperplanes,

$$
\sum_{i \in\{1 \ldots k\}} Q_{1, i} S_{i}+Q_{1, k+1}=0
$$

and

$$
\sum_{i \in\{1 \ldots k\}} Q_{2, i} S_{i}+Q_{2, k+1}=0
$$

where $Q_{1}, Q_{2} \in \mathbf{R}^{k+1}$ are the weights correspondng to $T_{1}, T_{2}$. If the hyperplanes of the arbitrarily weighted initial fud, $F_{R}$, intersect, the acute angle between them is expected to be $45^{\circ}$. That is, given an activation function, $\sigma$, which is a step function, or a binary set of discrete values, $D=\{0,1\}$, the probability distribution of the component cardinalities of the initial fud is bi-modal. If $\left(\cdot, C_{1}\right),\left(\cdot, C_{2}\right) \in\left(F_{R,\{0,1\}}^{\mathrm{T}}\right)^{-1}$ are such that $\left|C_{1}\right|<\left|C_{2}\right|$, then it is expected that $3\left|C_{1}\right|=\left|C_{2}\right|$. So the component cardinality entropy of the initial fud is expected to be less than maximal,

$$
\operatorname{entropy}\left(K^{\mathrm{C}} * F_{R, D}^{\mathrm{T}}\right)<\operatorname{entropy}\left(W_{D}^{\mathrm{C}}\right)
$$

The derived entropy of the initial fud is expected to be approximately equal to the component cardinality entropy,

$$
\operatorname{entropy}\left(A * F_{R, D}^{\mathrm{T}}\right) \approx \operatorname{entropy}\left(K^{\mathrm{C}} * F_{R, D}^{\mathrm{T}}\right)
$$

and so the component size cardinality relative entropy of the initial fud is expected to be small,

$$
\operatorname{entropyRelative}\left(A * F_{R, D}^{\mathrm{T}}, K^{\mathrm{C}} * F_{R, D}^{\mathrm{T}}\right) \approx 0
$$

If the histogram, $A$, is approximately uniformly distributed over the volume, then the component size cardinality relative entropy remains small during the optimisation,

$$
\text { entropyRelative }\left(A * F_{D}^{\mathrm{T}}, K^{\mathrm{C}} * F_{D}^{\mathrm{T}}\right) \approx 0
$$

In contrast, consider the case where the histogram, $A$, is not uniformly distributed, but clustered by label state. Let $Y_{L} \subset K^{\mathrm{CS}}$ be the set of the centres
of the clusters for effective label state $L \in(A \%(V \backslash K))^{\mathrm{FS}}$. The maximum radius $r_{L} \in \mathbf{R}_{>0}$ is such that

$$
\forall S \in A^{\mathrm{FS}} \diamond L=S \%(V \backslash K) \exists Q \in Y_{L}\left(\sum_{i \in\{1 \ldots k\}}\left(Q_{i}^{\square}-S_{i}^{\square}\right)^{2} \leq r_{L}^{2}\right)
$$

Let $r_{C}$ be the radius of component $C$. In the case where the histogram is clustered such that the cluster radius of a label state is much smaller than the least initial component radius, $\forall(\cdot, C) \in\left(F_{R,\{0,1\}}^{\mathrm{T}}\right)^{-1}\left(r_{L} \ll r_{C}\right)$, then optimised rotations of the hyperplanes, that sweep up nearby clusters in the same label state, tend to be such that the magnitude of the change in the fractional component size, $\left|\left(A * F_{2, D}^{\mathrm{T}}\right)(R)-\left(A * F_{1, D}^{\mathrm{T}}\right)(R)\right| / z$, is greater than magnitude of the change in the fractional component cardinality, $\mid\left(K^{\mathrm{C}} *\right.$ $\left.F_{2, D}^{\mathrm{T}}\right)(R)-\left(K^{\mathrm{C}} * F_{1, D}^{\mathrm{T}}\right)(R)\left|/\left|K^{\mathrm{C}}\right|\right.$. So, in the clustered case, as the optimisation decreases the derived entropy, entropy $\left(A * F_{D}^{\mathrm{T}}\right)$, the component sizes and component cardinalities become less synchronised and the component size cardinality relative entropy increases,

$$
\begin{aligned}
-\operatorname{lsq}\left(A, F_{D}, K\right) & \sim-z \times \operatorname{entropy}\left(A * F_{D}^{\mathrm{T}}\right) \\
& \sim z \times \operatorname{entropyRelative}\left(A * F_{D}^{\mathrm{T}}, K^{\mathrm{C}} * F_{D}^{\mathrm{T}}\right) \\
& =z \times \operatorname{entropyRelative}\left(A * F_{D}^{\mathrm{T}}, V^{\mathrm{C}} * F_{D}^{\mathrm{T}}\right)
\end{aligned}
$$

The same reasoning applies to fuds consisting of more than two transforms, $|F|>2$, but note that at higher fud cardinalities the initial component cardinality entropy, entropy ( $K^{\mathrm{C}} * F_{R, D}^{\mathrm{T}}$ ), tends to be multi-modal and so approximates more closely to the uniform cartesian derived entropy, entropy $\left(W_{D}^{\mathrm{C}}\right)$. So there is less freedom for the relative entropy of the fud to increase during optimisation. In the case of multi-layer fuds, however, the breadth can be constrained and so the relative entropy of deeper, narrrower fuds may be higher than in shallower, wider fuds of the same cardinality.

In general, in the clustered case, the optimised fud is such that high counts are in low cardinality components and high cardinality components have low counts. The maximisation of relative entropy is a property of classical induction.

The accuracy of the approximation of artificial neural network induction to classical induction can be defined as the ratio of the practicable model sampledistributed iso-derived conditional log likelihood to the maximum model sampledistributed iso-derived conditional log likelihood,

$$
0<\frac{\hat{Q}_{\mathrm{m}, \mathrm{~d}, F^{\mathrm{T}}, U}(A, z)(A)}{\hat{Q}_{\mathrm{m}, \mathrm{~d}, \tilde{T}, U}(A, z)(A)} \leq 1
$$

The accuracy varies against the sensitivity to model,
$\frac{\hat{Q}_{\mathrm{m}, \mathrm{d}, F^{\mathrm{T}}, U}(A, z)(A)}{\hat{Q}_{\mathrm{m}, \mathrm{d}, \tilde{T}, U}(A, z)(A)} \sim-\left(-\ln \left|\max \left(\left\{\left(M, \hat{Q}_{\mathrm{m}, \mathrm{d}, M, U}(A, z)(A)\right): M \in \mathcal{T}_{U, V}\right\}\right)\right|\right)$
and so varies with the log-likelihood,

$$
\frac{\hat{Q}_{\mathrm{m}, \mathrm{~d}, F^{\mathrm{T}}, U}(A, z)(A)}{\hat{Q}_{\mathrm{m}, \mathrm{~d}, \tilde{T}, U}(A, z)(A)} \sim \ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A)
$$

That is, although the model obtained from least squares gradient descent is merely an approximation, in the cases where the log-likelihood is high, and so the sensitivity to model is low, the approximation may be reasonably close nonetheless.

### 2.6.4 Aligned induction

Given substrate transform $T \in \mathcal{T}_{U, V}$, the abstract histogram valued integral substrate histograms function $Y_{U, \mathrm{i}, T, \mathrm{~W}, z}$ is defined

$$
Y_{U, \mathrm{i}, T, \mathrm{~W}, z}:=\left\{\left(A,(A * T)^{\mathrm{x}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
$$

The finite set of iso-abstracts of abstract histogram $(A * T)^{\mathrm{X}}$ is

$$
Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{~V}, z},(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}\right\}
$$

The degree to which an integral iso-set $I \subseteq \mathcal{A}_{U, \mathrm{i}, V, z}$ that contains the histogram, $A \in I$, is said to be entity-like is called the iso-abstractence. The iso-abstractence is defined as the ratio of (i) the cardinality of the intersection between the integral iso-set and the set of integral iso-abstracts, and (ii) the cardinality of the union,

$$
\frac{1}{\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right|} \leq \frac{\left|I \cap Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}{\left|I \cup Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|} \leq 1
$$

Law-like iso-sets are subsets of the set of iso-abstracts,

$$
D_{U, i, T, z}^{-1}(A * T) \subseteq Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)
$$

and so are also entity-like.

The formal histogram valued integral substrate histograms function $Y_{U, \mathrm{i}, T, \mathrm{~V}, z}$ is defined

$$
Y_{U, \mathbf{i}, T, \mathrm{~V}, z}:=\left\{\left(A, A^{\mathrm{X}} * T\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
$$

The finite set of iso-formals of formal histogram $A^{\mathrm{X}} * T$ is

$$
Y_{U, i, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{X}} * T=A^{\mathrm{X}} * T\right\}
$$

Aligned-like iso-sets are subsets of the set of iso-formals,

$$
Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right) \subseteq Y_{U, \mathrm{i}, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)
$$

The formal-abstract pair valued integral substrate histograms function $Y_{U, \mathbf{i}, T, z}$ is defined

$$
Y_{U, \mathrm{i}, T, z}:=\left\{\left(A,\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
$$

The finite set of iso-transform-independents of $\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)$ is

$$
\begin{aligned}
& Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{X}} * T,\right.\right. \\
& \left.\left.\quad(A * T)^{\mathrm{X}}\right)\right)= \\
& \quad\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{x}} * T=A^{\mathrm{x}} * T,(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}\right\}
\end{aligned}
$$

The iso-transform-independents is the intersection of the iso-formals and the iso-abstracts,

$$
Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right)=Y_{U, \mathrm{i}, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)
$$

In aligned modelled induction the history probability functions are constrained by formal and abstract histograms.

Let $P$ be a substrate history probability function, $P \in\left(\mathcal{H}_{U, V, z}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$. Given a history $H_{E} \in \mathcal{H}_{U, V, z_{E}}$, of size $z_{E}=\left|H_{E}\right|$, consider the case where both the formal histogram $A^{\mathrm{X}} * T$ of drawn histories is known to be necessary and the abstract histogram $(A * T)^{\mathrm{X}}$ of drawn histories is known to be necessary, $\sum\left(P(H): H \subseteq H_{E}, \operatorname{his}(H)^{\mathrm{X}} * T=A^{\mathrm{X}} * T,(\operatorname{his}(H) * T)^{\mathrm{X}}=(A * T)^{\mathrm{X}}\right)=1$. The maximum likelihood estimate which maximises the entropy, entropy $(\tilde{P})$,
is

$$
\begin{aligned}
\tilde{P}= & \{(H, 1): \\
& \left.H \subseteq H_{E}, \operatorname{his}(H)^{\mathrm{x}} * T=A^{\mathrm{x}} * T,(\operatorname{his}(H) * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}\right\}^{\wedge} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, Z}, G \nsubseteq H_{E}\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, Z}, \operatorname{his}(G)^{\mathrm{x}} * T \neq A^{\mathrm{x}} * T\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z},(\operatorname{his}(G) * T)^{\mathrm{X}} \neq(A * T)^{\mathrm{x}}\right\} \\
= & \left\{\left(H, 1 / \sum\left(Q_{\mathrm{h}, U}(E, z)(B): B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{x}} * T,(A * T)^{\mathrm{x}}\right)\right)\right)\right):\right. \\
& \left.H \subseteq H_{E}, \operatorname{his}(H)^{\mathrm{x}} * T=A^{\mathrm{x}} * T,(\operatorname{his}(H) * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, \operatorname{his}(G)^{\mathrm{X}} * T \neq A^{\mathrm{x}} * T\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z},(\operatorname{his}(G) * T)^{\mathrm{x}} \neq(A * T)^{\mathrm{x}}\right\}
\end{aligned}
$$

That is, the maximum likelihood estimate, $\tilde{P}$, is such that all drawn histories $H \subseteq H_{E}$ with both the formal, $\operatorname{his}(H)^{\mathrm{X}} * T=A^{\mathrm{X}} * T$ and the abstract, (his $(H) * T)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$, are uniformly probable and all other histories, $G \nsubseteq H_{E}$ or $\operatorname{his}(G)^{\mathrm{X}} * T \neq A^{\mathrm{X}} * T$ or $(\operatorname{his}(G) * T)^{\mathrm{X}} \neq(A * T)^{\mathrm{X}}$, are impossible, $\tilde{P}(G)=0$. If (i) the transform, $T$, is known, (ii) the formal, $A^{\mathrm{X}} * T$, is known, (iii) the abstract, $(A * T)^{\mathrm{X}}$, is known and (iv) the distribution histogram, $H_{E}$, is known, then the likely probability function, $\tilde{P}$, is known.

The likely probability of drawing histogram $A$ from necessary drawn formal $A^{\mathrm{X}} * T$ and necessary drawn abstract $(A * T)^{\mathrm{X}}$ is

$$
\begin{aligned}
\sum\left(\tilde{P}(H): H \in \mathcal{H}_{U, V, z},\right. & \operatorname{his}(H)=A)= \\
& \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum Q_{\mathrm{h}, U}(E, z)(B): B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right)}
\end{aligned}
$$

The likely history probability function entropy, entropy $(\tilde{P})$, is maximised when the sum of the iso-transform-independent historical frequencies,

$$
\sum Q_{\mathrm{h}, U}(E, z)(B): B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{x}} * T,(A * T)^{\mathrm{x}}\right)\right)
$$

is maximised.
Consider the case where the transform, $T$, is known, the formal, $A^{\mathrm{X}} * T$, is known, and the abstract, $(A * T)^{\mathrm{X}}$, is known, but the distribution histogram, $E$, is unknown and hence the likely history probability function, $\tilde{P}$, is
unknown. The maximum likelihood estimate $\tilde{E}$ for the distribution histogram, $E$, is a modal value of the likelihood function,

$$
\begin{aligned}
\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{h}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{x}} * T,(A * T)^{\mathrm{x}}\right)\right)\right)\right):\right.\right. \\
\left.\left.D \in \mathcal{A}_{U, \mathrm{i}, V, z_{E}}\right\}\right)
\end{aligned}
$$

The likely distribution histogram, $\tilde{E}$, is known if the distribution histogram size, $z_{E}$, is known, the transform, $T$, is known, the formal, $A^{\mathrm{X}} * T$, is known, and the abstract, $(A * T)^{\mathrm{X}}$, is known. If it is assumed that the distribution histogram equals the likely distribution histogram, $E=\tilde{E}$, then the likely history probability is known, $\tilde{P}(H)=1 / \sum\left(Q_{\mathrm{h}, U}(\tilde{E}, z)(B): B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{X}} *\right.\right.\right.$ $\left.\left.T,(A * T)^{\mathrm{X}}\right)\right)$ ) where $\operatorname{his}(H)^{\mathrm{X}} * T=A^{\mathrm{X}} * T$ and $(\operatorname{his}(H) * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}$.

In the case where the distribution histogram, $E$, is unknown, and the distribution histogram size, $z_{E}$, is also unknown, except that it is known to be large, $z_{E} \gg z$, then the maximum likelihood estimate $\tilde{E}$ for the distribution probability histogram, $\hat{E}$, may be approximated by a modal value of a likelihood function which depends on the multinomial distribution instead,

$$
\begin{array}{r}
\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right)\right)\right):\right.\right. \\
\left.\left.D \in \mathcal{A}_{U, V, 1}\right\}\right)
\end{array}
$$

If it is known, in addition, that the formal equals the abstract, $A^{\mathrm{x}} * T=$ $(A * T)^{\mathrm{X}}$, then the normalised naturalised abstract, $(\hat{A} * T)^{\mathrm{X}} * T^{\dagger}$, is a solution. In this case the naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$, or naturalised formal, $A^{\mathrm{X}} * T * T^{\dagger}=(A * T)^{\mathrm{X}} * T^{\dagger}$, is the independent analogue of the iso-transformindependents. So the maximum likelihood estimate, $\tilde{E}$, for the distribution probability histogram, $\hat{E}$, is the naturalised abstract probability histogram, ( $\hat{A} *$ $T)^{\mathrm{X}} * T^{\dagger}$,

$$
\tilde{E}=(\hat{A} * T)^{\mathrm{x}} * T^{\dagger}
$$

Formal-abstract equivalence, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, is also called mid transform. In this case the abstract equals the independent abstract, $(A * T)^{\mathrm{X}}=A^{\mathrm{X}} * T=$ $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, and so does not depend on the histogram alignment, algn $(A)$. The formal equals the formal independent, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, and so does not depend on its own alignment, $\operatorname{algn}\left(A^{\mathrm{X}} * T\right)=0$.

The naturalised abstract is the independent analogue of the iso-transformindependents, so, in the case where the naturalised abstract is integral, ( $A *$
$T)^{\mathrm{X}} * T^{\dagger} \in \mathcal{A}_{\mathbf{i}}$, the sum of the iso-transform-independent naturalised-abstractdistributed multinomial probabilities varies with the naturalised-abstract naturalised abstract-distributed multinomial probability,

$$
\begin{aligned}
& \sum Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}} * T^{\dagger}, z\right)(B): B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{x}} * T,(A * T)^{\mathrm{x}}\right)\right) \sim \\
& Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}} * T^{\dagger}, z\right)\left((A * T)^{\mathrm{x}} * T^{\dagger}\right)
\end{aligned}
$$

So, if it is assumed that the distribution probability histogram equals the likely distribution probability histogram, $\hat{E}=\tilde{E}=(\hat{A} * T)^{\mathrm{X}} * T^{\dagger}$, then the likely history probability varies against the naturalised-abstract-distributed multinomial probability of the naturalised abstract, $\tilde{P}(H) \sim 1 / \hat{Q}_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}} *\right.$ $\left.T^{\dagger}, z\right)\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)$. The likely history probability function entropy varies with the naturalised abstract entropy, entropy $(\tilde{P}) \sim \operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)$.

Given necessary formal, necessary abstract and mid transform, consider the case where a drawn histogram $A$ is known, but neither the distribution histogram, $E$, is known nor the transform, $T$, is known, and hence the likely history probability function, $\tilde{P}$, is unknown. The maximum likelihood estimate $(\tilde{E}, \tilde{T})$ for the pair of the distribution histogram, $E$, and the transform, $T$, is a modal value of the likelihood function,

$$
\begin{aligned}
& (\tilde{E}, \tilde{T}) \in \\
& \quad \operatorname{maxd}\left(\left\{\left((D, M), \sum\left(Q_{\mathrm{h}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, M, z}^{-1}\left(\left(A^{\mathrm{x}} * M,(A * M)^{\mathrm{x}}\right)\right)\right)\right):\right.\right. \\
& \left.\left.\quad D \in \mathcal{A}_{U, \mathrm{i}, V, z_{E}}, M \in \mathcal{T}_{U, V}, A^{\mathrm{x}} * M=(A * M)^{\mathrm{x}}\right\}\right)
\end{aligned}
$$

In some cases of drawn sample, $A$, the transform maximum likelihood estimate, $\tilde{T}$, is not trivial. That is, the transform maximum likelihood estimate is not necessarily unary, $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$, nor self, $T_{\mathrm{s}}=V^{\mathrm{CS}\{ \} \mathrm{T}}$. In the cases where the transform maximum likelihood estimate is trivial, $\tilde{T} \in\left\{T_{\mathrm{u}}, T_{\mathrm{s}}\right\}$, aligned modelled induction reduces to aligned non-modelled induction,

$$
\begin{aligned}
\tilde{P}= & \left\{(H, 1): H \subseteq H_{E}, \operatorname{his}(H)^{\mathrm{x}}=A^{\mathrm{x}}\right\}^{\wedge} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\} \cup \\
& \left\{(G, 0): G \in \mathcal{H}_{U, V, z}, \operatorname{his}(G)^{\mathrm{X}} \neq A^{\mathrm{X}}\right\}
\end{aligned}
$$

Define the transform-dependent $A^{\mathrm{Y}(T)} \in \mathcal{A}_{U, V, z}$ as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the
histogram, $A$, conditional that it is an iso-transform-independent,

$$
\begin{aligned}
& \left\{A^{\mathrm{Y}(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{x}} * T,(A * T)^{\mathrm{X}}\right)\right)}\right)\right.\right. \\
& \left.\left.\quad D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The transform-dependent, $A^{\mathrm{Y}(T)}$, is the dependent analogue of the iso transform independents. Note that the transform-dependent, $A^{\mathrm{Y}(T)}$, is not always computable, but an approximation to any accuracy can be made to it. In the case where the formal equals the abstract, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, and the histogram equals the naturalised abstract, the transform-dependent equals the naturalised abstract, $A=(A * T)^{\mathrm{X}} * T^{\dagger} \Longrightarrow A^{\mathrm{Y}(T)}=A=(A * T)^{\mathrm{X}} * T^{\dagger}$.

Now consider the case where, given necessary formal, necessary abstract and mid transform, it is known, in addition, that the sample histogram $A$ is the most probable histogram of the iso-transform-independents. That is, the likely probability of drawing histogram $A$ from necessary formal-abstract $\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)$,

$$
\begin{aligned}
\sum\left(\tilde{P}(H): H \in \mathcal{H}_{U, V, z},\right. & \operatorname{his}(H)=A)= \\
& \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum Q_{\mathrm{h}, U}(E, z)(B): B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right)}
\end{aligned}
$$

is maximised.
In the case where the transform, $T$, is known and the sample, $A$, is known, but the distribution histogram, $E$, is unknown, the maximum likelihood estimate $\tilde{E}$ for the distribution histogram, $E$, is a modal value of the likelihood function,

$$
\begin{array}{r}
\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{h}, U}(D, z)(A)}{\sum Q_{\mathrm{h}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right)}\right):\right.\right. \\
\left.\left.D \in \mathcal{A}_{U, \mathbf{i}, V, z_{E}}\right\}\right)
\end{array}
$$

The likely distribution histogram, $\tilde{E}$, is known if the distribution histogram size, $z_{E}$, is known, the transform, $T$, is known and the sample, $A$, is known. If it is assumed that the distribution histogram equals the likely distribution histogram, $E=\tilde{E}$, then the likely history probability is known, $\tilde{P}(H)=$ $1 / \sum\left(Q_{\mathrm{h}, U}(\tilde{E}, z)(B): B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right)\right)$ where $\operatorname{his}(H)^{\mathrm{x}} * T=$ $A^{\mathrm{X}} * T$ and $(\operatorname{his}(H) * T)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$.

If the histogram is naturalised abstract, $A=(A * T)^{\mathrm{X}} * T^{\dagger}$, then the additional constraint of probable sample makes no change to the maximum likelihood estimate, $\tilde{E}$,

$$
\left.\begin{array}{rl}
A= & (A * T)^{\mathrm{x}} * T^{\dagger} \Longrightarrow \\
& \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{h}, U}(D, z)(A)}{\sum Q_{\mathrm{h}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{x}} * T,(A * T)^{\mathrm{X}}\right)\right)}\right):\right.\right. \\
= & \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{h}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{x}} * T,(A * T)^{\mathrm{X}}\right)\right)\right)\right):\right.\right. \\
\left.\left.D \in \mathcal{A}_{U, \mathrm{i}, V,,_{,}, z_{E}}\right\}\right)
\end{array}\right)
$$

If the histogram is not naturalised abstract, $A \neq(A * T)^{\mathrm{X}} * T^{\dagger}$, however, then the likely history probability function entropy, entropy $(\tilde{P})$, is lower than it is in the case of necessary formal-abstract unconstrained by probable sample.

In the case where the distribution histogram, $E$, is unknown, and the distribution histogram size, $z_{E}$, is also unknown, except that it is known to be large, $z_{E} \gg z$, then the maximum likelihood estimate $\tilde{E}$ for the distribution probability histogram, $\hat{E}$, is now approximated by a modal value of the conditional likelihood function,

$$
\begin{array}{r}
\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right)}\right)\right.\right. \\
\left.\left.D \in \mathcal{A}_{U, V, 1}\right\}\right)
\end{array}
$$

The solution to this is the normalised transform-dependent, $\tilde{E}=\hat{A}^{\mathrm{Y}(T)}$. The maximum likelihood estimate is near the sample, $\tilde{E} \sim \hat{A}$, only in as much as it is far from the naturalised abstract, $\tilde{E} \nsim(\hat{A} * T)^{\mathrm{X}} * T^{\dagger}$.

The iso-transform-independent conditional multinomial probability distribution is defined

$$
\begin{aligned}
& \hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}(E, z)(A):= \\
& \quad \frac{1}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, T, z}\right)\right|} \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum Q_{\mathrm{m}, U}(E, z)(B): B \in Y_{U, \mathbf{i}, T, z}^{-1}\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right)}
\end{aligned}
$$

So the optimisation can be rewritten,

$$
\tilde{E} \in \operatorname{maxd}\left(\left\{\left(D, \hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}(D, z)(A)\right): D \in \mathcal{A}_{U, V, 1}\right\}\right)
$$

Consider the case where the distribution equals the transform-dependent, $\hat{E}=\hat{A}^{\mathrm{Y}(T)}$. First, the logarithm of the iso-transform-independent conditional multinomial probability of the histogram, $A$, with respect to the dependent analogue or transform-dependent, $A^{\mathrm{Y}(T)}$, varies against the logarithm of the iso-transform-independent conditional multinomial probability with respect to the independent analogue or naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$,

$$
\begin{aligned}
& \ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(B): B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right)} \\
\sim & -\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}} * T^{\dagger}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}} * T^{\dagger}, z\right)(B): B \in Y_{U, i, T, z}^{-1}\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right)}
\end{aligned}
$$

Second, the negative logarithm of the iso-transform-independent conditional multinomial probability of the histogram, A, with respect to the naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$, varies with the negative logarithm of the lifted iso-transform-independent conditional multinomial probability of the derived, $A *$ $T$, with respect to the abstract, $(A * T)^{\mathrm{X}}$,

$$
\begin{aligned}
& -\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}} * T^{\dagger}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}} * T^{\dagger}, z\right)(B): B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right)} \\
\sim & -\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}}, z\right)(A * T)}{\sum Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)\left(B^{\prime}\right): B^{\prime} \in Y_{U, \mathrm{i}, T, z}^{\prime-1}\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right)}
\end{aligned}
$$

where $Y_{U, \mathbf{i}, T, z}^{\prime-1}\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right)=\left\{B * T: B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right)\right\}$.
Third, the negative logarithm of the lifted iso-transform-independent conditional multinomial probability with respect to the abstract, $(A * T)^{\mathrm{X}}$, varies with the negative logarithm of the relative multinomial probability with respect to the abstract, $(A * T)^{\mathrm{X}}$, which is the derived alignment,

$$
\begin{aligned}
& -\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)(A * T)}{\sum Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)\left(B^{\prime}\right): B^{\prime} \in Y_{U, \mathrm{i}, T, z}^{\prime-1}\left(\left(A^{\mathrm{x}} * T,(A * T)^{\mathrm{X}}\right)\right)} \\
\sim & -\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)(A * T)}{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)\left((A * T)^{\mathrm{X}}\right)} \\
= & \operatorname{algn}(A * T)
\end{aligned}
$$

So the log-likelihood varies with the derived alignment,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}\left(A^{\mathrm{Y}(T)}, z\right)(A) \sim \operatorname{algn}(A * T)
$$

The mid transform constraint allows the log-likelihood, which is a function of the histogram, $A$, to be lifted to the derived alignment, which is a function of
the derived, $A * T$. So a model optimisation need only search in the derived volume, $\left|T^{-1}\right|$, which is typically much smaller than the underlying volume, $\left|T^{-1}\right| \ll\left|V^{\mathrm{C}}\right|$. It is this relation between the log-likelihood and the derived alignment that makes aligned induction practicable.

The case of classical modelled induction, where the derived is necessary, may be termed law-like because the set of iso-derived, $D_{U, i, T, z}^{-1}(A * T)$, is lawlike. All drawn histories $H \subseteq H_{E}$, are such that their derived histograms are fixed, $\operatorname{his}(H) * T=A * T$.

By contrast, the case of aligned modelled induction, where the abstract is necessary, may be termed entity-like because the set of iso-abstracts, $Y_{U, i, T, \mathrm{~W}, z}^{-1}((A *$ $T)^{\mathrm{X}}$ ), is entity-like. All drawn histories are such that their abstract histograms are fixed, $(\operatorname{his}(H) * T)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$. That is, the derived variables are separately necessary, $\forall u \in W(\operatorname{his}(H) * T \%\{u\}=A * T \%\{u\})$. Necessary abstract is a weaker constraint than necessary derived because the iso-abstracts are a superset of the iso-derived, $D_{U, \mathbf{i}, T, z}^{-1}(A * T) \subseteq Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$. In fact, aligned induction is stricter than pure entity-like because the formal is necessary too, his $(H)^{\mathrm{X}} * T=A^{\mathrm{X}} * T$, and so aligned induction is also aligned-like, $Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right) \subseteq Y_{U, i, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)$. Aligned induction, however, is not necessarily law-like, $\operatorname{his}(H) * T \neq A * T$, and so does not always approximate to classical induction. Mid transform is stricter still, but this constraint does not necessarily increase law-likeness, but merely allows lifting.

Consider the case where, given necessary formal, necessary abstract, mid transform and probable sample, it is known, in addition, that the sample histogram is ideal, $A=A * T * T^{\dagger A}$. The idealisation independent equals the independent, $\left(A * T * T^{\dagger A}\right)^{\mathrm{X}}=A^{\mathrm{X}}$, so the idealisation is aligned-like. The ideal sample approximates to the independent analogue of the iso-derived, which is the naturalisation, $A \approx A * T * T^{\dagger}$, and so, if it is also the case that derived alignment is high, $\operatorname{algn}(A * T) \gg 0$, the iso-transform-independent conditional multinomial log-likelihood with respect to the dependent analogue or transform-dependent, $A^{\mathrm{Y}(T)}$, varies with the iso-derived conditional multinomial log-likelihood with respect to the independent analogue or naturalisation, $A * T * T^{\dagger}$,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}\left(A^{\mathrm{Y}(T)}, z\right)(A) & \sim \ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}\left(A * T * T^{\dagger}, z\right)(A) \\
& \sim \ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A)
\end{aligned}
$$

So the log likelihood varies with the size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}\left(A^{\mathrm{Y}(T)}, z\right)(A) & \sim \\
\quad(z+v) \times \operatorname{entropy}(A * T & \left.+V^{\mathrm{C}} * T\right) \\
& -z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)
\end{aligned}
$$

and the maximum likelihood estimate derived approximates to the normalised sample derived,

$$
\begin{aligned}
\tilde{E} * T & =\hat{A}^{\mathrm{Y}(T)} * T \\
& \approx \hat{A} * T
\end{aligned}
$$

In the case where the underlying alignment is intermediate, $\operatorname{algn}(A) \gg 0$, and the component size cardinality relative entropy is high, entropy $\operatorname{Cross}(A *$ $\left.T, V^{\mathrm{C}} * T\right)>\ln \left|T^{-1}\right|$, the sum sensitivity varies against the log likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}\left(A^{\mathrm{Y}(T)}, z\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}\left(A^{\mathrm{Y}(T)}, z\right)(A)
$$

and the model sensitivity varies against the log likelihood,

$$
\begin{aligned}
-\ln \mid \max \left(\left\{\left(M, \hat{Q}_{\mathrm{m}, \mathrm{y}, M, U}\left(A^{\mathrm{Y}(M)}, z\right)(A)\right)\right.\right. & : M \in \mathcal{T}_{U, V} \\
A^{\mathrm{X}} * M=(A * M)^{\mathrm{X}}, A & \left.\left.=A * M * M^{\dagger A}\right\}\right) \mid \\
& \sim-\ln \hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}\left(A^{\mathrm{Y}(T)}, z\right)(A)
\end{aligned}
$$

That is, given mid-ideal transform, the maximisation of the derived alignment tends to make the properties of aligned modelled induction similar to those of classical modelled induction.

Given necessary formal-abstract, mid-ideal transform and probable sample, consider the case where a drawn histogram $A$ is known, but neither the distribution histogram, $E$, is known nor the transform, $T$, is known, and hence the likely history probability function, $\tilde{P}$, is unknown. In the case where the distribution histogram size, $z_{E}$, is also unknown, except that it is known to be large, $z_{E} \gg z$, then the maximum likelihood estimate $(\tilde{E}, \tilde{T})$ for the pair of the distribution histogram, $E$, and the transform, $T$, is approximated by a modal value of the conditional likelihood function,

$$
\begin{aligned}
& (\tilde{E}, \tilde{T}) \in \\
& \quad \operatorname{maxd}\left(\left\{\left((D, M), \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, M, z}^{-1}\left(\left(A^{\mathrm{X}} * M,(A * M)^{\mathrm{X}}\right)\right)}\right):\right.\right. \\
& \left.\left.\quad D \in \mathcal{A}_{U, V, 1}, M \in \mathcal{T}_{U, V}, A^{\mathrm{X}} * M=(A * M)^{\mathrm{x}}, A=A * M * M^{\dagger A}\right\}\right)
\end{aligned}
$$

So the likely distribution equals the likely transform-dependent, $\tilde{E}=\hat{A}^{Y(\tilde{T})}$, and the likely model is such that

$$
\begin{array}{r}
\tilde{T} \in \\
\operatorname{maxd}\left(\left\{\left(M, \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(M)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(M)}, z\right)(B): B \in Y_{U, \mathrm{i}, M, z}^{-1}\left(\left(A^{\mathrm{X}} * M,(A * M)^{\mathrm{X}}\right)\right)}\right):\right.\right. \\
\left.\left.M \in \mathcal{T}_{U, V}, A^{\mathrm{X}} * M=(A * M)^{\mathrm{X}}, A=A * M * M^{\dagger A}\right\}\right)
\end{array}
$$

The log-likelihood varies with the derived alignment, so an approximation to the likely model is

$$
\begin{aligned}
& \tilde{T} \in \operatorname{maxd}(\{(M, \operatorname{algn}(A * M)): \\
& \left.\left.\quad M \in \mathcal{T}_{U, V}, A^{\mathrm{X}} * M=(A * M)^{\mathrm{X}}, A=A * M * M^{\dagger A}\right\}\right)
\end{aligned}
$$

This optimisation is still intractable, because the cardinality of the substrate transforms, $\left|\mathcal{T}_{U, V}\right|$, is factorial in the volume, $v$. The computation of the derived alignment, $\operatorname{algn}(A * M)$, is tractable, however, and so limited searches can be made tractable and then practicable.

In classical modelled induction the constraint must be weakened from necessary derived to uniform possible derived if the likely model is to be nontrivial, $\tilde{T} \notin\left\{T_{\mathrm{u}}, T_{\mathrm{s}}\right\}$. Uniform possible is not required for aligned modelled induction because the likely model is sometimes non-trivial when constrained by necessary formal-abstract, which is already weaker than necessary derived.

Consider, however, the case where the formal-abstract pair is uniformly possible. Given substrate transform $T \in \mathcal{T}_{U, V}$, assume that the substrate history probability function $P \in\left(\mathcal{H}_{U, V, z}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$ is the distribution of an arbitrary history valued function, $\mathcal{X} \rightarrow \mathcal{H}$, given an arbitrary formal-abstract valued function, $\mathcal{X} \rightarrow \mathcal{A}^{2}$. In this case, the history valued function is chosen arbitrarily from the constrained subset

$$
\begin{aligned}
& \left\{G: F \in \mathcal{X} \rightarrow\left(\mathcal{A}^{2} \times(\mathcal{X} \rightarrow \mathcal{H})\right),\left(\cdot,\left(\left(A^{\prime}, B^{\prime}\right), G\right)\right) \in F,\right. \\
& \left.\forall(\cdot, H) \in G\left(\operatorname{his}(H)^{\mathrm{x}} * T=A^{\prime} \wedge(\operatorname{his}(H) * T)^{\mathrm{x}}=B^{\prime}\right)\right\} \subset \mathcal{X} \rightarrow \mathcal{H}
\end{aligned}
$$

In the case of mid transform, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, the constrained subset is simpler,

$$
\begin{aligned}
\{G: F \in \mathcal{X} \rightarrow & (\mathcal{A} \times(\mathcal{X} \rightarrow \mathcal{H})),\left(\cdot,\left(A^{\prime}, G\right)\right) \in F \\
& \left.\forall(\cdot, H) \in G\left(\operatorname{his}(H)^{\mathrm{x}} * T=(\operatorname{his}(H) * T)^{\mathrm{x}}=A^{\prime}\right)\right\} \subset \mathcal{X} \rightarrow \mathcal{H}
\end{aligned}
$$

This subset of the substrate history probability functions can be generalised for all substrate transforms as the subset derived from

$$
\bigcup_{T \in \mathcal{T}_{\mathfrak{f}}}\left(\mathcal{X} \rightarrow\left(\mathcal{A} \times_{T}(\mathcal{X} \rightarrow \mathcal{H})\right)\right)
$$

where $\mathcal{T}_{\mathrm{f}}$ is the set of all functional transforms, and the fibre product $\times_{T}$ is defined

$$
\begin{aligned}
\mathcal{A} \times_{T}(\mathcal{X} \rightarrow \mathcal{H}): & \\
\left\{\left(A^{\prime}, G\right):\right. & \left(A^{\prime}, G\right) \in \mathcal{A} \times(\mathcal{X} \rightarrow \mathcal{H}), \\
& \left.\forall(\cdot, H) \in G\left(\operatorname{his}(H)^{\mathrm{x}} * T=(\operatorname{his}(H) * T)^{\mathrm{x}}=A^{\prime}\right)\right\}
\end{aligned}
$$

In the case of uniform possible formal-abstract, where there is a distribution history $H_{E}$ and a substrate transform $T \in \mathcal{T}_{U, V}$, the maximum likelihood estimate which maximises the entropy, entropy $(\tilde{P})$, is

$$
\begin{aligned}
\tilde{P}= & \left(\bigcup \left\{\left\{(H, 1): H \subseteq H_{E}, \operatorname{his}(H)^{\mathrm{x}} * T=A^{\prime},(\operatorname{his}(H) * T)^{\mathrm{x}}=B^{\prime}\right\}^{\wedge}:\right.\right. \\
& \left.\left.\left(A^{\prime}, B^{\prime}\right) \in \operatorname{ran}\left(Y_{U, \mathbf{i}, T, z}\right)\right\}\right)^{\wedge} \cup \\
= & \left(\bigcup\left\{(G, 0): G \in \mathcal{H}_{U, V, z}, G \nsubseteq H_{E}\right\}\right. \\
& \left(\bigcup \left(H, 1 / \sum\left(Q_{\mathrm{h}, U}(E, z)(B): B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\prime}, B^{\prime}\right)\right)\right):\right.\right. \\
& \left.H \subseteq H_{E}, \operatorname{his}(H)^{\mathrm{x}} * T=A^{\prime},(\operatorname{his}(H) * T)^{\mathrm{X}}=B^{\prime}\right\}: \\
& \left.\left.\left(A^{\prime}, B^{\prime}\right) \in \operatorname{ran}\left(Y_{U, \mathbf{i}, T, z}\right)\right\}\right)^{\wedge} \cup
\end{aligned}
$$

That is, the maximum likelihood estimate, $\tilde{P}$, is such that all drawn formalabstracts are uniformly probable, and then all drawn histories $H \subseteq H_{E}$ with the same formal-abstract, his $(H)^{\mathrm{X}} * T=A^{\prime}$ and $(\operatorname{his}(H) * T)^{\mathrm{X}}=B^{\prime}$, are uniformly probable. If the distribution histogram, $H_{E}$, is known and the substrate transform, $T$, is known, then the likely probability function, $\tilde{P}$, is known.

The properties of uniformly possible formal-abstract are the same as for necessary formal-abstract, except that the probabilities are scaled by the fraction $1 /\left|\operatorname{ran}\left(Y_{U, \mathbf{i}, T, z}\right)\right|$.

Given uniform possible formal-abstract, mid-ideal transform and probable sample, consider the case where a drawn histogram $A$ is known, but neither the distribution histogram, $E$, is known nor the transform, $T$, is known, and
hence the likely history probability function, $\tilde{P}$, is unknown. In the case where the distribution histogram size, $z_{E}$, is also unknown, except that it is known to be large, $z_{E} \gg z$, then the maximum likelihood estimate $(\tilde{E}, \tilde{T})$ for the pair of the distribution histogram, $E$, and the transform, $T$, is approximated by a modal value of the conditional likelihood function,

$$
\begin{aligned}
& (\tilde{E}, \tilde{T}) \in \\
& \quad \operatorname{maxd}\left(\left\{\left((D, M), \hat{Q}_{\mathrm{m}, \mathrm{y}, M, U}(D, z)(A)\right):\right.\right. \\
& \left.\left.\quad D \in \mathcal{A}_{U, V, 1}, M \in \mathcal{T}_{U, V}, A^{\mathrm{X}} * M=(A * M)^{\mathrm{x}}, A=A * M * M^{\dagger A}\right\}\right)
\end{aligned}
$$

So the likely distribution equals the likely transform-dependent, $\tilde{E}=\hat{A}^{Y(\tilde{T})}$, and the likely model is such that

$$
\begin{aligned}
& \tilde{T} \in \operatorname{maxd}\left(\left\{\left(M, \hat{Q}_{\mathrm{m}, \mathrm{y}, M, U}\left(A^{\mathrm{Y}(M)}, z\right)(A)\right):\right.\right. \\
& \left.\left.\quad M \in \mathcal{T}_{U, V}, A^{\mathrm{X}} * M=(A * M)^{\mathrm{X}}, A=A * M * M^{\dagger A}\right\}\right)
\end{aligned}
$$

The log-likelihood varies with the derived alignment, so an approximation to the likely model is

$$
\begin{aligned}
& \tilde{T} \in \operatorname{maxd}(\{(M, \operatorname{algn}(A * M)): \\
& \left.\left.\quad M \in \mathcal{T}_{U, V}, A^{\mathrm{X}} * M=(A * M)^{\mathrm{X}}, A=A * M * M^{\dagger A}\right\}\right)
\end{aligned}
$$

Note, however, that this approximation is looser than in the necessary formalabstract case because the scaling fraction, $1 /\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, \tilde{T}, z}\right)\right|$, is ignored.

### 2.6.5 Tractable and practicable aligned induction

In the discussion of aligned induction above it is shown that, given necessary formal-abstract, mid-ideal transform and probable sample, the maximum likelihood estimate $\tilde{T}$ for the transform, $T$, is approximated by a maximisation of the derived alignment,

$$
\begin{aligned}
& \tilde{T} \in \operatorname{maxd}(\{(M, \operatorname{algn}(A * M)): \\
& \left.\left.\quad M \in \mathcal{T}_{U, V}, A^{\mathrm{X}} * M=(A * M)^{\mathrm{x}}, A=A * M * M^{\dagger A}\right\}\right)
\end{aligned}
$$

This optimisation is intractable because the cardinality of the substrate transforms, $\left|\mathcal{T}_{U, V}\right|$, is factorial in the volume, $v$. Consider how limited searches can be made tractable and then practicable.

Given sample histogram $A \in \mathcal{A}_{U, i, V, z}$, the tractable limited-models summed alignment valency-density substrate aligned non-overlapping infinite-layer fud
decomposition inducer is defined

$$
\begin{aligned}
& I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)= \\
& \qquad \begin{array}{l}
\left\{\left(M, I_{\approx \mathbf{R}}^{*}\left(\sum^{\operatorname{algn}}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}}:(C, F) \in \operatorname{cont}(M)\right)\right):\right. \\
\quad M \in \mathcal{D}_{\mathrm{F}, \infty, U, V} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right), \\
\left.\quad \forall(C, F) \in \operatorname{cont}(M)\left(\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)>0\right)\right\}
\end{array}
\end{aligned}
$$

where derived variables $W_{F}=\operatorname{der}(F)$, derived volume $w_{F}=\left|W_{F}^{\mathrm{C}}\right|$, derived dimension $m_{F}=\left|W_{F}\right|$ and $I_{\approx \mathbf{R}}^{*}$ computes an approximation to a real number. The geometric average of the fud derived valencies is $w_{F}^{1 / m_{F}}$.

Here the model has been extended from transforms, $M \in \mathcal{T}_{U, V}$, to functional definition set decompositions, $M \in \mathcal{D}_{\mathrm{F}, \infty, U, V}$. At the same time the set of fud decompositions has been restricted to those having (a) fuds that are non-overlapping, $\mathcal{F}_{\mathrm{n}}$, (b) fuds with a limited-underlying, limited-derived, limited-layer and limited-breadth structure, $\mathcal{F}_{\mathrm{q}}=\mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{d}} \cap \mathcal{F}_{\mathrm{h}} \cap \mathcal{F}_{\mathrm{b}}$, and (c) fuds with derived alignment, $\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)>0$. The tractable optimal model is

$$
D_{\mathrm{Sd}} \in \operatorname{maxd}\left(I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)\right)
$$

The maximisation of the contingent fud derived alignment valency-density, $\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}}$, of the non-overlapping fud $(C, F) \in \operatorname{cont}\left(D_{\mathrm{Sd}}\right)$ for the sample slice $A * C$, tends to mid fud transform, $(A * C)^{\mathrm{X}} * F^{\mathrm{T}} \approx\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{X}}$. Then the maximisation of the summed alignment valency-density, $\sum \operatorname{algn}(A *$ $\left.C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}}:(C, F) \in \operatorname{cont}\left(D_{\mathrm{Sd}}\right)$, for all of the contingent slices, tends to mid-ideal fud decomposition transform, $A \approx A * D_{\mathrm{Sd}}^{\mathrm{T}} * D_{\mathrm{Sd}}^{\mathrm{T} \dagger A}$. The summed alignment valency-density varies with the derived alignment, $\operatorname{algn}\left(A * D_{\mathrm{Sd}}^{\mathrm{T}}\right)$, so the tractable model approximates to the likely model, $D_{\mathrm{Sd}}^{\mathrm{T}} \approx \tilde{T}$, depending on the limits chosen.

The derived alignment accuracy of the approximation can be defined as the exponential of the difference in derived alignments,

$$
0<\frac{\exp \left(\operatorname{algn}\left(A * D_{\mathrm{Sd}}^{\mathrm{T}}\right)\right)}{\exp (\operatorname{algn}(A * \tilde{T}))} \leq 1
$$

This definition of accuracy is consistent with the gradient of the likelihood function at the mode, so the derived alignment accuracy varies against the
sensitivity to model,

$$
\begin{aligned}
& \frac{\exp \left(\operatorname{algn}\left(A * D_{\mathrm{Sd}}^{\mathrm{T}}\right)\right)}{\exp (\operatorname{algn}(A * \tilde{T}))} \sim \\
& \quad-\left(-\ln \mid \max \left(\left\{(M, \operatorname{algn}(A * M)): M \in \mathcal{T}_{U, V}\right.\right.\right. \\
& \left.\left.\left.\quad A^{\mathrm{X}} * M=(A * M)^{\mathrm{X}}, A=A * M * M^{\dagger A}\right\}\right) \mid\right)
\end{aligned}
$$

The log-likelihood varies against the sensitivity to model, so the derived alignment accuracy varies with the derived alignment,

$$
\frac{\exp \left(\operatorname{algn}\left(A * D_{\mathrm{Sd}}^{\mathrm{T}}\right)\right)}{\exp (\operatorname{algn}(A * \tilde{T}))} \sim \operatorname{algn}(A * T)
$$

That is, although the model obtained from the tractable summed alignment valency-density inducer is merely an approximation, in the cases where the log-likelihood or derived alignment is high, and so the sensitivity to model/distribution is low, the approximation may be reasonably close nonetheless.

The maximisation of derived alignment tends to make the properties of mid-ideal aligned induction similar to those of natural classical induction. This is also the case for the tractable optimisation, so the tractable model approximates to the likely classical model, $D_{\mathrm{Sd}}^{\mathrm{T}} \approx \tilde{T}$, where

$$
\tilde{T} \in \operatorname{maxd}\left(\left\{\left(M, \hat{Q}_{\mathrm{m}, \mathrm{~d}, M, U}(A, z)(A)\right): M \in \mathcal{T}_{U, V}, A=A * M * M^{\dagger}\right\}\right)
$$

That this is true may be seen by considering the entropy properties. The correlations for summed alignment valency-density are similar to those for iso-derived log-likelihood. The summed alignment valency-density (a) varies against the derived volume $w^{\prime}=\left|\left(D_{\mathrm{Sd}}^{\mathrm{T}}\right)^{-1}\right|$,

$$
\operatorname{algnValDensSum}(U)\left(A, D_{\mathrm{Sd}}\right) \sim 1 / w^{\prime}
$$

(b) varies against the derived entropy,

$$
\operatorname{algnValDensSum}(U)\left(A, D_{\mathrm{Sd}}\right) \sim-z \times \operatorname{entropy}\left(A * D_{\mathrm{Sd}}^{\mathrm{T}}\right)
$$

(c) varies with the component size cardinality relative entropy,

$$
\operatorname{algnValDensSum}(U)\left(A, D_{\mathrm{Sd}}\right) \sim z \times \operatorname{entropyRelative}\left(A * D_{\mathrm{Sd}}^{\mathrm{T}}, V^{\mathrm{C}} * D_{\mathrm{Sd}}^{\mathrm{T}}\right)
$$

and (d) varies with the expected component entropy,

$$
\operatorname{algnValDensSum}(U)\left(A, D_{\mathrm{Sd}}\right) \sim z \times \text { entropyComponent }\left(A, D_{\mathrm{Sd}}^{\mathrm{T}}\right)
$$

where

$$
\begin{aligned}
& \operatorname{algnValDensSum}(U)(A, D):= \\
& \qquad \sum \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}}:(C, F) \in \operatorname{cont}(D)
\end{aligned}
$$

The maximisation of the derived alignment valency-density, $\operatorname{algn}(A * C *$ $\left.F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}}$, of the contingent fud $(C, F) \in \operatorname{cont}\left(D_{\mathrm{Sd}}\right)$, tends to diagonalise the mid fud transform, diagonal $\left(A * C * F^{\mathrm{T}}\right)$, so minimising the fud derived entropy, entropy $\left(A * C * F^{\mathrm{T}}\right)$, and hence minimising the overall decomposition transform derived entropy, entropy $\left(A * D_{\mathrm{Sd}}^{\mathrm{T}}\right)$. The component cardinality entropy, entropy $\left(C * F^{\mathrm{T}}\right)$, also decreases but is synchronised with the derived entropy, entropy $\left(A * C * F^{\mathrm{T}}\right)$, so the mid component size cardinality relative entropy tends to remain small, entropyRelative $\left(A * C * F^{\mathrm{T}}, C * F^{\mathrm{T}}\right) \approx 0$. The maximisation of the valency-density, however, shortens the diagonal and so the off-diagonal derived states tend to be ineffective. The recursive slicing during the decomposition then removes the ineffective components, concentrating the effective derived states in smaller components, and so maximising the overall decomposition transform component size cardinality relative entropy, entropyRelative $\left(A * D_{\mathrm{Sd}}^{\mathrm{T}}, V^{\mathrm{C}} * D_{\mathrm{Sd}}^{\mathrm{T}}\right)$, when fully idealised.

The limited-models summed alignment valency-density substrate aligned non-overlapping infinite-layer fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, limits the optimisation to make aligned induction tractable. By additionally imposing a sequence on the search and other constraints, tractable induction is made practicable in the highest-layer summed shuffle content alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}$. (The details of the implementation are defined later.) Now, given a set of search parameters $P$, the fud decomposition is

$$
D_{\mathrm{Scsd}, P} \in \operatorname{maxd}\left(I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime *}(A)\right)
$$

The set of practicable searched models is approximately a subset of the tractable searched models, so the practicable derived alignment is less than or equal to the tractable derived alignment,

$$
\operatorname{algn}\left(A * D_{\mathrm{Scsd}, P}^{\mathrm{T}}\right) \leq \operatorname{algn}\left(A * D_{\mathrm{Sd}}^{\mathrm{T}}\right)
$$

Even so, in the cases where the log-likelihood or derived alignment is high, and so both the sensitivity to model and the sensitivity to distribution are low, the approximation to the maximum likelihood estimate, $D_{\mathrm{Scsd}, P}^{\mathrm{T}} \approx \tilde{T}$, may be reasonably close nonetheless.

The highest-layer summed shuffle content alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}$, is an example of practicable aligned induction. Artificial neural network induction is an example of practicable classical induction. Let the ANN classical model $F_{\mathrm{gr}, \mathrm{lsq}, P}^{\mathrm{T}} \approx \tilde{T}$ be obtained by least squares gradient descent given a sample $A$ subject to the constraints of (i) real valued variables, (ii) causal histogram, (iii) a literal frame, and (iv) clustered histogram. The ANN classical induction is supervised, requiring that there is a causal relation between query variables $K \subset V$ and label variables, $V \backslash K$,

$$
\operatorname{split}\left(K, A^{\mathrm{FS}}\right) \in K^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}
$$

At the optimum there is no error and the relation between the classical derived variables and the label variables is functional,

$$
\operatorname{split}\left(W,(A * X \%(W \cup V \backslash K))^{\mathrm{FS}}\right) \in W^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}
$$

where $(X, W)=F_{\mathrm{gr}, \mathrm{lsq}, P}^{\mathrm{T}}$.
By contrast, aligned induction is unsupervised, so no label is required. Aligned induction, however, must have alignments between the underlying variables,

$$
\operatorname{algn}(A)>0
$$

If there is a label, the aligned induction model does not necessarily have a causal relation between the derived variables and the label variables, so the label entropy may be non-zero,

$$
\sum_{(R, C) \in T^{-1}}(A * T)_{R} \times \operatorname{entropy}(A * C \%(V \backslash K)) \geq 0
$$

or

$$
\sum_{(R,) \in T^{-1}}(A * T)_{R} \times \operatorname{entropy}\left(\{R\}^{\mathrm{U}} * T^{\odot A} \%(V \backslash K)\right) \geq 0
$$

where $T=D_{\mathrm{Scsd}, P}^{\mathrm{T}}$.
The ANN classical induction also requires that the sample, $A$, is clustered. This implies that the query variables, $K$, are real-valued, so that there is a metric. The practicable aligned inducer requires that the underlying variables be discrete, so they must be bucketed if they are in fact continuous.

The $A N N$ fud, $F_{\mathrm{gr}, \mathrm{lsq}, P}$, has a fixed graph so that the derived variables have a literal frame mapping to the label variables in the loss function. This graph is defined a priori in the parameter set, $P$, and depends on the query variables, $K$, and the label variables, $V \backslash K$. The aligned inducer model, $D_{\text {Scsd }, P}$, is a fud decomposition in which the fuds are built upwards from the substrate, and the only parameters are limits to gross fud structure. In addition, a decomposition allows fuds to be built on contingent slices, $A * C$ where $(C, F) \in \operatorname{cont}\left(D_{\mathrm{Scs}, ~}, P\right)$, which depend on the components corresponding to effective derived states of ancestor fuds. In this way, the derived variables near the root of the decomposition are most general, applying to the largest slices, while the derived variables near the leaves of the decomposition are most specific, applying to the smallest slices as the alignments are removed in the idealisation. So in the decomposition, $D_{\mathrm{Scsd}, P}$, each contingent fud derived, $A * C * F^{\mathrm{T}}$, may be meaningful in the problem domain. By contrast, the ANN fud derived variables apply to the entire query volume, $K^{\mathrm{C}}$, and so the derived, $A * F_{\mathrm{gr}, \mathrm{lsq}, P}^{\mathrm{T}}$, is less context specific.

## 3 Terminology

### 3.1 Systems

The set of all systems $\mathcal{U}$ is the set of all functional relations between the set of all variables $\mathcal{V}$ and non-empty subsets of the set of all values $\mathcal{W}$,

$$
\mathcal{U}=\mathcal{V} \rightarrow(\mathrm{P}(\mathcal{W}) \backslash\{\emptyset\})
$$

where P is the powerset function.
The function vars $\in \mathcal{U} \rightarrow \mathrm{P}(\mathcal{V})$ is the set of variables in a system $U \in \mathcal{U}$. It is a synonym for the domain of $U$,

$$
\operatorname{vars}(U):=\operatorname{dom}(U)=\{v:(v, W) \in U\}
$$

The set of values is $U_{v}$ for some variable $v \in \operatorname{vars}(U)$. The valency of a variable is the cardinality of its values, $\left|U_{v}\right|$. The values of a variable are unordered.

The set $\mathcal{U}$ of all systems is defined such that each variable must have at least one value,

$$
\forall U \in \mathcal{U} \forall v \in \operatorname{vars}(U)\left(\left|U_{v}\right| \geq 1\right)
$$

In a system of finite variables, $\forall v \in \operatorname{vars}(U)\left(\left|U_{v}\right|<\infty\right)$, each variable has a set of discrete values.

For any subset of variables in a system, $V \subseteq \operatorname{vars}(U)$, define the parameterised function volume, volume $(U) \in \mathrm{P}(\operatorname{vars}(U)) \rightarrow \mathbf{N}_{>0}$

$$
\operatorname{volume}(U)(V):=\prod_{v \in V}\left|U_{v}\right|
$$

In the case that $V=\emptyset$, define volume $(U)(\emptyset):=1$.

### 3.2 States

The set of all states $\mathcal{S}$ is the set of all functional relations between the set of all variables $\mathcal{V}$ and the set of all values $\mathcal{W}$,

$$
\mathcal{S}=\mathcal{V} \rightarrow \mathcal{W}
$$

State $S \in \mathcal{S}$ is a functional relation between variables and values,

$$
\forall S \in \mathcal{S}(|\operatorname{vars}(S)|=|S|)
$$

where the function vars $\in \mathcal{S} \rightarrow \mathrm{P}(\mathcal{V})$ is the set of variables in the state

$$
\operatorname{vars}(S):=\operatorname{dom}(S)=\{v:(v, w) \in S\}
$$

So a variable is an index of the state. The cardinality of the set of variables $|\operatorname{vars}(S)|$ is the dimension. The variables of a set of states is vars $\in \mathrm{P}(\mathcal{S}) \rightarrow$ $\mathrm{P}(\mathcal{V})$ defined $\operatorname{vars}(Q):=\bigcup\{\operatorname{vars}(S): S \in Q\}$.

The parameterised set $\mathcal{S}_{U}$ where $\mathcal{S}_{U} \subseteq \mathcal{S}$ of all states in a particular system $U$ is further constrained such that the variables of the state is a subset of the variables of its system

$$
\forall U \in \mathcal{U} \forall S \in \mathcal{S}_{U}(\operatorname{vars}(S) \subseteq \operatorname{vars}(U))
$$

Also, each value of any variable-value pair in a state must be an element of the set of values for that variable in the system

$$
\forall U \in \mathcal{U} \forall S \in \mathcal{S}_{U} \forall(v, w) \in S\left(w \in U_{v}\right)
$$

For any subset of variables in a system, $V \subseteq \operatorname{vars}(U)$, define a parameterised cartesian set of states, cartesian $(U) \in \mathrm{P}(\operatorname{vars}(U)) \rightarrow \mathrm{P}\left(\mathcal{S}_{U}\right)$

$$
\operatorname{cartesian}(U)(V):=\prod_{v \in V}\left\{(v, w): w \in U_{v}\right\}
$$

or

$$
\operatorname{cartesian}(U)(V):=\prod_{v \in V}\{v\} \times U_{v}
$$

and cartesian $(U)(\emptyset):=\{\emptyset\}$. So volume $(U)(V)=|\operatorname{cartesian}(U)(V)|$.

The function filter $\in \mathrm{P}(\mathcal{V}) \times \mathcal{S} \rightarrow \mathcal{S}$ is defined

$$
\operatorname{filter}(V, S):=\{(v, u):(v, u) \in S, v \in V\}
$$

Define the shorthand $(\%) \in \mathcal{S} \times \mathrm{P}(\mathcal{V}) \rightarrow \mathcal{S}$ as $S \% V:=\operatorname{filter}(V, S)$. The application of a filter is also known as a reduction.

The function split $\in \mathrm{P}(\mathcal{V}) \times \mathrm{P}(\mathcal{S}) \rightarrow \mathrm{P}(\mathcal{S} \times \mathcal{S})$ is defined

$$
\operatorname{split}(V, Q):=\{(\operatorname{filter}(V, S), \text { filter }(\operatorname{vars}(S) \backslash V, S))): S \in Q\}
$$

Two states $S, T \in \mathcal{S}$ are said to join if their union is also a state, $S \cup T \in \mathcal{S}$. That is, a join is functional,

$$
\begin{aligned}
S \cup T \in \mathcal{S} & \Longleftrightarrow|\operatorname{vars}(S) \cup \operatorname{vars}(T)|=|S \cup T| \\
& \Longleftrightarrow \forall v \in \operatorname{vars}(S) \cap \operatorname{vars}(T)\left(S_{v}=T_{v}\right)
\end{aligned}
$$

States in disjoint variables always join, $\forall S, T \in \mathcal{S}(\operatorname{vars}(S) \cap \operatorname{vars}(T)=$ $\emptyset \Longrightarrow S \cup T \in \mathcal{S}$ ). States in the same variables only join if they are equal, $\forall S, T \in \mathcal{S}(\operatorname{vars}(S)=\operatorname{vars}(T) \Longrightarrow(S \cup T \in \mathcal{S} \Longleftrightarrow S=T))$.

The literal reframing reframe $\in(\mathcal{V} \leftrightarrow \mathcal{V}) \times \mathcal{S} \rightarrow \mathcal{S}$ is defined reframe $(X, S):=$

$$
\left\{\left(X_{v}, u\right):(v, u) \in S, v \in \operatorname{dom}(X)\right\} \cup\{(v, u):(v, u) \in S, v \notin \operatorname{dom}(X)\}
$$

which is defined if $\operatorname{ran}(X) \cap(\operatorname{vars}(S) \backslash \operatorname{dom}(X))=\emptyset$. If the state $S$ is in some system $U, S \in \mathcal{S}_{U}$, then the reframed state is in $U$, $\operatorname{reframe}(X, S) \in \mathcal{S}_{U}$, if $\forall(v, w) \in X\left(U_{v} \subseteq U_{w}\right)$.

The non-literal reframing reframe $\in(\mathcal{V} \leftrightarrow(\mathcal{V} \times(\mathcal{W} \leftrightarrow \mathcal{W})) \times \mathcal{S} \rightarrow \mathcal{S}$ is defined

$$
\begin{aligned}
& \operatorname{reframe}(X, S):= \\
& \qquad\left\{\left(w, W_{u}\right):(v, u) \in S, v \in \operatorname{dom}(X),(w, W)=X_{v}, u \in \operatorname{dom}(W)\right\} \cup \\
& \left\{(w, u):(v, u) \in S, v \in \operatorname{dom}(X),(w, W)=X_{v}, u \notin \operatorname{dom}(W)\right\} \cup \\
& \{(v, u):(v, u) \in S, v \notin \operatorname{dom}(X)\}
\end{aligned}
$$

which is defined if $\operatorname{dom}(\operatorname{ran}(X)) \cap(\operatorname{vars}(S) \backslash \operatorname{dom}(X))=\emptyset$. If the state $S$ is in some system $U, S \in \mathcal{S}_{U}$, then the reframed state is in $U$, $\operatorname{reframe}(X, S) \in \mathcal{S}_{U}$, if $\forall(w, W) \in \operatorname{ran}(X)\left(\operatorname{ran}(W) \subseteq U_{w}\right)$.

When there exists a literal or non-literal frame between sets of variables $V, W \subset \operatorname{vars}(U)$ in a system, $|V|=|W| \wedge\left(\exists Q \in V \cdot W \forall(v, w) \in Q\left(\left|U_{v}\right|=\right.\right.$ $\left.\left|U_{w}\right|\right)$ ), they are said to have the same geometry.

### 3.3 Histories

An event identifier is any member of the universal set $\mathcal{X}$. An event is a pair of an event identifier and a state, $\mathcal{X} \times \mathcal{S}$. A history $H$ is a state valued function of event identifiers. The set of all histories $\mathcal{H}$ is a subset of all functional relations of events

$$
\mathcal{H} \subset \mathcal{X} \rightarrow \mathcal{S}
$$

Note that the event identifier in a history need not form a contiguous sequence nor a chronological series. There is no order required or implied with respect to the event identifier.

The size of a history is defined, size $\in \mathcal{H} \rightarrow \mathbf{N}$,

$$
\operatorname{size}(H):=|H|
$$

The set of states of a history is defined, states $\in \mathcal{H} \rightarrow \mathrm{P}(\mathcal{S})$. It is the range of the history

$$
\operatorname{states}(H):=\operatorname{ran}(H)=\{S:(x, S) \in H\}
$$

Define the shorthand ()$^{\mathrm{S}} \in \mathcal{H} \rightarrow \mathrm{P}(\mathcal{S})$ as $H^{\mathrm{S}}:=\operatorname{states}(H)$.
The set of event identifiers of a history is the domain of the history, ids $\in$ $\mathcal{H} \rightarrow \mathrm{P}(\mathcal{X})$

$$
\operatorname{ids}(H):=\operatorname{dom}(H)=\{x:(x, S) \in H\}
$$

A history's states must all have exactly the same set of variables

$$
\forall H \in \mathcal{H} \forall S \in \operatorname{states}(H)(\operatorname{vars}(S)=\operatorname{vars}(H))
$$

where vars $\in \mathcal{H} \rightarrow \mathrm{P}(\mathcal{V})$ is defined

$$
\operatorname{vars}(H):=\{v: S \in \operatorname{states}(H), v \in \operatorname{vars}(S)\}
$$

The parameterised subset $\mathcal{H}_{U}$ where $\mathcal{H}_{U} \subseteq \mathcal{H}$ is the set of all histories in system $U$ such that

$$
\forall U \in \mathcal{U} \forall H \in \mathcal{H}_{U}\left(\operatorname{states}(H) \subseteq \mathcal{S}_{U}\right)
$$

The parameterised volume of a history is the volume of its variables vars $(H) \subseteq$ $\operatorname{vars}(U)$, defined volume $(U) \in \mathcal{H}_{U} \rightarrow \mathbf{N}_{>0}$

$$
\operatorname{volume}(U)(H):=\operatorname{volume}(U)(\operatorname{vars}(H))
$$

Define the reduction of a history as the reduction of its events, reduce $\in$ $\mathrm{P}(\mathcal{V}) \rightarrow(\mathcal{H} \rightarrow \mathcal{H})$ as

$$
\text { reduce }(V)(H):=\{(x, S \% V):(x, S) \in H\}
$$

Define $H \% V:=\operatorname{reduce}(V)(H)$.
The addition operation of histories is defined as the disjoint union if both histories have the same variables. Define $(+) \in \mathcal{H} \times \mathcal{H} \rightarrow \mathcal{H}$ as

$$
H_{1}+H_{2}:=\left\{((x, \cdot), S):(x, S) \in H_{1}\right\} \cup\left\{((\cdot, y), T):(y, T) \in H_{2}\right\}
$$

where $\operatorname{vars}\left(H_{1}\right)=\operatorname{vars}\left(H_{2}\right)$. The size of the sum equals the sum of the sizes, $\left|H_{1}+H_{2}\right|=\left|H_{1}\right|+\left|H_{2}\right|$.

The multiplication operation of histories is defined as the product where the states join. Define $(*) \in \mathcal{H} \times \mathcal{H} \rightarrow \mathcal{H}$ as

$$
\begin{aligned}
& H_{1} * H_{2}:=\left\{((x, y), S \cup T):(x, S) \in H_{1},(y, T) \in H_{2},\right. \\
&\left.\forall v \in \operatorname{vars}(S) \cap \operatorname{vars}(T)\left(S_{v}=T_{v}\right)\right\}
\end{aligned}
$$

The size of the product equals the product of the sizes if the variables are disjoint, $\operatorname{vars}\left(H_{1}\right) \cap \operatorname{vars}\left(H_{2}\right)=\emptyset \Longrightarrow\left|H_{1} * H_{2}\right|=\left|H_{1}\right| \times\left|H_{2}\right|$. The variables of the product is the union of the variables if the size is non-zero, $H_{1} * H_{2} \neq \emptyset \Longrightarrow \operatorname{vars}\left(H_{1} * H_{2}\right)=\operatorname{vars}\left(H_{1}\right) \cup \operatorname{vars}\left(H_{2}\right)$.

### 3.4 Histograms

### 3.4.1 Definition

A histogram $A$ is a functional relation between states and positive rational counts. The set of all histograms $\mathcal{A}$ is a subset

$$
\mathcal{A} \subset \mathcal{S} \rightarrow \mathrm{Q}_{\geq 0}
$$

The histogram is a functional relation so any state may appear no more than once in the histogram. The histogram is indexable by state

$$
\forall A \in \mathcal{A}(|\operatorname{states}(A)|=|A|)
$$

where states $\in \mathcal{A} \rightarrow \mathrm{P}(\mathcal{S})$ is defined

$$
\operatorname{states}(A):=\operatorname{dom}(A)=\{S:(S, c) \in A\}
$$

Define the shorthand ()$^{\mathrm{S}} \in \mathcal{A} \rightarrow \mathrm{P}(\mathcal{S})$ as $A^{\mathrm{S}}:=\operatorname{states}(A)$.
Similar to history, a histogram's states must all have exactly the same set of variables, so defining vars $\in \mathcal{A} \rightarrow \mathrm{P}(\mathcal{V})$,

$$
\operatorname{vars}(A):=\{v: S \in \operatorname{states}(A), v \in \operatorname{vars}(S)\}
$$

require that

$$
\forall A \in \mathcal{A} \forall S \in \operatorname{states}(A)(\operatorname{vars}(S)=\operatorname{vars}(A))
$$

Also, the counts of a histogram must always be positive,

$$
\forall A \in \mathcal{A} \forall S \in \operatorname{states}(A)\left(A_{S} \geq 0\right)
$$

The size of a histogram is size $\in \mathcal{A} \rightarrow \mathbf{Q}_{\geq 0}$,

$$
\operatorname{size}(A):=\sum A_{S}: S \in \operatorname{states}(A)
$$

and $\operatorname{size}(\emptyset):=0$. The size must always be greater than or equal to zero,

$$
\forall A \in \mathcal{A}(\operatorname{size}(A) \geq 0)
$$

The empty histogram $A$ equals the empty set, $A=\emptyset$. Its size is zero, $\operatorname{size}(\emptyset)=0$. The empty histogram has no variables, $\operatorname{vars}(\emptyset)=\emptyset$.

The scalar histogram of some positive count $c \in \mathbf{Q}_{\geq 0}$ is defined $A=\{(\emptyset, c)\}$. Define the constructor scalar $\in \mathbf{Q}_{\geq 0} \rightarrow \mathcal{A}$ such that $\operatorname{scalar}(c):=\{(\emptyset, c)\}$. A scalar histogram has no variables, $\forall c \in \mathbf{Q}_{\geq 0}(\operatorname{vars}(\operatorname{scalar}(c))=\emptyset)$.

A trimmed histogram has only non-zero counts. Define $\operatorname{trim} \in \mathcal{A} \rightarrow \mathcal{A}$

$$
\operatorname{trim}(A):=\{(S, c):(S, c) \in A, c>0\}
$$

Histogram $A$ is congruent to histogram $B$, if both have the same variables and size. Define congruent $\in \mathcal{A} \times \mathcal{A} \rightarrow \mathbf{B}$

$$
\operatorname{congruent}(A, B):=(\operatorname{vars}(A)=\operatorname{vars}(B)) \wedge(\operatorname{size}(A)=\operatorname{size}(B))
$$

Histogram $A$ is equivalent to histogram $B$, if the non-zero count states are equal,

$$
A \equiv B:=\operatorname{trim}(A)=\operatorname{trim}(B)
$$

Note that this definition implies that zero histograms, which are those that are such that all counts are zero, even if in different variables, are all equivalent.

A sub-histogram $A$ of a histogram $B$ is such that the trimmed states of $A$ are a subset of the states of $B$ and the counts of $A$ are less than or equal to those of $B,(\leq) \in \mathcal{A} \times \mathcal{A} \rightarrow \mathbf{B}$

$$
A \leq B:=(\operatorname{st}(\operatorname{tm}(A)) \subseteq \operatorname{st}(B)) \wedge\left(\forall S \in \operatorname{st}(\operatorname{tm}(A))\left(A_{S} \leq B_{S}\right)\right)
$$

where st $=$ states and $\mathrm{tm}=$ trim. The relation is a pre-order. The empty histogram $A=\emptyset$ is a sub-histogram of all histograms, $\forall B \in \mathcal{A}(\emptyset \leq B)$. Equivalent histograms are sub-histograms of each other, $A \equiv B \Longrightarrow(A \leq$ $B) \wedge(B \leq A)$. The super-histogram operator is typed $(\geq) \in \mathcal{A} \times \mathcal{A} \rightarrow$ $B$ and defined $A \geq B:=B \leq A$. The proper sub-histogram is defined $A<B:=(A \leq B) \wedge \neg(A \equiv B)$, and the proper super-histogram is defined $A>B:=(A \geq B) \wedge \neg(A \equiv B)$. It is not necessary that the relation between $A$ and $B$ is sub-histogram or super-histogram. It may be the case that neither holds $\exists A, B \in \mathcal{A}(\operatorname{vars}(A)=\operatorname{vars}(B) \wedge \neg(A \leq B \vee A \geq B))$.

A system can be implied by a histogram. Define implied $\in \mathcal{A} \rightarrow \mathcal{U}$ as

$$
\operatorname{implied}(A):=\left\{\left(v,\left\{S_{v}: S \in A^{\mathrm{S}}\right\}\right): v \in \operatorname{vars}(A)\right\}
$$

Given a system $U$, the parameterised subset $\mathcal{A}_{U}$ where $\mathcal{A}_{U} \subseteq \mathcal{A}$ is the set of all histograms in $U$ such that

$$
\forall A \in \mathcal{A}_{U}\left(\operatorname{states}(A) \subseteq \mathcal{S}_{U}\right)
$$

Similar to history, the parameterised volume of a histogram is the volume of its variables $\operatorname{vars}(A) \subseteq \operatorname{vars}(U)$, defined volume $(U) \in \mathcal{A}_{U} \rightarrow \mathbf{N}_{>0}$

$$
\text { volume }(U)(A):=\operatorname{volume}(U)(\operatorname{vars}(A))
$$

If a pair of histograms $A$ and $B$, in the same system $U$, have a variables mapping $X$ such that $\exists X \in \operatorname{vars}(A) \cdot \operatorname{vars}(B) \forall(v, u) \in X\left(U_{v}=U_{u}\right)$ then the variables of $A$ and the variables of $B$ are said to be literal frames of each other mapped by $X$.

The function reframe $\in(\mathcal{V} \leftrightarrow \mathcal{V}) \times \mathcal{A} \rightarrow \mathcal{A}$ is defined

$$
\operatorname{reframe}(X, A):=\{(\operatorname{reframe}(X, S), c):(S, c) \in A\}
$$

which is defined if $\operatorname{ran}(X) \cap(\operatorname{vars}(A) \backslash \operatorname{dom}(X))=\emptyset$. If the histogram $A$ is in some system $U, A \in \mathcal{A}_{U}$, then reframe $(X, A) \in \mathcal{A}_{U}$ if $\forall(v, w) \in X\left(U_{v} \subseteq U_{w}\right)$.

If a pair of histograms $A$ and $B$, in the same system $U$, have a variables mapping $X$ such that $\exists X \subset\{(v,(w, W)): Q \in \operatorname{vars}(A) \cdot \operatorname{vars}(B),(v, w) \in$ $\left.Q, W \in U_{v} \cdot U_{w}\right\}\left(X \in \mathcal{V}_{U} \leftrightarrow\left(\mathcal{V}_{U} \times\left(\mathcal{W}_{U} \leftrightarrow \mathcal{W}_{U}\right)\right)\right)$ then the variables of $A$ and the variables of $B$ are said to be non-literal frames of each other mapped by $X$.

The function reframe $\in(\mathcal{V} \leftrightarrow(\mathcal{V} \times(\mathcal{W} \leftrightarrow \mathcal{W})) \times \mathcal{A} \rightarrow \mathcal{A}$ is defined

$$
\operatorname{reframe}(X, A):=\{(\operatorname{reframe}(X, S), c):(S, c) \in A\}
$$

which is defined if reframe $(X, S)$ is defined for each state. In other words, $\operatorname{reframe}(X, A)$ is defined if $\operatorname{dom}(\operatorname{ran}(X)) \cap(\operatorname{vars}(A) \backslash \operatorname{dom}(X))=\emptyset$. If the histogram $A$ is in some system $U, A \in \mathcal{A}_{U}$, then the reframed histogram is in $U$, $\operatorname{reframe}(X, A) \in \mathcal{A}_{U}$, if $\forall(w, W) \in \operatorname{ran}(X)\left(\operatorname{ran}(W) \subseteq U_{w}\right)$.

The function resize $\in \mathrm{Q}_{\geq 0} \times \mathcal{A} \rightarrow \mathcal{A}$ is defined

$$
\operatorname{resize}(z, A):=\left\{\left(S, c z / z_{A}\right):(S, c) \in A, z_{A}=\operatorname{size}(A)\right\}
$$

which is defined if $\operatorname{size}(A)>0$. The resize is such that $\operatorname{size}(\operatorname{resize}(z, A))=z$.
Define the ceiling and floor functions that return integral histograms. Define ceiling $\in \mathcal{A} \rightarrow \mathcal{A}_{\mathrm{i}}$

$$
\operatorname{ceiling}(A):=\{(S, d):(S, c) \in A, d \in \mathbf{N}, d \geq c, d-c<1\}
$$

where the integral histograms is the set $\mathcal{A}_{\mathrm{i}}=\mathcal{A} \cap(\mathcal{S} \rightarrow \mathbf{N})$. Define floor $\in$ $\mathcal{A} \rightarrow \mathcal{A}_{\mathrm{i}}$

$$
\text { floor }(A):=\{(S, d):(S, c) \in A, d \in \mathbf{N}, d \leq c, c-d<1\}
$$

Thus size $($ floor $(A)) \leq \operatorname{size}(A) \leq \operatorname{size}(\operatorname{ceiling}(A))$.

### 3.4.2 Unit histograms

A unit histogram $A^{\mathrm{U}} \in \mathcal{A}$ is a special case in which all its counts equal 1. Define unit $\in \mathcal{A} \rightarrow \mathcal{A}_{\mathrm{i}}$

$$
\operatorname{unit}(A):=\operatorname{states}(A) \times\{1\}=\{(S, 1):(S, c) \in A\}
$$

where the integral histograms is the set $\mathcal{A}_{\mathbf{i}}=\mathcal{A} \cap(\mathcal{S} \rightarrow \mathbf{N})$. Define the shorthand $A^{\mathrm{U}}:=\operatorname{unit}(A)$. Thus $\forall S \in \operatorname{states}\left(A^{\mathrm{U}}\right)\left(A_{S}^{\mathrm{U}}=1\right)$. In such a histogram, $\operatorname{size}\left(A^{\mathrm{U}}\right)=\left|\operatorname{states}\left(A^{\mathrm{U}}\right)\right|=\left|A^{\mathrm{U}}\right|$. Unit histograms provide a useful shorthand for the states. Define a convenience function to promote a set of states to a unit histogram, define unit $\in \mathrm{P}(\mathcal{S}) \rightarrow(\mathcal{S} \rightarrow\{1\})$ as unit $(Q):=$ $Q \times\{1\}$, with a shorthand $Q^{\mathrm{U}}:=\operatorname{unit}(Q)$. Depending on the argument set of states $Q$ the function $Q^{\mathrm{U}}$ may be a histogram, $\exists Q \in \mathrm{P}(\mathcal{S})\left(\operatorname{unit}(Q) \in \mathcal{A}_{\mathfrak{i}}\right)$.

A zero histogram $A^{\mathrm{Z}} \in \mathcal{A}$ is a special case in which all its counts equal 0 . Define zero $\in \mathcal{A} \rightarrow \mathcal{A}_{\mathrm{i}}$

$$
\operatorname{zero}(A):=\operatorname{states}(A) \times\{0\}
$$

and the shorthand $A^{\mathrm{Z}}:=\operatorname{zero}(A)$.

There are a couple of useful variations on the theme of unit histograms, unit effective histogram $A^{\mathrm{F}} \in \mathcal{A}_{\mathrm{i}}$ and unit cartesian histogram $A^{\mathrm{C}} \in \mathcal{A}_{U, \mathrm{i}}$.

The unit effective histogram $A^{\mathrm{F}}$ of a histogram $A$ only includes states where the count is non-zero. Defining effective $\in \mathcal{A} \rightarrow \mathcal{A}_{\mathrm{i}}$

$$
\operatorname{effective}(A):=\{(S, 1):(S, c) \in A, c>0\}=\operatorname{unit}(\operatorname{trim}(A))
$$

Define the shorthand $A^{\mathrm{F}}:=\operatorname{effective}(A)$.
Histogram equivalence can be defined in terms of effective histograms, $A \equiv$ $B:=\left\{\left(S, A_{S}\right): S \in A^{\mathrm{FS}}\right\}=\left\{\left(T, B_{T}\right): T \in B^{\mathrm{FS}}\right\}$.

The function cartesian $(U) \in \mathrm{P}(\operatorname{vars}(U)) \rightarrow \mathrm{P}\left(\mathcal{S}_{U}\right)$ is the cartesian set of states for some set of variables in a system. Define a shorthand $V^{\mathrm{C}}$ which is the histogram for this set, ()$^{\mathrm{C}} \in \mathrm{P}(\operatorname{vars}(U)) \rightarrow \mathcal{A}_{U, \mathrm{i}}$

$$
V^{\mathrm{C}}:=\operatorname{cartesian}(U)(V) \times\{1\}
$$

where the context of system $U$ is implicit. Define a similar shorthand for the unit cartesian histogram $A^{\mathrm{C}} \in \mathcal{A}_{U, \mathrm{i}}$ which includes all states of $\operatorname{vars}(A)$ in system $U,()^{\mathrm{C}} \in \mathcal{A}_{U} \rightarrow \mathcal{A}_{U, \mathrm{i}}$

$$
A^{\mathrm{C}}:=(\operatorname{vars}(A))^{\mathrm{C}}
$$

assuming the context of system $U$. Clearly the unit cartesian histogram $A^{\mathrm{C}}$ does not depend on the counts in $A$, only on the variables of $A$ in the system $U$. Also $\forall A \in \mathcal{A}_{U}\left(A^{\mathrm{F}} \leq A^{\mathrm{C}}\right)$ and $\forall A \in \mathcal{A}_{U}\left(\left|A^{\mathrm{F}}\right| \leq\left|A^{\mathrm{C}}\right|\right)$ and $\forall A \in \mathcal{A}_{U}\left(\left|A^{\mathrm{C}}\right|=\operatorname{volume}(U)(A)\right)$.

A histogram is complete in some system when the unit histogram equals the unit cartesian histogram, $A^{\mathrm{U}}=A^{\mathrm{C}}$.

The unit effective complement histogram of a histogram $A$ is $A^{\mathrm{C}} \backslash A^{\mathrm{F}}$.

### 3.4.3 Arithmetic operators

The addition operation of histograms is defined if both histograms have the same variables. For histograms $A$ and $B$, if $\operatorname{vars}(A)=\operatorname{vars}(B)$, define $(+) \in \mathcal{A} \times \mathcal{A} \rightarrow \mathcal{A}$

$$
\begin{aligned}
A+ & B:= \\
& \{(S, c):(S, c) \in A, S \notin \operatorname{states}(B)\} \cup \\
& \{(S, c+d):(S, c) \in A,(T, d) \in B, S=T\} \cup \\
& \{(T, d):(T, d) \in B, T \notin \operatorname{states}(A)\}
\end{aligned}
$$

Clearly $\operatorname{size}(A+B)=\operatorname{size}(A)+\operatorname{size}(B)$. Completeness is cumulative for addition, $(A+B)^{\mathrm{U}}=A^{\mathrm{U}} \cup B^{\mathrm{U}}$. Addition is associative and commutative.

Negative counts are not allowed, so subtraction is not constructed in terms of addition of a negative but instead as a binary operation $(-) \in \mathcal{A} \times \mathcal{A} \rightarrow \mathcal{A}$

$$
\begin{aligned}
A- & B:= \\
& \{(S, c):(S, c) \in A, S \notin \operatorname{states}(B)\} \cup \\
& \{(S, c-d):(S, c) \in A,(T, d) \in B, S=T, c \geq d\} \cup \\
& \{(S, 0):(S, c) \in A,(T, d) \in B, S=T, c<d\} \cup \\
& \{(T, 0):(T, d) \in B, T \notin \operatorname{states}(A)\}
\end{aligned}
$$

Subtraction explicitly prevents negative counts. Completeness is cumulative for subtraction, $(A-B)^{\mathrm{U}}=A^{\mathrm{U}} \cup B^{\mathrm{U}}$. Construct a zero, the identity histogram for addition, $A^{\mathrm{C}}-A^{\mathrm{C}}$. To make a histogram complete add the zero, $A+A^{\mathrm{C}}-A^{\mathrm{C}}$.

The sub-histogram relation can be defined in terms of addition and subtraction operators, $A \leq B \Longleftrightarrow(B-A+A) \equiv B$.

To define the multiplication operation of histograms cross the states of each histogram, keeping only those that join, where a pair of states $S$ and $T$ join if their union is a state, $|\operatorname{vars}(S \cup T)|=|S \cup T|$. In other words, the intersection of the variables of the states must also be the intersection of the variable-value pairs. Defining $(*) \in \mathcal{A} \times \mathcal{A} \rightarrow \mathcal{A}$,

$$
A * B:=\{(S \cup T, c d):(S, c) \in A,(T, d) \in B,|\operatorname{vars}(S \cup T)|=|S \cup T|\}
$$

Define $A * \emptyset:=\emptyset$ and $\emptyset * A:=\emptyset$.

Multiplication unions the variables of non-empty histograms, $\operatorname{vars}(A * B)=$ $\operatorname{vars}(A) \cup \operatorname{vars}(B)$. If both $A$ and $B$ are unit, their product $A * B$ is also unit. If the variables of $A$ and $B$ are disjoint, then the cross is cartesian and $|A * B|=|A| \times|B|$ and $\operatorname{size}(A * B)=\operatorname{size}(A) \times \operatorname{size}(B)$. Multiplication is complete if the variables of $A$ and $B$ are disjoint and $A$ and $B$ are both complete. Multiplication is associative and commutative. Multiplication and addition together are distributive. If negative counts were allowed, histograms would obey the algebra of fields. The identity histogram for multiplication is the unit cartesian histogram, $A^{\mathrm{C}}$. Multiplication of a histogram $A$ by a scalar $w$ can be accomplished by promoting the scalar to a histogram with an empty state, $A *\{(\emptyset, c)\}$ or $A * \operatorname{scalar}(c)$, so that $\operatorname{size}(A * \operatorname{scalar}(c))=\operatorname{size}(A) \times c$.

Division is calculated by defining the reciprocal of a histogram as the reciprocal of its counts, $(1 /) \in \mathcal{A} \rightarrow \mathcal{A}$,

$$
1 / A:=\{(S, 1 / c):(S, c) \in A, c>0\}
$$

Define $1 / \emptyset:=\emptyset$. Define division $(/) \in \mathcal{A} \times \mathcal{A} \rightarrow \mathcal{A}$, as $B / A:=B *(1 / A)$. The reciprocal $1 / A$ ignores any count which is zero. The reciprocal $1 / A$ is defined even if $\operatorname{size}(A)=0$. The reciprocal $1 / A$ is as complete as the effective states of $A,(1 / A)^{\mathrm{U}}=A^{\mathrm{F}} \subseteq A^{\mathrm{U}}$. If $A$ is a zero histogram then the reciprocal is empty $(1 / A)=\emptyset$. A unit histogram is its own reciprocal $1 / A^{\mathrm{U}}=A^{\mathrm{U}}$. Division is often used when normalising by a scalar.

### 3.4.4 Reduction

Define reduction of a histogram as the reduction of the set of its variables to some subset, reduce $\in \mathrm{P}(\mathcal{V}) \rightarrow(\mathcal{A} \rightarrow \mathcal{A})$
reduce $(V)(A):=\left\{\left(S, \sum(c:(T, c) \in A, T \supseteq S)\right): S \in\left\{R \% V: R \in A^{\mathrm{S}}\right\}\right\}$
Define the shorthand operator $(\%) \in \mathcal{A} \times \mathrm{P}(\mathcal{V}) \rightarrow \mathcal{A}$ as $A \% V:=\operatorname{reduce}(V)(A)$. By definition, $\forall V \in \mathrm{P}(\mathcal{V})(\operatorname{vars}(A \% V)=V \cap \operatorname{vars}(A))$. Reduction leaves the size of a histogram unchanged, $\operatorname{size}(A \% V)=\operatorname{size}(A)$, but the number of states may be fewer, $|A \% V| \leq|A|$. Reduction of a histogram by its own variables leaves the histogram unchanged, $A \% \operatorname{vars}(A)=A$. Reduction of a histogram by the empty set, leaves a scalar, $A \% \emptyset=\{(\emptyset, c)\}$ where $c=\operatorname{size}(A)$. Sometimes it shall be assumed that the set $Z$ is a relation between all histograms and the scalars of their sizes, $Z=\{(A$, scalar(size $(A))): A \in \mathcal{A}\}$. For example, $Z_{X}=X \% \emptyset=\{(\emptyset, \operatorname{size}(X))\}$.

A histogram $A$ is completely effective in some set of variables $V$ if $(A \% V)^{\mathrm{F}}=$ $(A \% V)^{\mathrm{C}}$. Similarly, $A$ is cartesian in some set of variables $V$ if $A \% V=$ $(A \% V)^{\mathrm{C}}$. If $A$ is cartesian in $V$ then it is also completely effective in $V$.

### 3.4.5 Histogram expressions

A histogram expression $N \in \mathcal{E}_{U}$ in system $U$ is an expression consisting of the histogram arithmetic operators, the histogram reduction operator, constant histograms and free variable identifiers. A histogram expression can be evaluated by substitution of the free variable identifiers by histograms and then evaluation of the dependent operators to yield a resultant histogram. The histogram expression application is denoted $N(A) \in \mathcal{A}_{U}, N(A, B) \in \mathcal{A}_{U}$, $N(A, B, C) \in \mathcal{A}_{U}$, etc where $A, B, C \in \mathcal{A}_{U}$.

A model $M \in \mathcal{M}_{U} \subset \mathcal{E}_{U}$ is a special case of a histogram expression which has a single free variable identifier. A model's resultant histogram, $M(A)$, is in the same variables as the argument histogram, $\operatorname{vars}(M(A))=\operatorname{vars}(A)$. A further constraint is that at some point during the evaluation none of the variables of the argument histogram remain, having been removed by reduction. Thus a model can be thought of as a path from an argument histogram in some set of underlying variables via an intermediate set of derived variables and back to the given set of variables. The underlying variables are called the substrate.

See appendix 'Histogram expressions' for more formal definitions.

### 3.4.6 Types of histogram

An empty histogram $A$ equals the empty set, $A=\emptyset$. Its size is zero, $\operatorname{size}(\emptyset)=0$. An empty histogram has no variables, $\operatorname{vars}(\emptyset)=\emptyset$. Its volume is one in all systems, $\left|\emptyset^{\mathrm{C}}\right|=1$.

A zero histogram $A$ is a non-empty histogram that has unique zero count, $A \neq \emptyset \wedge \operatorname{trim}(A)=\emptyset$. Its size is zero. The only zero histogram that has no variables is the scalar histogram $\{(\emptyset, 0)\}$. All zero histograms are equivalent to the empty histogram, $\forall A \in \mathcal{A}(\operatorname{trim}(A)=\emptyset \Longrightarrow A \equiv \emptyset)$.

A uniform histogram $A$ has unique non-zero count, $|\operatorname{ran}(\operatorname{trim}(A))|=1$. A bi-form histogram $A$ has two non-zero counts, $|\operatorname{ran}(\operatorname{trim}(A))|=2$.

The counts of an integral histogram are positive integers, $\operatorname{ran}(A) \subset \mathbf{N}$. The set of all integral histograms $\mathcal{A}_{\mathrm{i}}$ is

$$
\mathcal{A}_{\mathrm{i}}=\mathcal{A} \cap(\mathcal{S} \rightarrow \mathbf{N})=\{A: A \in \mathcal{A}, \operatorname{ran}(A) \subset \mathbf{N}\}
$$

A singleton histogram $A$ has unique non-zero state, $|\operatorname{trim}(A)|=1$.
A regular histogram $A$ of variables $V=\operatorname{vars}(A) \neq \emptyset$ in system $U$ has unique valency of its variables, $\left|\left\{\left|U_{v}\right|: v \in V\right\}\right|=1$. The volume of a regular histogram is $d^{n}$ where valency $d$ is such that $\{d\}=\left\{\left|U_{v}\right|: v \in V\right\}$ and dimension $n=|V|$. (The use of $d$ here suggests diagonal rather than dimension.)

If a histogram $A$ has no variables, $\operatorname{vars}(A)=\emptyset$, then either the histogram is empty $A=\emptyset$ or it is a scalar $A=\{(\emptyset, c)\}$ of some positive count $c \in \mathbf{Q}_{\geq 0}$. Define constructor scalar $\in \mathbf{Q}_{\geq 0} \rightarrow \mathcal{A}$ such that $\operatorname{scalar}(c):=\{(\emptyset, c)\}$.

When a histogram has exactly one variable, $|\operatorname{vars}(A)|=1$, it is mono-variate.
Pluri-variate histograms can be classified by incidence, incidence $\in \mathcal{A} \times$ $\mathcal{S} \times \mathbf{N} \rightarrow \mathcal{A}$

$$
\text { incidence }(A, S, i):=\{(T, d):(T, d) \in \operatorname{trim}(A),|S \cap T|=i\}
$$

where $i$ is the degree of incidence of state $S$. If state $S \in \operatorname{states}(A)$, the maximum cardinality of incidence |incidence $(A, S, i) \mid$ for a particular degree of incidence $i$ of a regular histogram of variables $V$ of valency $d$ and volume $d^{n}$ where dimension $n=|V|$ is

$$
\frac{n!}{i!(n-i)!}(d-1)^{n-i}
$$

The maximum cardinality of incidence having some degree of incidence is $d^{n}-(d-1)^{n}$.

A pluri-variate histogram, $|\operatorname{vars}(A)|>1$, is causal if the effective states can be functionally split. Define causal $\in \mathcal{A} \rightarrow \mathbf{B}$

$$
\operatorname{causal}(A):=|V|>1 \wedge\left(\exists K \subset V\left(K \neq V \Longrightarrow \operatorname{split}\left(K, A^{\mathrm{FS}}\right) \in \mathcal{S} \rightarrow \mathcal{S}\right)\right)
$$

where $V=\operatorname{vars}(A)$. If $A$ is causal the variables $K$ are said to cause the remaining variables $V \backslash K$.

A histogram is planar if all effective states are incident on some value $u$ of variable $w, A^{\mathrm{F}} \subseteq\left\{S: S \in V^{\mathrm{CS}},(w, u) \in S\right\}^{\mathrm{U}}$. Define planar $\in \mathcal{A} \rightarrow \mathbf{B}$

$$
\operatorname{planar}(A):=\exists(w, u) \in \bigcup A^{\mathrm{FS}} \forall S \in A^{\mathrm{FS}}((w, u) \in S)
$$

A pluri-variate histogram, $|\operatorname{vars}(A)|>1$, is anti-planar if each reduction has at least two effective states. Define antiplanar $\in \mathcal{A} \rightarrow \mathbf{B}$

$$
\operatorname{antiplanar}(A):=|V|>1 \wedge\left(\forall w \in V\left(\left|(A \%\{w\})^{\mathrm{F}}\right|>1\right)\right)
$$

A pluri-variate histogram, $|\operatorname{vars}(A)|>1$, is diagonalised if no pair of effective states shares any value, $\forall S, T \in A^{\mathrm{FS}}(S \neq T \Longrightarrow S \cap T=\emptyset)$ or $\forall(S, c) \in \operatorname{trim}(A)(\operatorname{trim}(A) \backslash\{(S, c)\}=$ incidence $(A, S, 0))$. Define diagonal $\in$ $\mathcal{A} \rightarrow \mathbf{B}$

$$
\operatorname{diagonal}(A):=|V|>1 \wedge\left(\forall S, T \in A^{\mathrm{FS}}(S \neq T \Longrightarrow|S \cap T|=0)\right)
$$

A diagonalised histogram $A$ is fully diagonalised if its non-zero cardinality equals its minimum valency of its variables, $|\operatorname{trim}(A)|=\operatorname{minr}\left(\left\{\left(v,\left|U_{v}\right|\right): v \in\right.\right.$ $\operatorname{vars}(A)\})$. Define diagonalFull $(U) \in \mathcal{A} \rightarrow \mathbf{B}$ in system $U$

$$
\operatorname{diagonalFull}(U)(A):=\operatorname{diagonal}(A) \wedge\left|A^{\mathrm{F}}\right|=\operatorname{minr}\left(\left\{\left(v,\left|U_{v}\right|\right): v \in V\right\}\right)
$$

where $V=\operatorname{vars}(A)$. A full diagonal has the maximum cardinality of effective states of diagonal histogram for the given variables, diagonalFull $(U)(A) \Longrightarrow$ $\left|A^{\mathrm{F}}\right|=\operatorname{maxr}\left(\left\{(B,|B|): B \subseteq V^{\mathrm{C}}\right.\right.$, diagonal $\left.\left.(B)\right\}\right)$. In a fully diagonalised regular histogram of valency $d$, where $\{d\}=\left\{\left|U_{v}\right|: v \in V\right\}$, the cardinality of non-zero states is $\left|A^{\mathrm{F}}\right|=d$. The cardinality of the subsets of a regular cartesian which are fully diagonalised is $\mid\left\{A: A \subseteq A^{\mathrm{C}}\right.$, diagonalFull $\left.(U)(A)\right\} \mid=$ $(d!)^{n-1}$ where $\{d\}=\left\{\left|U_{v}\right|: v \in V\right\}, n=|V|$ and $V \neq \emptyset$.

An anti-diagonal histogram $A$ is such that all pairs of effective states share at least one value. Define antidiagonal $\in \mathcal{A} \rightarrow \mathbf{B}$

$$
\operatorname{antidiagonal}(A):=\forall S, T \in A^{\mathrm{FS}}(|S \cap T|>0)
$$

A full anti-diagonal histogram $A$ is such that all states that are incident on some value $u$ of variable $w$ are effective, $A^{\mathrm{F}}=\left\{S: S \in V^{\mathrm{CS}},(w, u) \in\right.$ $S\}^{U}$. Thus a full anti-diagonal histogram is planar. The cardinality of a full anti-diagonal regular histogram of valency $d$ and dimension $n$ is $d^{n-1}$. The cardinality of fully anti-diagonal planar subsets of a cartesian, $V^{\mathrm{C}}$, is $\sum_{w \in V}\left|U_{w}\right|$. If $V$ is regular this is $n d$.

A histogram is a line if each pair of non-zero states differs in no more than one of the variables, $\forall S, T \in A^{\mathrm{FS}}(|S \cap T|>=n-1)$ where $V=\operatorname{vars}(A)$ and $n=|V|$. Define line $\in \mathcal{A} \rightarrow \mathbf{B}$

$$
\operatorname{line}(A):=\forall S, T \in A^{\mathrm{FS}}(|S \cap T|>=n-1)
$$

A pluri-variate histogram is a crown if (i) it is anti-planar, and (ii) each pair of non-zero states differs in exactly two of the variables, $\forall S, T \in A^{\mathrm{FS}}(S \neq$ $T \Longrightarrow|S \cap T|=n-2)$ where $V=\operatorname{vars}(A)$ and $n=|V|$. Define crown $\in$ $\mathcal{A} \rightarrow \mathrm{B}$
$\operatorname{crown}(A):=\operatorname{antiplanar}(A) \wedge\left(\forall S, T \in A^{\mathrm{FS}}(S \neq T \Longrightarrow|S \cap T|=n-2)\right)$
A crown histogram $A$ is a full crown if its non-zero cardinality equals the dimension. Define crownFull $\in \mathcal{A} \rightarrow \mathbf{B}$

$$
\operatorname{crownFull}(A):=\operatorname{crown}(A) \wedge\left|A^{\mathrm{F}}\right|=n
$$

where $V=\operatorname{vars}(A)$. Crown histograms are also called orthogonal. The pivot of a full crown is the zero state which is the union of the intersections $\bigcup\left\{S \cap T: S, T \in A^{\mathrm{FS}}\right\} \in A^{\mathrm{CS}} \backslash A^{\mathrm{FS}}$.

A histogram is an axial histogram $A$ if there exists exactly one pivot state $P \in V^{\mathrm{CS}}$ such that non-zero states differ in no more than one of the variables, $\forall S \in A^{\mathrm{FS}}(|S \cap P|>=n-1)$ where $V=\operatorname{vars}(A)$ and $n=|V|$
$\operatorname{axial}(A):=\left|\left\{P: P \in\left(\prod_{w \in V} A \%\{w\}\right)^{\mathrm{FS}},\left(\forall S \in A^{\mathrm{FS}}(|S \cap P|>=n-1)\right)\right\}\right|=1$
So an axial histogram is intermediate between a line and a crown. The pivot state the union of the intersections $P=\bigcup\left\{S \cap T: S, T \in A^{\mathrm{FS}}\right\}$. If $A$ is tri-variate, $n=3$, then some non-full anti-diagonal histograms, $\forall S, T \in$ $A^{\mathrm{FS}}(|S \cap T| \geq 1)$, are axial. An anti-diagonal histogram is less orthogonal than axial which in turn is less orthogonal than crown. An axial histogram $A$ is full if its effective cardinality equals one plus the sum of the valencies less one, $\left|A^{\mathrm{F}}\right|=1+\sum_{w \in V}\left(\left|U_{w}\right|-1\right)$. A full axial regular histogram has effective cardinality of $1+n(d-1)$. The cardinality of fully axial subsets of a cartesian, $V^{\mathrm{C}}$, is the volume, $\prod_{w \in V}\left|U_{w}\right|$. If $V$ is regular this is $d^{n}$.

A skeletal histogram is such that all reductions to pairs of variables are linear or axial. Define skeletal $\in \mathcal{A} \rightarrow \mathbf{B}$

$$
\operatorname{skeletal}(A):=\forall K \subseteq V(|K|=2 \Longrightarrow \operatorname{line}(A \% K) \vee \operatorname{axial}(A \% K))
$$

where $V=\operatorname{vars}(A)$. All axial histograms are skeletal, $\operatorname{axial}(A) \Longrightarrow \operatorname{skeletal}(A)$. If a skeletal histogram is not itself axial, then it has no pivot state

$$
\operatorname{skeletal}(A) \wedge \neg \operatorname{axial}(A) \Longrightarrow \bigcup\left\{S \cap T: S, T \in A^{\mathrm{FS}}\right\} \notin A^{\mathrm{CS}}
$$

A singleton histogram can be defined in terms of effective states too, $\forall S, T \in A^{\mathrm{FS}}(|S \cap T|=n)$.

A histogram is pivoted if there exists exactly one effective state $P \in A^{\mathrm{FS}}$ which shares no value with any other effective state, $\forall S \in A^{\mathrm{FS}}(S \neq P \Longrightarrow$ $S \cap P=\emptyset)$. The state $P$ is called the pivot. Define pivot $\in \mathcal{A} \rightarrow \mathbf{B}$

$$
\operatorname{pivot}(A):=\left|\left\{P: P \in A^{\mathrm{FS}},\left(\forall S \in A^{\mathrm{FS}}(S \neq P \Longrightarrow S \cap P=\emptyset)\right)\right\}\right|=1
$$

A histogram is a full pivot if $\left|A^{\mathrm{F}}\right|=1+\prod_{w \in V}\left(\left|U_{w}\right|-1\right)$. If the valency of a regular full pivoted histogram is two, $d=2$, then the histogram is a full diagonal. Thus a pivoted histogram can be viewed as weakly diagonal. A full pivoted histogram is less diagonal than a full diagonal subset because it is more cartesian. A full pivoted regular histogram has effective cardinality of $1+(d-1)^{n}$. The cardinality of full pivoted subsets of a cartesian, $V^{\mathrm{C}}$, is the volume, $\prod_{w \in V}\left|U_{w}\right|$. If $V$ is regular this is $d^{n}$.

A histogram is anti-pivoted if there exists exactly one zero state $P \in\left(A^{\mathrm{C}} \backslash A^{\mathrm{F}}\right)$ which shares at least one value with all effective states, $\forall S \in A^{\mathrm{FS}}(S \cap P \neq \emptyset)$. Define antipivot $\in \mathcal{A} \rightarrow \mathbf{B}$
$\operatorname{antipivot}(A):=\left|\left\{P: P \in\left(\prod_{w \in V} A \%\{w\}\right)^{\mathrm{FS}} \backslash A^{\mathrm{FS}},\left(\forall S \in A^{\mathrm{FS}}(S \cap P \neq \emptyset)\right)\right\}\right|=1$
An anti-pivoted histogram, $A$, is the unit effective complement of a pivoted histogram, antipivot $(A) \Longrightarrow \operatorname{pivot}\left(A^{\mathrm{C}} \backslash A^{\mathrm{F}}\right)$. Thus the cardinality of the full anti-pivot equals the volume minus the cardinality of the full pivot, $\left|A^{\mathrm{F}}\right|=$ $\left|A^{\mathrm{C}}\right|-\left(1+\prod_{w \in V}\left(\left|U_{w}\right|-1\right)\right)$. If the dimension equals two, $n=2$, the effective full anti-pivot, $A^{\mathrm{F}}$, unioned with the effective singleton at the pivot state, $P \notin A^{\mathrm{FS}}$, equals the effective full axial, $A^{\mathrm{F}} \cup\{P\}^{\mathrm{U}}$. Thus the cardinality of the bi-variate full anti-pivot equals the cardinality of the superset full axial less one, $\left|A^{\mathrm{F}}\right|=\sum_{w \in V}\left(\left|U_{w}\right|-1\right)$. A bi-variate full anti-pivoted histogram is more orthogonal than its full axial superset because it is less cartesian. A full anti-pivoted regular histogram has effective cardinality of $d^{n}-\left(1+(d-1)^{n}\right)$. The cardinality of full anit-pivoted subsets of a cartesian, $V^{\mathrm{C}}$, is the volume, $\prod_{w \in V}\left|U_{w}\right|$. If $V$ is regular this is $d^{n}$.

Histograms may be classified in terms of their counts. A histogram is unit if $A=A^{\mathrm{U}}$. A histogram is complete in some system when $A^{\mathrm{U}}=A^{\mathrm{C}}$. A histogram is unit or zero if $A \supseteq A^{\mathrm{F}}$. A non-empty histogram is zero or none if $A^{\mathrm{F}}=\emptyset$. A histogram is one or cartesian if $A=A^{\mathrm{C}}$. A histogram is one or zero in some system if it is complete and unit or zero $\left(A^{\mathrm{U}}=A^{\mathrm{C}}\right) \wedge\left(A \supseteq A^{\mathrm{F}}\right)$. A histogram is not zero or any if $A^{\mathrm{F}} \neq \emptyset$. A histogram is none zero or all or completely effective in some system when $A^{\mathrm{F}}=A^{\mathrm{C}}$.

A histogram is a cartesian sub-volume if the cartesian product of the values for each variable in the trimmed states is equal to the trimmed states

$$
\prod\{\{\operatorname{filter}(\{v\}, S): S \in \operatorname{states}(\operatorname{trim}(A))\}: v \in \operatorname{vars}(A)\}=\operatorname{states}(\operatorname{trim}(A))
$$

Full planar histograms, linear histograms and singleton histograms are all cartesian sub-volumes.

A cardinal substrate histogram is such that the variables and values are integral, $V=\{1 \ldots|V|\}$ where $V=\operatorname{vars}(A)$, and $\forall w \in V \diamond W=\left\{S_{w}: S \in\right.$ $\left.A^{\mathrm{S}}\right\}(W=\{1 \ldots|W|\})$. Define the set of cardinal substrate histograms $\mathcal{A}_{\mathrm{c}}$

$$
\begin{aligned}
\mathcal{A}_{\mathrm{c}} & =\{A: A \in \mathcal{A}, V=\operatorname{vars}(A), V=\{1 \ldots|V|\} \\
& \left.\forall w \in V \diamond W=\left\{S_{w}: S \in A^{\mathrm{S}}\right\}(W=\{1 \ldots|W|\})\right\}
\end{aligned}
$$

A cardinal substrate histogram in system $U, A \in \mathcal{A}_{U} \cap \mathcal{A}_{c}$, is such that $\forall w \in V\left(U_{w}=\left\{1 \ldots\left|U_{w}\right|\right\}\right)$.

A histogram $A \in \mathcal{A}_{U}$ in system $U$ that is not necessarily a cardinal substrate histogram, $A \in \mathcal{A}_{\mathrm{c}} \vee A \notin \mathcal{A}_{\mathrm{c}}$, can be reframed to a cardinal substrate histogram of the same geometry given enumerations in the variables and values. Let $X \in \mathcal{V} \leftrightarrow\left(\mathbf{N}_{>0} \times\left(\mathcal{W} \leftrightarrow \mathbf{N}_{>0}\right)\right)$ such that $\{(w, i):(w,(i, \cdot)) \in X\} \in$ enums $(V)$ where $V=\operatorname{vars}(A)$, and $\forall(\cdot,(\cdot, Y)) \in X(Y \in \operatorname{enums}(\operatorname{dom}(Y)))$, so that $\operatorname{reframe}(X, A)$ is defined and $\operatorname{reframe}(X, A) \in \mathcal{A}_{\mathrm{c}}$. The frame mapping, $X$, is called a cardinal substrate permutation. There are $|V|!\prod_{w \in V}\left|U_{w}\right|!$ cardinal substrate permutations of a histogram $A \in \mathcal{A}_{U}$ in system $U$. If histogram $A$ is regular having dimension $n=|V|$ and valency $\{d\}=\left\{\left|U_{w}\right|: w \in V\right\}$ then the cardinality of cardinal substrate permutations is $n!(d!)^{n}$.

Given some slice state $R \in K^{\mathrm{CS}}$, where $K \subset V$ and $V=\operatorname{vars}(A)$, the slice histogram, $A *\{R\}^{\mathrm{U}} \subset A$, is said to be contingent on the incident slice state, $A *\{R\}^{\mathrm{U}}=$ incidence $(A, R,|R|)$. For example, if the slice histogram is
diagonalised, diagonal $\left(A *\{R\}^{\mathrm{U}} \%(V \backslash K)\right)$, then the histogram, $A$, is said to be contingently diagonalised. Let slices $\in \mathrm{P}(\mathcal{V}) \times \mathcal{A} \rightarrow(\mathcal{S} \rightarrow \mathcal{A})$ be defined

$$
\operatorname{slices}(K, A):=\left\{\left(R, A *\{R\}^{\mathrm{U}}\right): R \in(A \% K)^{\mathrm{S}}\right\}
$$

A histogram $P \in \mathcal{A}$ is a probability function if its size is $1, \operatorname{size}(P)=1 \Longrightarrow$ $P \in \mathcal{P}$, where the set of probability functions, $\mathcal{P}$, is defined in appendix 'Probability functions'. In this case the histogram is called a probability histogram.

In the case where a histogram $P^{\prime} \in \mathcal{A}$ has a size less than or equal to 1 , it is a weak probability function, $\operatorname{size}\left(P^{\prime}\right) \leq 1 \Longrightarrow P^{\prime} \in \mathcal{P}^{\prime}$, and is called a weak probability histogram.

The normalisations of two histograms may be compared as probability histograms by calculating the relative entropy. Let $\hat{A}=\operatorname{normalise}(A)$. Let $A_{1}, A_{2} \in \mathcal{A}$ be such that $\operatorname{vars}\left(A_{1}\right)=\operatorname{vars}\left(A_{2}\right), \operatorname{size}\left(A_{1}\right)>0$ and $\operatorname{size}\left(A_{2}\right)>0$, then $\hat{A}_{1}, \hat{A}_{2} \in \mathcal{A} \cap \mathcal{P}$ and the relative entropy of $A_{2}$ with respect to $A_{1}$ is

$$
\text { entropyRelative }\left(A_{1}, A_{2}^{\prime}\right)=\sum_{S \in A_{1}^{\mathrm{FS}}} \hat{A}_{1}(S) \ln \frac{\hat{A}_{1}(S)}{\hat{A}_{2}^{\prime}(S)}
$$

where $A_{2}^{\prime}=A_{2}+\left(A_{1}^{\mathrm{F}}-A_{2}^{\mathrm{F}}\right)^{\wedge}$. The relative entropy is with respect to the effective states of histogram $A_{1}$. The histogram $A_{2}$ is stuffed with one event uniformly distributed over the ineffective states with respect to the histogram $A_{1},\left(A_{1}^{\mathrm{F}}-A_{2}^{\mathrm{F}}\right)^{\wedge}$. In the case where histogram $A_{2}$ is as effective as the histogram $A_{1}$, then no stuffing is needed, $A_{2}^{\mathrm{F}} \geq A_{1}^{\mathrm{F}} \Longrightarrow A_{2}^{\prime}=A_{2}$. The relative entropy is zero when the histograms are equal, entropyRelative $\left(A_{1}, A_{1}\right)=$ 0 . Maximum relative entropy occurs when there is no effective intersection $A_{1}^{\mathrm{F}} \cap A_{2}^{\mathrm{F}}=\emptyset$ and the histogram $A_{1}$ is uniform over all but one state $S \in V^{\mathrm{CS}}$, entropyRelative $\left(\operatorname{resize}\left(z, V^{\mathrm{C}}-\{S\}^{\mathrm{U}}\right)\right.$, $\left.\operatorname{resize}\left(z,\{S\}^{\mathrm{U}}\right)\right)=\ln (z+1) /(v-1)$ where $v=\left|V^{\mathrm{C}}\right|$ and $z \geq v \geq 2$.

### 3.4.7 Classifications

A histogram may be obtained from a history by counting the event identifiers of each state, histogram $\in \mathcal{H} \rightarrow \mathcal{A}$,

$$
\operatorname{histogram}(H):=\operatorname{count}(\operatorname{flip}(H))=\operatorname{count}(\{(S, x):(x, S) \in H\})
$$

That is, the histogram, histogram $(H)$, is the distribution of events over states of the history $H$.

Let $A=\operatorname{histogram}(H)$ where $H \in \mathcal{H}_{U}$, then $A \in \mathcal{A}_{U},|A| \leq|H|$, states $(A)=$ $\operatorname{states}(H), \operatorname{vars}(A)=\operatorname{vars}(H), \operatorname{size}(A)=\operatorname{size}(H)$, and $\operatorname{volume}(U)(A)=$ volume $(U)(H)$. If each state appears only once in a history the resultant histogram will be unit and $|A|=|H|$.

The converse operation to construct a history from a histogram can be implemented only if the counts in the histogram are all integral, $\forall(S, c) \in A(c \in$ $\mathbf{N}$ ), or $A \in \mathcal{S} \rightarrow \mathbf{N}$. If that is the case, then a history can be created, for example $\{((S, i), S):(S, c) \in A, c>0, i \in\{1 \ldots c\}\}$.

All histories have the equivalent histogram in the set of integral histograms

$$
\forall H \in \mathcal{H}\left(\operatorname{histogram}(H) \in \mathcal{A}_{\mathbf{i}}\right)
$$

A converse operation can be defined history $\in \mathcal{A}_{\mathrm{i}} \rightarrow \mathcal{H}$

$$
\operatorname{history}(A):=\{((S, i), S):(S, c) \in \operatorname{trim}(A), i \in\{1 \ldots c\}\}
$$

But note that in general history $($ histogram $(H)) \neq H$.
Now consider the intermediate step between history and classification. Classify a history $H$ by its states, to make a functional relation between the states and subsets of the history, $J \in \mathcal{S} \rightarrow \mathcal{H}$

$$
J=\{(S,\{(x, T):(x, T) \in H, T=S\}): S \in \operatorname{states}(H)\}
$$

This structure is constrained $\forall(S, F) \in J$ (states $(F)=\{S\})$ and $\sum(|F|$ : $F \in \operatorname{ran}(J))=|\operatorname{ids}(H)|$. The second constraint means that the event identifiers are unique in the whole structure $J$. The next step from histories to classifications is to throw away the duplicated state.

Let $\mathcal{G}$ be the set of classifications, $\mathcal{G} \subset \mathcal{S} \rightarrow(\mathrm{P}(\mathcal{X}) \backslash\{\emptyset\})$. The set of states of a classification is defined, states $\in \mathcal{G} \rightarrow \mathrm{P}(\mathcal{S})$ as states $(G):=\operatorname{dom}(G)$. A classification's states must all have exactly the same set of variables

$$
\forall G \in \mathcal{G} \forall S \in \operatorname{states}(G)(\operatorname{vars}(S)=\operatorname{vars}(G))
$$

where vars $\in \mathcal{G} \rightarrow \mathrm{P}(\mathcal{V})$ is defined

$$
\operatorname{vars}(G):=\{v: S \in \operatorname{states}(G), v \in \operatorname{vars}(S)\}
$$

In addition, the classification partitions its event identifiers,

$$
\forall G \in \mathcal{G} \forall(S, C),(T, D) \in G(S \neq T \Longrightarrow C \cap D=\emptyset)
$$

or

$$
\forall G \in \mathcal{G}(\operatorname{ran}(G) \in \mathrm{B}(\operatorname{ids}(G)))
$$

where ids $\in \mathcal{G} \rightarrow \mathrm{P}(\mathcal{X})$ is defined $\operatorname{ids}(G):=\bigcup \operatorname{ran}(G)$. Define size $\in \mathcal{G} \rightarrow \mathbf{N}$ as $\operatorname{size}(G):=|\operatorname{ids}(G)|$.

A classification is the inverse of a history. That is, a classification is an event identifier component valued function of state. Define classification $\in$ $\mathcal{H} \rightarrow \mathcal{G}$

$$
\begin{aligned}
\text { classification }(H) & :=\text { inverse }(H) \\
& =\{(S,\{x:(x, T) \in H, T=S\}): S \in \operatorname{states}(H)\}
\end{aligned}
$$

Another inverse restores the history, define history $\in \mathcal{G} \rightarrow \mathcal{H}$

$$
\text { history }(G):=\{(x, S):(S, C) \in G, x \in C\}
$$

Thus classifications and histories are isomorphic

$$
\begin{aligned}
& \forall H \in \mathcal{H}(\text { history }(\text { classification }(H))=H) \\
& \forall G \in \mathcal{G}(\text { classification(history }(G))=G)
\end{aligned}
$$

or $G \cong H$.
To construct a histogram from a classification, define histogram $\in \mathcal{G} \rightarrow \mathcal{A}_{\mathrm{i}}$

$$
\operatorname{histogram}(G):=\{(S,|C|):(S, C) \in G\}
$$

So the construction of a histogram from a history can also be defined

$$
\operatorname{histogram}(H)=\left\{(S,|C|):(S, C) \in H^{-1}\right\}
$$

where $H^{-1}:=$ classification $(H)$.
The histogram of a reduction of a history equals the reduction of the histogram of the history,

$$
\operatorname{histogram}(H \% V)=\operatorname{histogram}(H) \% V
$$

The histogram of an addition of histories equals the addition of the histograms of the histories,

$$
\operatorname{histogram}\left(H_{1}+H_{2}\right)=\operatorname{histogram}\left(H_{1}\right)+\operatorname{histogram}\left(H_{2}\right)
$$

Multiplication is also homomorphic,

$$
\operatorname{histogram}\left(H_{1} * H_{2}\right)=\operatorname{histogram}\left(H_{1}\right) * \operatorname{histogram}\left(H_{2}\right)
$$

### 3.4.8 Histogram entropy

The definitions of probability function and entropy in the context of histograms that follow are discussed more generally in appendices 'Probability functions' and 'Entropy and Gibbs' inequality', below.

Let $A \in \mathcal{A}$ be a non-zero histogram of size $z=\operatorname{size}(A)>0$. The normalised histogram,

$$
\hat{A}=\operatorname{normalise}(A)=\{(S, c / z):(S, c) \in A\}
$$

is a probability function, $\hat{A} \in \mathcal{P}$. That is, the normalised counts are between zero and one, $\operatorname{ran}(\hat{A}) \subset \mathbf{Q}_{[0,1]}$, and sum to one, $\sum_{S \in A^{\mathrm{S}}} \hat{A}_{S}=1$.

Entropy is defined for any probability function, so may be defined for non-zero histograms, entropy $\in \mathcal{A} \rightarrow \mathbf{Q}_{\geq 0} \ln \mathbf{Q}_{>0}$, as

$$
\operatorname{entropy}(A):=-\sum_{S \in A^{\mathrm{FS}}} \hat{A}_{S} \ln \hat{A}_{S}
$$

Entropy is undefined for zero or empty histograms, $A^{\mathrm{F}}=\emptyset$. The scaled entropy or size scaled entropy is $z \times \operatorname{entropy}(A)$.

Entropy is positive, entropy $(A) \geq 0$. The minimum entropy occurs where the histogram is singleton,

$$
\forall S \in V^{\mathrm{CS}}(\operatorname{entropy}(\{(S, z)\})=0)
$$

That is, the least uniform histograms, which have singular effective volume, $\left|\{(S, z)\}^{\mathrm{F}}\right|=1$, have the lowest entropy.

If the histogram is integral, $A \in \mathcal{A}_{\mathrm{i}}$, the entropy is less than or equal to the log$\operatorname{arithm}$ of the size, entropy $(A) \leq \ln z$. Given a set of variables $V=\operatorname{vars}(A)$ the maximum entropy occurs where the histogram is the scaled cartesian, entropy $\left(V_{z}^{\mathrm{C}}\right)=\ln z$, where $v=\left|V^{\mathrm{C}}\right|, z / v \in \mathbf{N}_{>0}$, and $V_{z}^{\mathrm{C}}=\operatorname{scalar}(z / v) * V^{\mathrm{C}}$. That is, the most uniform histogram, $\operatorname{ran}\left(V_{z}^{\mathrm{C}}\right)=\{z / v\}$, with the highest effective volume, $\left|\left(V_{z}^{\mathrm{C}}\right)^{\mathrm{F}}\right|=v$, has the highest entropy.

Any non-empty, finite $\mathcal{X}$-valued function of $\mathcal{Y}$ implies a distribution of $\mathcal{Y}$ over $\mathcal{X}$ and hence a probability function by normalisation,

$$
\forall R \in \mathcal{Y} \rightarrow \mathcal{X}\left(0<|R|<\infty \Longrightarrow\left\{(x,|C|):(x, C) \in R^{-1}\right\}^{\wedge} \in \mathcal{P}\right)
$$

Similarly, every non-empty, finite history implies an integral histogram which is the distribution of event identifiers over states. The normalised histogram is a probability function,

$$
\forall H \in \mathcal{H}\left(0<|H|<\infty \Longrightarrow\left\{(S,|C| /|H|):(S, C) \in H^{-1}\right\} \in \mathcal{A} \cap \mathcal{P}\right)
$$

Let $I \in \mathcal{H} \rightarrow \mathcal{A}$ be the histogram valued function of all possible histories of size $z$ in variables $V$,

$$
\begin{aligned}
I & =\left\{\left(H,\left\{(S,|C|):(S, C) \in H^{-1}\right\}\right): H \in\{1 \ldots z\}: \rightarrow V^{\mathrm{CS}}\right\} \\
& =\left\{(H, \operatorname{histogram}(H)): H \in\{1 \ldots z\}: \rightarrow V^{\mathrm{CS}}\right\}
\end{aligned}
$$

Let $W \in \mathcal{A} \rightarrow \mathbf{N}_{>0}$ be the cardinality of histories for each histogram,

$$
\begin{aligned}
W & =\left\{(A,|D|):(A, D) \in I^{-1}\right\} \\
& =\left\{\left(A, \frac{z!}{\prod_{S \in A^{\mathrm{s}}} A_{S}!}\right):(A, \cdot) \in I^{-1}\right\}
\end{aligned}
$$

The cardinality of histories for a histogram $A$ is the multinomial coefficient,

$$
W(A)=\frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \in \mathbf{N}_{>0}
$$

In the case where the histogram counts are large, $\forall(\cdot, c) \in A(c>0 \Longrightarrow c \gg$ $\ln c)$, Stirling's approximation, $\ln n!=n \ln n-n+\mathrm{O}(\ln n)$, may be applied,

$$
\begin{aligned}
\ln W(A) & =\ln z!-\sum_{S \in A^{\mathrm{S}}} \ln A_{S}! \\
& \approx(z \ln z-z)-\sum_{S \in A^{\mathrm{FS}}}\left(A_{S} \ln A_{S}-A_{S}\right) \\
& =-z \sum_{S \in A^{\mathrm{FS}}} \hat{A}_{S} \ln \hat{A}_{S} \\
& =z \times \operatorname{entropy}(A)
\end{aligned}
$$

That is, the logarithm of the probability of a histogram of an arbitrary history of size $z$ in variables $V$ varies with the entropy of the histogram,

$$
\ln \hat{W}(A) \sim \operatorname{entropy}(A)
$$

The history probability function, $\left(\{1 \ldots z\}: \rightarrow V^{\mathrm{CS}}\right) \times\left\{1 / v^{z}\right\} \in \mathcal{P}$, is uniform, but the corresponding histogram probability function, $\hat{W} \in \mathcal{P}$, is not uniform.

The least probable histograms are the singletons,

$$
\operatorname{mind}(W)=\left\{\{(S, z)\}: S \in V^{\mathrm{CS}}\right\}
$$

which have a cardinality of one, $\operatorname{minr}(W)=1$,

$$
\left\{\{(S, z)\}: S \in V^{\mathrm{CS}}\right\} \quad: \leftrightarrow: \quad\left\{\{1 \ldots z\} \times\{S\}: S \in V^{\mathrm{CS}}\right\}
$$

and zero entropy, $\forall A \in \operatorname{mind}(W)(\operatorname{entropy}(A)=0)$.
The modal histogram is the scaled cartesian,

$$
\operatorname{maxd}(W)=\left\{V_{z}^{\mathrm{C}}\right\}
$$

which has a cardinality of $\operatorname{maxr}(W)=z!/((z / v)!)^{v}$, and maximum entropy, $\ln \operatorname{maxr}(\hat{W}) \sim \operatorname{entropy}\left(V_{z}^{\mathrm{C}}\right)=\ln z$.

### 3.5 Transforms

### 3.5.1 Definition

A histogram $X$ which has its variables partitioned into two components, the underlying variables $V$ and the derived variables $W$, such that $\operatorname{vars}(X)=$ $V \cup W$, forms a pair $(X, W)$ called a transform. The underlying and derived variables are disjoint $V \cap W=\emptyset$. The set of all transforms $\mathcal{T}$ such that $\mathcal{T} \subset \mathcal{A} \times \mathrm{P}(\mathcal{V})$ is

$$
\mathcal{T}=\{(X, W): X \in \mathcal{A}, W \in \mathrm{P}(\operatorname{vars}(X))\}
$$

Define various accessor functions, histogram $\in \mathcal{T} \rightarrow \mathcal{A}$ as histogram $((X, W)):=$ $X$, and underlying $\in \mathcal{T} \rightarrow \mathrm{P}(\mathcal{V})$ as underlying $((X, W)):=\operatorname{vars}(X) \backslash W$, and derived $\in \mathcal{T} \rightarrow \mathrm{P}(\mathcal{V})$ as derived $((X, W)):=W$.

The transform function is a special case of a histogram expression that applies the transform to some histogram $A$ by multiplying by the transform histogram and then reducing by the derived variables, transform $\in \mathcal{T} \times \mathcal{A} \rightarrow$ $\mathcal{A}$

$$
\operatorname{transform}((X, W), A):=A * X \% W
$$

Extend the histogram multiplication operator to transforms to make a convenient shorthand, $(*) \in \mathcal{A} \times \mathcal{T} \rightarrow \mathcal{A}$

$$
\begin{aligned}
A *(X, W) & :=\operatorname{transform}((X, W), A) \\
& =A * X \% W
\end{aligned}
$$

Often the variables of $A$ will be the same as the underlying variables of the transform, but this is not necessary.

There are a some special cases of transforms of a histogram $A$ in variables $V=\operatorname{vars}(A)$. A disjoint transform $T=(X, \operatorname{vars}(X))$ has an empty set of underlying variables underlying $(T)=\emptyset$. If $V \cap \operatorname{derived}(T)=\emptyset$ and because $V \cap \operatorname{underlying}(T)=\emptyset$

$$
\operatorname{transform}((X, \operatorname{vars}(X)), A)=Z_{A} * X
$$

where $Z_{A}$ is the scalar histogram $Z_{A}=\{(\emptyset, \operatorname{size}(A))\}$.
On the other hand, the null transform $T=(X, \emptyset)$ has an empty set of derived variables derived $(T)=\emptyset$

$$
\operatorname{transform}((X, \emptyset), A)=Z_{A * X}
$$

where $V=\operatorname{underlying}(T)$ and $Z_{A * X}$ is the scalar histogram $Z_{A * X}=\{(\emptyset, \operatorname{size}(A *$ $X)$ ) .

The empty transform, $(\emptyset, \emptyset)$, is both null and disjoint, but when applied to histogram $A$ produces the empty histogram, $A *(\emptyset, \emptyset)=\emptyset$.

The set of all transforms $\mathcal{T}_{U} \subset \mathcal{T}$ in a particular system $U$ is defined explicitly

$$
\mathcal{T}_{U}=\left\{(X, W): Y \subseteq \operatorname{vars}(U), W \subseteq Y, X \in \operatorname{cartesian}(U)(Y) \rightarrow \mathbf{Q}_{\geq 0}\right\}
$$

A transform $T \in \mathcal{T}_{U}$ in system $U$, having transform histogram $X=\operatorname{his}(T)$, underlying variables $V=\operatorname{und}(T)$ and derived variables $W=\operatorname{der}(T)$, is a frame transform if there exists either (i) a literal frame map $Y \in V \cdot W$, or (ii) a non-literal frame map $Y \in V \cdot\left(W \times\left(\mathcal{W}_{U} \leftrightarrow \mathcal{W}_{U}\right)\right)$, such that reframe $(Y, X \% V)$ is defined in system $U$. The underlying dimension of frame transforms equals the derived dimension, $|V|=|W|$. The valencies of the variables of the pairs of the frame map are equal. That is, for (i) the literal case, $\forall(v, w) \in Y\left(\left|U_{v}\right|=\left|U_{w}\right|\right)$, and for (ii) the non-literal case, $\forall(v,(w, \cdot)) \in$ $Y\left(\left|U_{v}\right|=\left|U_{w}\right|\right)$. Hence the underlying volume equals the derived volume, $\left|V^{\mathrm{C}}\right|=\left|W^{\mathrm{C}}\right|$. A special case of a frame transform is a reframe transform, where the derived histogram equals the reframe of the underlying histogram, $X \% W=\operatorname{reframe}(Y, X \% V)$, or $\left(V^{\mathrm{C}} * T\right)^{\mathrm{F}}=\operatorname{reframe}\left(Y, V^{\mathrm{C}}\right)$.

If a pair of transforms $R, T \in \mathcal{T}_{U}$ in the same system $U$ have variables such that $\exists Y \in \operatorname{vars}(R) \cdot \operatorname{vars}(T) \forall(v, u) \in Y\left(U_{v}=U_{u}\right)$ then the variables of
$R$ and the variables of $T$ are said to be literal frames of each other mapped by $Y$. If underlying $(R)=\operatorname{underlying}(T)$ then the variables of $R$ and the variables of $T$ are derived frames.

The function reframe $\in(\mathcal{V} \leftrightarrow \mathcal{V}) \times \mathcal{T} \rightarrow \mathcal{T}$ is defined

$$
\begin{aligned}
\operatorname{reframe}(Y, T):= & (\operatorname{reframe}(Y, \operatorname{his}(T)), \\
& \left.\left\{Y_{w}: w \in \operatorname{der}(T) \cap \operatorname{dom}(Y)\right\} \cup(\operatorname{der}(T) \backslash \operatorname{dom}(Y))\right)
\end{aligned}
$$

his $=$ histogram and der $=$ derived. $\operatorname{reframe}(Y, T)$ is defined if the underlying $\operatorname{reframe}(Y, \operatorname{his}(T))$ is defined.

Similarly for pairs of transforms having variables which are non-literal frames of each other. Define reframe $\in(\mathcal{V} \leftrightarrow(\mathcal{V} \times(\mathcal{W} \leftrightarrow \mathcal{W})) \times \mathcal{T} \rightarrow \mathcal{T}$

$$
\begin{aligned}
\operatorname{reframe}(Y, T):= & (\operatorname{reframe}(Y, \operatorname{his}(T)), \\
& \left\{w^{\prime}: w \in \operatorname{der}(T) \cap \operatorname{dom}(Y),\left(w^{\prime}, \cdot\right)=Y_{w}\right\} \cup \\
& (\operatorname{der}(T) \backslash \operatorname{dom}(Y)))
\end{aligned}
$$

$\operatorname{reframe}(Y, T)$ is defined if $\operatorname{reframe}(Y, \operatorname{his}(T))$ is defined.

An important subset of the transforms is the set of functional transforms. The functional transforms $\mathcal{T}_{\mathrm{f}} \subset \mathcal{T}$ is the subset of all transforms which form a functional relation between the underlying states and the derived states having non-zero count

$$
\mathcal{T}_{\mathrm{f}}=\left\{T: T \in \mathcal{T}, X=\operatorname{his}(T), V=\operatorname{und}(T), \operatorname{split}\left(V, X^{\mathrm{FS}}\right) \in \mathcal{S} \rightarrow \mathcal{S}\right\}
$$

where the his $=$ histogram and $u n d=$ underlying. The histogram of a functional transform is causal, causal(his( $T)$ ). The underlying variables, und $(T)$, are said to cause the derived variables, $\operatorname{der}(T)$.

If a transform is functional, $T \in \mathcal{T}_{\mathrm{f}}$, then an inverse function can be defined. First define another function stateDeriveds $\in \mathcal{T} \rightarrow \mathrm{P}(\mathcal{S})$ as

$$
\text { stateDeriveds }((X, W)):=\operatorname{states}(X \% W)
$$

Then define inverse $\in \mathcal{T}_{\mathrm{f}} \rightarrow(\mathcal{S} \rightarrow \mathcal{A})$

$$
\begin{aligned}
\text { inverse }(T) & :=\{(R,\{(S \backslash R, c):(S, c) \in X, S \supseteq R\}): R \in \operatorname{std}(T)\} \\
& =\left\{\left(R, X *\{R\}^{\mathrm{U}} \% V\right): R \in \operatorname{std}(T)\right\} \\
& =\{(R, B \% V):(R, B) \in \operatorname{slices}(W, X)\}
\end{aligned}
$$

where std $=$ stateDeriveds, $X=\operatorname{his}(T), W=\operatorname{der}(T)$ and $V=\operatorname{und}(T)$. So $\operatorname{dom}(\operatorname{inverse}(T))=\operatorname{std}(T)$ and $\sum \operatorname{ran}(\operatorname{inverse}(T))=X \% V$.

The inverse function can be defined in terms of the relational inverse function, inverse $\in(\mathcal{X} \rightarrow \mathcal{Y}) \rightarrow(\mathcal{Y} \rightarrow \mathrm{P}(\mathcal{X}))$

$$
\operatorname{inverse}(T):=\operatorname{inverse}(\{((S \% V, c), S \% W):(S, c) \in X\})
$$

where $(X, W)=T$ and $V=\operatorname{und}(T)$. The inverse function can be defined in terms of incidence

$$
\text { inverse }(T)(R)=\operatorname{incidence}(X, R,|R|) \% V
$$

where $R \in \operatorname{std}(T)$.
A functional transform $T \in \mathcal{T}_{\mathrm{f}}$ is said to be effective with respect to a histogram $A \in \mathcal{A}$, where vars $(A)=$ underlying $(T)$, if the effective underlying states of the transform are a superset of the effective states of the histogram, $(X \% V)^{\mathrm{F}} \geq A^{\mathrm{F}}$ where $X=\operatorname{his}(T)$ and $V=\operatorname{his}(T)$. Define the function effective $\in \mathcal{A} \times \mathcal{T}_{\mathrm{f}} \rightarrow \mathcal{T}_{\mathrm{f}}$ which returns the smallest cardinality effective transform of a transform $T$ with respect to a histogram $A$ as

$$
\operatorname{effective}(A, T):=\left(\sum\left\{(A * C)^{\mathrm{F}} *\{R\}^{\mathrm{U}}:(R, C) \in \operatorname{inverse}(T)\right\}, \operatorname{der}(T)\right)
$$

The function effective $(A, T)$ is undefined if there is no effective intersection $X=\emptyset$. The transform $T$ of the cartesian histogram $V^{\mathrm{C}}$ is already minimally effective, effective $\left(V^{\mathrm{C}}, T\right)=T$.

A functional transform $T \in \mathcal{T}_{\mathrm{f}}$ has a set of reduced transforms with respect to a histogram $A \in \mathcal{A}$, where $\operatorname{vars}(A)=$ underlying $(T)$. The transform is functional and so has an inverse. If the transform is effective with respect to the given histogram, $(X \% V)^{\mathrm{F}} \geq A^{\mathrm{F}}$, the set of the trimmed applications of the elements of the range of the inverse, $\operatorname{ran}(\operatorname{inverse}(T)) \subset \mathcal{A}$, partitions the given trimmed histogram, $(X \% V)^{\mathrm{F}} \geq A^{\mathrm{F}} \Longrightarrow\{\operatorname{trim}(A * C): C \in$ $\operatorname{ran}(\operatorname{inverse}(T))\} \backslash\{\emptyset\} \in \mathrm{B}(\operatorname{trim}(A))$. Each of the reduced transforms has a subset of the derived variables such that the partition of the set of trimmed applications is unchanged. Define reductions $\in \mathcal{A} \times \mathcal{T}_{\mathrm{f}} \rightarrow \mathrm{P}\left(\mathcal{T}_{\mathrm{f}}\right)$

$$
\begin{aligned}
& \text { reductions }(A, T):= \\
& \quad\{R: K \subseteq W, R=(X \%(V \cup K), K), \\
& \left.\quad\left\{A^{\mathrm{F}} * D:(\cdot, D) \in R^{-1}\right\} \backslash\{\emptyset\}=\left\{A^{\mathrm{F}} * C:(\cdot, C) \in T^{-1}\right\} \backslash\{\emptyset\}\right\}
\end{aligned}
$$

where $T^{-1}=\operatorname{inverse}(T),(X, W)=T$ and $V=\operatorname{vars}(A) \supseteq \operatorname{und}(T)$. The set of reductions contains the transform itself, $T \in \operatorname{reductions}(A, T)$. The set of reductions of a null transform is the singleton of the null transform, reductions $(A,(X \% V, \emptyset))=\{(X \% V, \emptyset)\}$. The application of a reduction has the same size as the transformed histogram, $\forall R \in \operatorname{reductions}(A, T)$ ( $\operatorname{size}(A *$ $R)=\operatorname{size}(A * T))$. If a transformed histogram is diagonal, diagonal $(A * T)$, then the set of reductions has cardinality equal to the cardinality of the powerset of the derived variables, diagonal $(A * T) \Longrightarrow|\operatorname{reductions}(A, T)|=$ $|\mathrm{P}(W)|-1=2^{|W|}-1$, which is at least the cardinality of the derived variables. That is, the transform can be reduced to any of the derived variables

$$
\operatorname{diagonal}(A * T) \Longrightarrow\{(X \%(V \cup\{w\}),\{w\}): w \in W\} \subseteq \operatorname{reductions}(A, T)
$$

The subset of functional transforms that contains only transforms in a particular system $U$ is $\mathcal{T}_{U, \mathrm{f}}=\mathcal{T}_{U} \cap \mathcal{T}_{\mathrm{f}}$. A functional transform $T \in \mathcal{T}_{U, \mathrm{f}}$ is left total if it is completely effective in its underlying $(X \% V)^{\mathrm{F}}=V^{\mathrm{C}}$, where $(X, W)=T$ and $V=\operatorname{und}(T)$. Similarly $T$ is right total if it is completely effective in its derived $(X \% W)^{\mathrm{F}}=W^{\mathrm{C}}$. A full functional transform $T$ is (i) left total, (ii) right total, and (iii) such that the underlying volume equals the derived volume, $\left|V^{\mathrm{C}}\right|=\left|W^{\mathrm{C}}\right|$. A full functional transform is bijective between its underlying states and derived states, $\operatorname{split}\left(V, X^{\mathrm{S}}\right) \in V^{\mathrm{CS}} \leftrightarrow W^{\mathrm{CS}}$. A special case of a full functional transform is a frame full functional transform, where $V$ and $W$ are frames of each other, $\exists Y \in V \cdot W \forall(v, w) \in Y\left(\left|U_{v}\right|=\right.$ $\left.\left|U_{w}\right|\right)$. In this case, not only are the underlying volume and the derived volume equal, $\left|V^{\mathrm{C}}\right|=\left|W^{\mathrm{C}}\right|$, but the underlying dimension equals the derived dimension, $|V|=|W|$, and the underlying valencies equal the derived valencies, $\forall(v, w) \in Y\left(\left|U_{v}\right|=\left|U_{w}\right|\right)$. A special case of a frame full functional transform is a value full functional transform which is a reframe transform, $X \% W=\operatorname{reframe}(Y, X \% V)$. In this case the derived states, $(X \% W)^{\mathrm{S}}$, are reframed underlying states, $(X \% V)^{\mathrm{S}}$. That is, $\exists Y \in V \cdot W \forall(v, w) \in$ $Y\left(\operatorname{split}\left(\{v\},(X \%\{v, w\})^{\mathrm{S}}\right) \in\{v\}^{\mathrm{CS}} \leftrightarrow\{w\}^{\mathrm{CS}}\right)$.

The subset of transforms that contains only unit transforms is defined $\mathcal{T}_{\mathrm{U}} \subset \mathcal{T}$

$$
\mathcal{T}_{\mathrm{U}}=\left\{T: T \in \mathcal{T}, X=\operatorname{his}(T), X=X^{\mathrm{U}}\right\}
$$

The subset of unit functional transforms in a particular system $U$ is $\mathcal{T}_{U, f, \mathrm{U}}=$ $\mathcal{T}_{U} \cap \mathcal{T}_{\mathrm{f}} \cap \mathcal{T}_{\mathrm{U}}$.

Consider unit functional transform $T \in \mathcal{T}_{U, \mathrm{f}, \mathrm{U}}$ that is also left total $(X \% V)^{\mathrm{F}}=$ $V^{\mathrm{C}}$ where $X=\operatorname{his}(T)$ and $V=\operatorname{und}(T)$. Left total unit functional transforms are also known as one functional transforms $T \in \mathcal{T}_{U, \mathrm{f}, 1}$. The size
and cardinality of the histogram of the transform equals the volume of the underlying variables size $(X)=|X|=\left|V^{\mathrm{C}}\right|$. A one functional transform is size-conservative when applied to a given argument histogram A, $\operatorname{size}(A * T)=\operatorname{size}(A)$, where $\operatorname{und}(T)=\operatorname{vars}(A)$. The empty transform is not one functional, $(\emptyset, \emptyset) \notin \mathcal{T}_{U, \mathrm{f}, 1}$.

A one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ is a functor (or monoid homomorphism) of the histogram addition operator, $(A * T)+(I * T)=(A+I) * T$ where $I \in \mathcal{A}$ and $\operatorname{vars}(I)=\operatorname{und}(T)=\operatorname{vars}(A)$. A one functional transform is also a functor of histogram subtraction, $(A * T)-(D * T)=(A-D) * T$ where $D \in \mathcal{A}$ and $\operatorname{vars}(D)=\operatorname{und}(T)=\operatorname{vars}(A)$ if the subtraction has an inverse addition, $A-D+D=A$, or $D \leq A$.

The histogram $X$ of one functional transform $T$ is argument-conservative where it is multiplied by an argument histogram $A$ and then reduced by the variables of $A$, if the derived variables of $T$ are disjoint, $\operatorname{vars}(A) \cap$ $\operatorname{derived}(T)=\emptyset$. That is, $A * X \% \operatorname{vars}(A)=A$. Also, $\operatorname{size}(A * X)=\operatorname{size}(A)$ and $|A * X|=|A|$. These constraints hold even if the variables of $A$ and the underlying variables of $T$ do not overlap, $\operatorname{vars}(A) \cap \operatorname{vars}(T)=\emptyset$. One can think of the histograms of left total unit functional transforms as adding derived variables while conserving the given histogram as an invariant.

If unit functional transform $T \in \mathcal{T}_{U, \mathrm{f}, \mathrm{U}}$ is not left total, then there are weaker constraints $A * X \% \operatorname{vars}(A) \subseteq A$, size $(A * X) \leq \operatorname{size}(A)$ and $|A * X| \leq|A|$. By contrast if $T$ is a full functional transform, but is not necessarily unit, it may not be argument-conservative but it does obey the constraint $|A * T|=|A|$.

The set of one functional transforms $\mathcal{T}_{U, f, 1}$ can be constructed explicitly

$$
\begin{aligned}
& \mathcal{T}_{U, \mathrm{f}, 1}= \\
& \quad\{(X, W): V, W \in \mathrm{P}(\operatorname{vars}(U)), V \cap W=\emptyset \\
& \quad Q \in \operatorname{cartesian}(U)(V) \rightarrow \operatorname{cartesian}(U)(W),|Q|=\left|V^{\mathrm{C}}\right|, \\
& \quad X=\{(S \cup R, 1):(S, R) \in Q\}\}
\end{aligned}
$$

The set of one functional models $\mathcal{M}_{U, \mathrm{f}, 1}$ is such that each model $M \in \mathcal{M}_{U, \mathrm{f}, 1}$ has a corresponding one functional transform, $\operatorname{transform}(M) \in \mathcal{T}_{U, f, 1}$, where transform $\in \bigcup_{U \in \mathcal{U}}\left(\mathcal{M}_{U, \mathrm{f}, 1} \rightarrow \mathcal{T}_{U, \mathrm{f}, 1}\right)$. There is a shorthand defined $M^{\mathrm{T}}:=$ transform $(M)$.

The one functional transforms, $\mathcal{T}_{U, f, 1}$, are derived state valued left total functions of underlying state,

$$
\forall T \in \mathcal{T}_{U, \mathrm{f}, 1}\left(\operatorname{split}\left(V, X^{\mathrm{S}}\right) \in V^{\mathrm{CS}}: \rightarrow W^{\mathrm{CS}}\right)
$$

where $(X, W)=T$ and $V=\operatorname{und}(T)$. In order to construct a coordinate from a state define ()$^{\mathbb{l}} \in \mathcal{S} \rightarrow \mathcal{L}(\mathcal{W})$ as

$$
S^{\mathbb{1}}:=\left\{(i, u):((v, u), i) \in \operatorname{order}\left(D_{\mathcal{V} \times \mathcal{W}}, S\right)\right\}
$$

where $D_{\mathcal{V} \times \mathcal{W}}$ is an order on the variables and values. The converse function to construct a state from a coordinate ()$^{V} \in \mathcal{L}(\mathcal{W}) \rightarrow \mathcal{S}$ is

$$
S^{V}:=\left\{\left(v, S_{i}\right):(v, i) \in \operatorname{order}\left(D_{\mathcal{V}}, V\right)\right\}
$$

Now one functional transforms may be represented as derived value coordinate valued left total functions of underlying value coordinate,

$$
\begin{aligned}
\left\{\left(S^{\square}, R^{\square}\right):(S, R) \in \operatorname{split}\left(V, X^{\mathrm{S}}\right)\right\} & \in\left\{S^{\square}: S \in V^{\mathrm{CS}}\right\}: \rightarrow\left\{R^{\square}: R \in W^{\mathrm{CS}}\right\} \\
& \subset \mathcal{W}^{n} \rightarrow \mathcal{W}^{m}
\end{aligned}
$$

where $n=|V|$ and $m=|W|$.
So an alternative definition for a one functional transform is a tuple of (i) the underlying variables, $V$, (ii) the derived variables, $W$, and (iii) a derived value coordinate valued left total function of underlying value coordinate, $f$,

$$
\begin{aligned}
& \mathcal{T}_{U, f, 1}= \\
& \quad\{(V, W, f): V, W \in \mathrm{P}(\operatorname{vars}(U)), V \cap W=\emptyset \\
& \left.\quad f \in\left\{S^{\square}: S \in V^{\mathrm{CS}}\right\}: \rightarrow\left\{R^{\square}: R \in W^{\mathrm{CS}}\right\}\right\}
\end{aligned}
$$

The histogram of a function-defined one functional transform $T=(V, W, f) \in$ $\mathcal{T}_{U, f, 1}$ is

$$
\operatorname{histogram}(T):=\left\{S \cup f\left(S^{\square}\right)^{W}: S \in V^{\mathrm{CS}}\right\} \times\{1\}
$$

In the special case where the transform is mono-derived-variate, $T=(V,\{w\}, f)$, the function may be simplified to $f \in\left\{S^{\rrbracket}: S \in V^{\mathrm{CS}}\right\}: \rightarrow U_{w}$, and the histogram is

$$
\operatorname{histogram}(T):=\left\{S \cup\left\{\left(w, f\left(S^{\rrbracket}\right)\right)\right\}: S \in V^{\mathrm{CS}}\right\} \times\{1\}
$$

In the further special case of mono-derived-variate transform where its variables are real, $\forall v \in V\left(U_{v}=\mathbf{R}\right)$ and $U_{w}=\mathbf{R}$, then the function is a real
valued left total function of a real coordinate, $f \in \mathbf{R}^{n}: \rightarrow \mathbf{R}$. Here the cartesian states are $V^{\mathrm{CS}}=\prod_{v \in V}(\{v\} \times \mathbf{R})$, so the histogram is

$$
\begin{aligned}
\operatorname{histogram}(T) & =\left\{S \cup\left\{\left(w, f\left(S^{\square}\right)\right)\right\}: S \in \prod_{v \in V}(\{v\} \times \mathbf{R})\right\} \times\{1\} \\
& =\left\{S^{V} \cup\{(w, f(S))\}: S \in \mathbf{R}^{n}\right\} \times\{1\}
\end{aligned}
$$

The cartesian volume is infinite, $\left|V^{\mathrm{C}}\right|=\left|\mathbf{R}^{n}\right|$, so the cardinality of the histogram is infinite, $\mid$ histogram $(T)\left|=\left|\mathbf{R}^{n}\right|\right.$.

The reals form a metric space so a real valued function of real coordinates may be discretised given a finite subset of the reals $D \subset \mathbf{R}:|D|<\infty$. The discretised function is

$$
\operatorname{discrete}(D, n)(f):=\left\{(X, \operatorname{nearest}(D, f(X))): X \in D^{n}\right\} \in D^{n}: \rightarrow D
$$

where nearest $\in \mathrm{P}(\mathbf{R}) \times \mathbf{R} \rightarrow \mathbf{R}$ is defined

$$
\operatorname{nearest}(D, r):=t:\{t\} \in \operatorname{mind}(\{(s,(|r-s|, s)): s \in D\})
$$

The cardinality of the discretised transform's histogram is finite,

$$
|\operatorname{histogram}((V,\{w\}, \operatorname{discrete}(D, n)(f)))|=\left|D^{n}\right|=|D|^{n}
$$

An example of a transform defined by a real valued function occurs in the function composition of artificial neural networks. Here a transform represents a model of a neuron called a perceptron $T=(V,\{w\}, f(K, Q))$ where the function $f(K, Q) \in \mathbf{R}^{n}: \rightarrow \mathbf{R}$ is parameterised by (i) some differentiable function $K \in \mathbf{R}: \rightarrow \mathbf{R}$, called the activation function, and (ii) a vector of weights, $Q \in \mathbf{R}^{n+1}$, and is defined

$$
f(K, Q)(X):=K\left(\sum_{i \in\{1 \ldots n\}} Q_{i} X_{i}+Q_{n+1}\right)
$$

A functional transform $T \in \mathcal{T}_{f}$ may be applied to a history $H \in \mathcal{H}$ in the underlying variables of the transform, $\operatorname{vars}(H)=\operatorname{und}(T)$, to construct a derived history. Define transform $\in \mathcal{T}_{\mathrm{f}} \times \mathcal{H} \rightarrow \mathcal{H}$ as

$$
\operatorname{transform}(T, H):=\left\{\left(x, P_{S}\right):(x, S) \in H\right\}
$$

where $V=\operatorname{und}(T)$, and $P=\operatorname{split}\left(V, \operatorname{his}(T)^{\mathrm{FS}}\right) \in \mathcal{S} \rightarrow \mathcal{S}$. Let $H * T:=$ $\operatorname{transform}(T, H)$. So vars $(H * T)=W$ where $W=\operatorname{der}(T)$. If the transform is one functional, $T \in \mathcal{T}_{U, f, 1}$, the size is unchanged, $|H * T|=|H|$, and the event identifiers are conserved, $\operatorname{ids}(H * T)=\operatorname{ids}(H)$.

### 3.5.2 Converses

The simple converse of a transform $T \in \mathcal{T}$ is straightforwardly defined as the pair of the reciprocal of the histogram and the underlying variables. Define converseSimple $\in \mathcal{T} \rightarrow \mathcal{T}$ as

$$
\text { converseSimple }(T):=(1 / X, V)
$$

where $X=\operatorname{histogram}(T)$ and $V=\operatorname{und}(T)$.

The natural converse, which is denoted by a dagger, is similar but also scales inversely by the effective incident volume of each of the derived states. Define converseNatural $\in \mathcal{T} \rightarrow \mathcal{T}$ as

$$
\operatorname{converseNatural}(T):=\left(\frac{X^{\mathrm{F}}}{X \% W}, V\right)
$$

where $(X, W)=T$ and $V=\operatorname{und}(T)$. Denote the natural converse with a dagger, $T^{\dagger}=\operatorname{converseNatural}(T)$.

In the case of the natural converse $T^{\dagger}=(X /(X \% W), V)$ of unit functional transform $T \in \mathcal{T}_{U, \mathrm{f}, \mathrm{U}}$, the incident volume of any state $S \in \operatorname{states}(X)$ is $(X \% W)_{R}=\operatorname{incidence}(X, R,|W|)$ where $R=\operatorname{filter}(W, S)$. The counts of the natural converse histogram of a unit functional transform are greater than zero and less than or equal to one, $\forall(S, c) \in X /(X \% W)(0<c \leq 1)$. The reduction of the natural converse histogram of a unit functional transform to the derived states is a unit histogram, $(X /(X \% W)) \% W \subseteq W^{\mathrm{C}}$.

In the case of the natural converse $T^{\dagger}=(X /(X \% W), V)$ of a one functional transform $T \in \mathcal{T}_{U, f, 1}$, the natural converse may be expressed in terms of components,

$$
T^{\dagger}:=\left(\sum_{(R, C) \in T^{-1}}\{R\}^{\mathrm{U}} * \hat{C}, V\right)
$$

where the normalisation is defined $\hat{A}=A /(A \% \emptyset)$.
There are other converses which are variations on the definition of natural converse that scale each state $S \in \operatorname{states}(X)$ inversely by different degrees of incidence incidence $(X, R, i)$ where $R=\operatorname{filter}(W, S)$ and $i \in\{0 \ldots|W|-1\}$. For example, a complement, $|X|$ - incidence $(X, R,|W|)$.

Converses may be parameterised by a normalised sample histogram $\hat{A} \in \mathcal{A}$, having variables $V=\operatorname{vars}(A)$, which is such that $\operatorname{size}(\hat{A})=1$. Given a
transform $T=(X, W) \in \mathcal{T}$, having underlying variables equal to the sample variables, $\operatorname{und}(T)=V$, the sample converse converseSample $\in \mathcal{A} \times \mathcal{T} \rightarrow \mathcal{T}$ is defined as

$$
\text { converseSample }(A, T):=(\hat{A} * X, V)
$$

In the case of unit functional transform $T \in \mathcal{T}_{U, \mathrm{f}, \mathrm{U}}$, and $A=(X /(X \% W)) \% V$, the sample converse equals the natural converse,

$$
\operatorname{converseSample}(X /(X \% W), T)=\operatorname{converseNatural}(T)
$$

The actual converse is very similar to the natural converse except that the normalised application of the component to an argument histogram is used, rather than just the normalised component. The actual converse is defined converseActual $\in \mathcal{A} \times \mathcal{T}_{\mathrm{f}} \rightarrow \mathcal{T}$

$$
\begin{aligned}
& \text { converseActual }(B, T):= \\
& \qquad\left(\sum \frac{B * C}{(B * C) \% \emptyset} *\{R\}^{\mathrm{U}}:(R, C) \in \operatorname{inverse}(T), V\right)
\end{aligned}
$$

where $\operatorname{size}(B)>0$ and $\operatorname{vars}(B)=V=$ underlying $(T)$. Define notation

$$
T^{\odot B}=\operatorname{converseActual}(B, T)
$$

The argument transform must be functional $T \in \mathcal{T}_{\mathrm{f}}$. The actual converse may be expressed more concisely,

$$
\begin{equation*}
T^{\odot B}:=\left(\sum_{(R, C) \in T^{-1}}\{R\}^{\mathrm{U}} *(B * C)^{\wedge}, V\right) \tag{1}
\end{equation*}
$$

The actual converse, $T^{\odot A}$, equals the sample converse, $(\hat{A} * X, V)$, if each of the components are normalised,

$$
\forall(R, C) \in T^{-1}\left(\{R\}^{\mathrm{U}} * X * \hat{A}=\{R\}^{\mathrm{U}} *(A * C)^{\wedge}\right)
$$

A converse transform $T$ is conversely functional if the transform formed from its underlying variables is functional, $(\operatorname{his}(T), \operatorname{und}(T)) \in \mathcal{T}_{\mathrm{f}}$. The converse of a full functional transform is also a full functional transform. If a full functional transform is also unit, then it is its own natural converse. In fact, the converse of a unit full functional transform is an identity, $A * T * T^{\dagger}=A$, where $\operatorname{und}(T)=\operatorname{vars}(A)$.

An action $C=(L, R)=((X, W),(Y, V))$ is special case of a model histogram expression which is a pair of transforms having the same variables $\operatorname{vars}(X)=\operatorname{vars}(Y)$ and such that the underlying variables for the first transform are the derived variables of the second transform and vice-versa,

$$
\begin{aligned}
\operatorname{underlying}(L) & =\operatorname{derived}(R) \\
\text { derived }(L) & =\operatorname{underlying}(R)
\end{aligned}
$$

The set of all actions actions $\subset \mathcal{T} \times \mathcal{T}$ is defined

$$
\text { actions }=\{((X, W),(Y, V)):(X, W),(Y, V) \in \mathcal{T}, V \cap W=\emptyset, \operatorname{vars}(X)=\operatorname{vars}(Y)\}
$$

Define function action $\in$ actions $\times \mathcal{A} \rightarrow \mathcal{A}$

$$
\begin{aligned}
\operatorname{action}(((X, W),(Y, V)), A) & :=\operatorname{transform}((Y, V), \operatorname{transform}((X, W), A)) \\
& =A *(X, W) *(Y, V) \\
& =A * X \% W * Y \% V
\end{aligned}
$$

The simple action is defined as a transform and its simple converse

$$
\left((X, W),\left(\frac{1}{X}, V\right)\right)
$$

where $(X, W)$ is a transform with derived variables $W$ and underlying variables $V$. Similarly, sample actions are the pair of the transform and its sample converse

$$
(T,(\hat{A} * X, V))
$$

Again, natural actions are the pair of the transform and its natural converse

$$
\left(T, T^{\dagger}\right)=\left((X, W),\left(\frac{X^{\mathrm{F}}}{X \% W}, V\right)\right)
$$

The natural action expression applied to a given argument $A$ is the naturalisation,

$$
\operatorname{action}\left(\left(T, T^{\dagger}\right), A\right)=A * T * T^{\dagger}=A * X \% W * \frac{X^{\mathrm{F}}}{X \% W} \% V
$$

The natural action conserves the size of the given argument $A$ if the transform $T$ is one functional $T \in \mathcal{T}_{U, \mathrm{f}, 1}$

$$
\operatorname{size}\left(A * T * T^{\dagger}\right)=\operatorname{size}(A)
$$

Note that there are some functional transforms that conserve size but are not one functional. These, however, must be none zero and uniform in each of the derived states, $\forall R \in \operatorname{states}(X \% W)(|\{c:(S, c) \in X, R \subseteq S\}|=1)$. For each of the actions constructed from one of these functional transforms and the natural converse, there is an equivalent action constructed from a one functional transform, because the uniform count cancels out.

The set of states of a one functional naturalisation is a superset of the set of states of the given argument $A$

$$
\operatorname{states}\left(A * T * T^{\dagger}\right) \supseteq \operatorname{states}(A)
$$

Or to put it another way, the one functional naturalisation may be more effective $\left(A * T * T^{\dagger}\right)^{\mathrm{F}} \geq A^{\mathrm{F}}$. In the extreme case of a one full functional naturalisation the argument histogram is unchanged, $A * T * T^{\dagger}=A$, because one full functional natural converses are inverses. At the other extreme the null one functional naturalisation scales the cartesian of the underlying $A * T * T^{\dagger}=Z_{A} * V^{\mathrm{C}} /\left(V^{\mathrm{C}} \% \emptyset\right)$.

The extremes between the null $\left|A * T * T^{\dagger}\right|=\left|V^{\mathrm{C}}\right|$ and the full $\left|A * T * T^{\dagger}\right|=$ $|A|$, show that the cardinality of the states of the applied action lies between $|A|$ and $\left|V^{\mathrm{C}}\right|$, that is $|A| \leq\left|A * T * T^{\dagger}\right| \leq\left|A^{\mathrm{C}}\right|$.

In addition, one functional naturalisations are limited in the changes that can be made to the counts of the argument histogram $A$ where the variables $V$ of $A$ are the underlying variables of the first transform of the action. Consider a single state $(S, c) \in A$, and a one functional natural action $\left(T, T^{\dagger}\right)$ and the derived state $Q$ such that $\{(Q, 1)\}=\{(S, 1)\} * T$. Let $(X, W)=T$. In the case where there is only one incident state on $Q,(X \% W)_{Q}=|X *\{(Q, 1)\}|=1$, then $(A * T)_{Q}=c$ and so $\left(A * T * T^{\dagger}\right)_{S}=c$. In the case where the incident volume $(X \% W)_{Q}=2$ then there is another state $R$ other than $S$ contributing to $(A * T)_{Q}$. That is, $X *\{(Q, 1)\}=\{(Q \cup S, 1),(Q \cup R, 1)\}$ such that $0 \leq A_{R} \leq z-c$ where $z=\operatorname{size}(A)$. Thus $z / 2 \geq\left(A * T * T^{\dagger}\right)_{S} \geq c / 2$. Finally, extend the incident volume to $(X \% W)_{Q}=v-1$ where $v=\left|V^{\mathrm{C}}\right|$. Here $z /(v-1) \geq\left(A * T * T^{\dagger}\right)_{S} \geq c /(v-1)$. Overall, $z / 2 \geq\left(A * T * T^{\dagger}\right)_{S} \geq c /(v-1)$ except in the case where $c \geq z / 2$ and the incident volume $(X \% W)_{Q}=1$. The count of a state is limited in its possible increase under the action. It cannot decrease to below its original count approximately inversely scaled by the volume.

The action of a one functional transform $T \in \mathcal{T}_{U, f, 1}$ and its actual converse, $\left(T, T^{\odot B}\right)$, is size conserving if all of the components of $T$ are non-zero when
applied to $B$. Thus

$$
\operatorname{size}\left(A * T * T^{\odot B}\right)=\operatorname{size}(A)
$$

where $\forall C \in \operatorname{ran}(\operatorname{inverse}(T))(\operatorname{size}(B * C)>0)$. In fact, the action is sizeconserving under the weaker condition that the transform applied to $B$ is at least as effective as the transform applied to $A,(B * T)^{\mathrm{F}} \geq(A * T)^{\mathrm{F}}$.

When $B=A$, then the application of the action $\left(T, T^{\odot A}\right)$ is equivalent to $A$

$$
A * T * T^{\odot A} \equiv A
$$

The application of the action ( $T, T^{\odot A}$ ) to the scaled cartesian is called the unnaturalisation,

$$
V_{z}^{\mathrm{C}} * T * T^{\odot A}
$$

where $V=\operatorname{vars}(A), z=\operatorname{size}(A), v=\left|V^{\mathrm{C}}\right|$ and $V_{z}^{\mathrm{C}}=\operatorname{scalar}(z / v) * V^{\mathrm{C}}$.

### 3.5.3 Transforms and probability

Let probability histogram $P \in \mathcal{A} \cap \mathcal{P}$ have variables $\operatorname{vars}(P)=X \cup Y$ where $X$ and $Y$ are disjoint, $X \cap Y=\emptyset$. A probability histogram has unit size, $\operatorname{size}(P)=1$.

The conditional probability histogram given $X$ is $P /(P \% X)$. The conditional probability histogram given $Y$ is $P /(P \% Y)$. Bayes' theorem may be expressed in terms of conditional probability histograms. Let $P[Y \mid X]=P /(P \% X)$, $P[X \mid Y]=P /(P \% Y), P[Y]=P \% Y$ and $P[X]=P \% X$, then

$$
\begin{aligned}
P[Y \mid X] & =\frac{P[X \mid Y] P[Y]}{P[X]} \\
& =\frac{P /(P \% Y) *(P \% Y)}{P \% X} \\
& =\frac{P}{P \% X} \\
& =P[Y \mid X]
\end{aligned}
$$

Let query probability histogram $Q \in \mathcal{A} \cap \mathcal{P}$ have variables $\operatorname{vars}(Q)=$ $X$. The product of the query probability histogram, $Q$, and the probability histogram, $P$, is a weak probability histogram,

$$
Q * P \in \mathcal{A} \cap \mathcal{P}^{\prime}
$$

A weak probability histogram has size less than or equal to one, $\operatorname{size}(Q * P) \leq$ 1.

If the set of query variables is empty, $X=\emptyset$, then the query histogram is scalar one, $Q=\{(\emptyset, 1)\}$, and the product is the given histogram, $Q * P=P$.

If the effective states of the histograms do not intersect, then the product is the empty histogram, which has a size of 0 ,

$$
Q^{\mathrm{F}} \cap(P \% X)^{\mathrm{F}}=\emptyset \Longrightarrow Q * P=\emptyset
$$

If the probability histogram is as effective as the query probability histogram and either histogram is an effective singleton then the product is a probability histogram,

$$
\left(Q^{\mathrm{F}} \leq(P \% X)^{\mathrm{F}}\right) \wedge\left(\left|Q^{\mathrm{F}}\right|=1\right) \Longrightarrow Q * P \in \mathcal{A} \cap \mathcal{P}
$$

The transform implied by $P$ and $Q$ is $T_{P}=(P, Y) \in \mathcal{T}$. The transformed product is

$$
Q * T_{P}=Q *(P, Y)=Q * P \% Y \in \mathcal{A} \cap \mathcal{P}^{\prime}
$$

The conditional transform implied by $P$ and $Q$ is $T_{P}^{\prime}=(P /(P \% X), Y) \in \mathcal{T}$. The transformed conditional product is

$$
Q * T_{P}^{\prime}=Q *\left(\frac{P}{P \% X}, Y\right)=\frac{Q * P}{P \% X} \% Y \in \mathcal{A} \cap \mathcal{P}^{\prime}
$$

In the case where the reduction of $P$ is as effective as $Q$, the transformed conditional product is a probability histogram,

$$
Q^{\mathrm{F}} \leq(P \% X)^{\mathrm{F}} \Longrightarrow Q * T_{P}^{\prime}=Q *\left(\frac{P}{P \% X}, Y\right) \in \mathcal{A} \cap \mathcal{P}
$$

because $(P /(P \% X)) \% X=(P \% X)^{\mathrm{F}}$. In this case the conditional product $R=Q * P /(P \% X)$ is such that $R \% X=Q$ and $R \% Y=Q *(P /(P \% X), Y)$.

If the set of variables $Y$ is empty, $Y=\emptyset$, then $\operatorname{vars}(P)=X, P \% X=P$ and $P /(P \% X)=P^{\mathrm{F}}$. If in addition $P$ is as effective as $Q, Q^{\mathrm{F}} \leq P^{\mathrm{F}}$, then the transformed conditional product is scalar one, $Q *(P /(P \% X), Y)=Q \% \emptyset=$ $\{(\emptyset, 1)\}$.

If (i) the reduced probability histogram $P \% X$ is uniform, $P \% X=(P \% X)^{\mathrm{FS}} \times$ $\left\{1 /\left|(P \% X)^{\mathrm{FS}}\right|\right\}$, and (ii) the probability histogram is as effective as the query probability histogram, $Q^{\mathrm{F}} \leq(P \% X)^{\mathrm{F}}$, then the transformed conditional product is the normalised transformed product probability histogram,

$$
\begin{aligned}
& (|\operatorname{ran}(P \% X)|=1) \wedge\left(Q^{\mathrm{F}} \leq(P \% X)^{\mathrm{F}}\right) \Longrightarrow \\
& \quad Q * T_{P}^{\prime}=Q *\left(\frac{P}{P \% X}, Y\right)=(Q *(P, Y))^{\wedge}=\left(Q * T_{P}\right)^{\wedge} \in \mathcal{A} \cap \mathcal{P}
\end{aligned}
$$

where $(Q *(P, Y))^{\wedge}=\operatorname{normalise}(Q *(P, Y))$ and $\left(Q * T_{P}\right)^{\wedge}=\operatorname{normalise}(Q *$ $\left.T_{P}\right)$.

If the probability histogram is the normalised cartesian histogram $P=(X \cup$ $Y)^{\mathrm{C} \wedge}=$ normalise $\left((X \cup Y)^{\mathrm{C}}\right)$, then the transformed product is the normalised cartesian in variables $Y$,

$$
P=(X \cup Y)^{\mathrm{C} \wedge} \Longrightarrow Q * T_{P}=Q *\left((X \cup Y)^{\mathrm{C} \wedge}, Y\right)=Y^{\mathrm{C} \wedge} \in \mathcal{A} \cap \mathcal{P}
$$

where $Y^{\mathrm{C} \wedge}=$ normalise $\left(Y^{\mathrm{C}}\right)=\operatorname{scalar}\left(1 /\left|Y^{\mathrm{C}}\right|\right) * Y^{\mathrm{C}}$. That is, the transformed product, $Q * T_{P}$, is a constant, $Y^{\mathrm{C} \wedge}$, and so independent of the query probability histogram, $Q$.

The opposite extreme to normalised cartesian histogram, $(X \cup Y)^{\mathrm{C} \wedge}$, is where the probability histogram, $P$, is causal, causal $(P)$. In particular, if the variables $Y$ are a function of the variables $X, \operatorname{split}\left(X, P^{\mathrm{FS}}\right) \in X^{\mathrm{CS}} \rightarrow Y^{\mathrm{CS}}$, then the transform implied by $Q$ and $P, T_{P}=(P, Y)$, is functional, $T_{P} \in \mathcal{T}_{\mathrm{f}}$. In this case, the conditional transform is also functional, $T_{P}^{\prime} \in \mathcal{T}_{\mathrm{f}}$.

If the probability histogram, $P$, is (i) causal between variables $X$ and variables $Y$, so that $T_{P} \in \mathcal{T}_{\mathrm{f}}$, and (ii) completely effective in variables $X$, so that $(P \% X)^{\mathrm{F}}=X^{\mathrm{C}}$, then the conditional transform is one functional,

$$
\left(T_{P} \in \mathcal{T}_{\mathrm{f}}\right) \wedge\left((P \% X)^{\mathrm{F}}=X^{\mathrm{C}}\right) \Longrightarrow T_{P}^{\prime}=\left(\frac{P}{P \% X}, Y\right) \in \mathcal{T}_{U, \mathrm{f}, 1}
$$

In this case the reduction of the probability histogram is necessarily as effective as the query probability histogram, $Q^{\mathrm{F}} \leq(P \% X)^{\mathrm{F}}=X^{\mathrm{C}}$, and hence the transformed conditional product is necessarily a probability histogram,

$$
(P \% X)^{\mathrm{F}}=X^{\mathrm{C}} \Longrightarrow Q * T_{P}^{\prime}=Q *\left(\frac{P}{P \% X}, Y\right) \in \mathcal{A} \cap \mathcal{P}
$$

So the one functional probability histogram, $P$, is a one functional model, $P \in \mathcal{M}_{U, \mathrm{f}, 1}$, such that $P^{\mathrm{T}}=T_{P}^{\prime}$, with underlying variables $\operatorname{und}\left(P^{\mathrm{T}}\right)=X$ and derived variables $\operatorname{der}\left(P^{\mathrm{T}}\right)=Y$.

Conversely, all one functional transforms are conditional in the underlying variables,

$$
\forall T \in \mathcal{T}_{U, \mathrm{f}, 1}(\operatorname{his}(T)=\operatorname{his}(T) /(\operatorname{his}(T) \% \operatorname{und}(T)))
$$

because the transform histogram reduction to underlying variables is cartesian,

$$
\forall T \in \mathcal{T}_{U, \mathrm{f}, 1}\left(\operatorname{his}(T) \% \operatorname{und}(T)=(\operatorname{und}(T))^{\mathrm{C}}\right)
$$

If the probability histogram, $P$, is causal between the variables $X$ and $Y$, $\operatorname{split}\left(X, P^{\mathrm{FS}}\right) \in X^{\mathrm{CS}} \rightarrow Y^{\mathrm{CS}}$, then the transform is functional, $T_{P} \in \mathcal{T}_{\mathrm{f}}$, and so may have size-conserving converses. The natural converse is $T_{P}^{\dagger}=$ $(P /(P \% Y), X) \in \mathcal{T}$. The natural converse is the conditional transform implied by $P$ and $N$, where $N$ is a query probability histogram in variables $Y$, $N \in \mathcal{A} \cap \mathcal{P}$ and $\operatorname{vars}(N)=Y$. That is, the transformed conditional product of $N$ and $P$ is

$$
N * T_{P}^{\dagger}=N *\left(\frac{P}{P \% Y}, X\right) \in \mathcal{A} \cap \mathcal{P}^{\prime}
$$

If the probability histogram, $P$, is as effective as $N$, then the transformed conditional product is a probability histogram,

$$
N^{\mathrm{F}} \leq(P \% Y)^{\mathrm{F}} \Longrightarrow N * T_{P}^{\dagger}=N *\left(\frac{P}{P \% Y}, X\right) \in \mathcal{A} \cap \mathcal{P}
$$

The natural action applied to query probability histogram $Q$ is

$$
Q * T_{P} * T_{P}^{\dagger}=Q *(P, Y) *\left(\frac{P}{P \% Y}, X\right) \in \mathcal{A} \cap \mathcal{P}^{\prime}
$$

If the probability histogram is bijective, $\operatorname{split}\left(X, P^{\mathrm{FS}}\right) \in X^{\mathrm{CS}} \leftrightarrow Y^{\mathrm{CS}}$, then the transform is a full functional transform. The simple converse is also functional, $(1 / P, X) \in \mathcal{T}_{\mathrm{f}}$, and the simple action leaves the query unchanged, $Q *(P, Y) *(1 / P, X)=Q$, if $Q^{\mathrm{F}} \leq(P \% X)^{\mathrm{F}}$. The natural converse is also functional, $T_{P}^{\dagger} \in \mathcal{T}_{\mathrm{f}}$, and so it has a natural converse, which equals the simple converse implied by $P$ and $N$,

$$
T_{P}^{\dagger \dagger}=\left(\frac{P /(P \% Y)}{P \% X}, Y\right)=(1 / P, Y)
$$

So the natural action applied to $N$ is

$$
N * T_{P}^{\dagger} * T_{P}^{\dagger \dagger}=N *\left(\frac{P}{P \% Y}, X\right) *(1 / P, Y) \in \mathcal{A} \cap \mathcal{P}^{\prime}
$$

The normalisation of a non-zero sample histogram $A \in \mathcal{A}_{U}$, having nonempty variables $V=\operatorname{vars}(A) \neq \emptyset$, is a probability histogram, $\hat{A} \in \mathcal{A} \cap \mathcal{P}$, because $\operatorname{size}(\hat{A})=1$, where $\hat{A}=A /(A \% \emptyset)$. The normalisation of a non-zero query histogram $Q \in \mathcal{A}_{U}$, having variables $K=\operatorname{vars}(Q)$ that are a subset of the sample variables, $K \subseteq V$, is a probability histogram, $\hat{Q} \in \mathcal{A} \cap \mathcal{P}$. The transform implied by $A$ and $Q$ is $T_{A}=(\hat{A},(V \backslash K)) \in \mathcal{T}$. The transformed product is $\hat{Q} * T_{A}=\hat{Q} *(\hat{A},(V \backslash K)) \in \mathcal{A} \cap \mathcal{P}^{\prime}$. The conditional transform
implied by $A$ and $Q$ is $T_{A}^{\prime}=(A /(A \% K),(V \backslash K)) \in \mathcal{T}$. The transformed conditional product is $\hat{Q} * T_{A}^{\prime}=\hat{Q} *(A /(A \% K),(V \backslash K)) \in \mathcal{A} \cap \mathcal{P}^{\prime}$. In the case where the reduction of $A$ is as effective as $Q$, the transformed conditional product is a probability histogram, $Q^{\mathrm{F}} \leq(A \% K)^{\mathrm{F}} \Longrightarrow \hat{Q} * T_{A}^{\prime} \in \mathcal{A} \cap \mathcal{P}$.

If the effective states of the query histogram, $Q$, and the sample histogram, $A$, do not intersect, then both the transformed product and transformed conditional product are empty, $Q^{\mathrm{F}} \cap(A \% K)^{\mathrm{F}}=\emptyset \quad \Longrightarrow \hat{Q} * T_{A}=\emptyset$ and $Q^{\mathrm{F}} \cap(A \% K)^{\mathrm{F}}=\emptyset \Longrightarrow \hat{Q} * T_{A}^{\prime}=\emptyset$. Less drastically, if the sample histogram is not as effective as the query histogram, $\left|Q^{\mathrm{F}} \cap(A \% K)^{\mathrm{F}}\right|<\left|Q^{\mathrm{F}}\right|$, then the transformed conditional product cannot be a probability histogram, $\hat{Q} * T_{A}^{\prime} \notin$ $\mathcal{P}$. However, if there exists a one functional transform $T=(M, W) \in \mathcal{T}_{U, \mathrm{f}, 1}$, having underlying variables $J=\operatorname{und}(T)$ which are a subset of the sample variables, $J \subseteq V$, then a model analog to the product may be computed via the intermediate derived variables, $W$. In the case where the underlying variables are a subset of the query variables, $J \subseteq K$, the model substitute for the transformed product, $\hat{Q} * T_{A} \in \mathcal{A} \cap \mathcal{P}^{\prime}$, is

$$
\hat{Q} * M \% W * M * \hat{A} \%(V \backslash K) \in \mathcal{A} \cap \mathcal{P}^{\prime}
$$

This is equivalent to the application of the normalised sample action, ( $T,(\hat{A} *$ $M, V)$ ), to the query probability histogram, $\hat{Q}$, followed by reduction to $V \backslash K$,

$$
\hat{Q} * T *(\hat{A} * M, V) \%(V \backslash K) \in \mathcal{A} \cap \mathcal{P}^{\prime}
$$

Now the intersection of effective states is $(Q * T)^{\mathrm{F}} \cap(A * T)^{\mathrm{F}}$. The states for which there is no effective derived sample state, $(Q * T)^{\mathrm{F}} \backslash(A * T)^{\mathrm{F}}$, are said to be over-fitted. That is, over-fitted states, $\left(\left((Q * T)^{\mathrm{F}} \backslash(A * T)^{\mathrm{F}}\right) * T^{\dagger}\right)^{\mathrm{S}} \subseteq K^{\mathrm{CS}}$, have zero probability.

The modelled transformed product procedure is: (i) the transform, $T=$ $(M, W)$, is applied, raising the query into the derived variables, $\operatorname{vars}(\hat{Q} *$ $(M, W))=W$, then (ii) the sample converse transform, $(\hat{A} * M, V)$, is applied, lowering back to the sample variables, $\operatorname{vars}(\hat{Q} * T *(\hat{A} * M, V))=V$, which is followed by (iii) the removal of the query variables, $\operatorname{vars}(\hat{Q} * T *(\hat{A} *$ $M, V) \%(V \backslash K))=V \backslash K$.

In the case where the underlying variables are a proper superset of the query variables, $J \supset K$, the query histogram can be expanded by assuming a uniform probability function in the additional variables,

$$
(J \backslash K)^{\mathrm{C} \wedge}=(J \backslash K)^{\mathrm{CS}} \times\left\{1 /\left|(J \backslash K)^{\mathrm{C}}\right|\right\} \in \mathcal{A} \cap \mathcal{P}
$$

The expanded query probability histogram is $\hat{Q}_{J}=\hat{Q} *(J \backslash K)^{\mathrm{C} \wedge} \in \mathcal{A} \cap \mathcal{P}$. It has variables $\operatorname{vars}\left(\hat{Q}_{J}\right)=K \cup J$. Now the application of the model transform is functional, $\operatorname{split}\left(K \cup J,\left(\hat{Q}_{J} * M\right)^{\mathrm{S}}\right) \in(K \cup J)^{\mathrm{CS}} \rightarrow W^{\mathrm{S}}$. The modelled transformed product becomes

$$
\hat{Q}_{J} * T *(\hat{A} * M, V) \%(V \backslash K) \in \mathcal{A} \cap \mathcal{P}^{\prime}
$$

In the absence of a wholly effective intersection between the query and the sample, $\left|Q^{\mathrm{F}} \cap(A \% K)^{\mathrm{F}}\right|<\left|Q^{\mathrm{F}}\right|$, a model analog for the transformed conditional product, $\hat{Q} * T_{A}^{\prime}=\hat{Q} *(A /(A \% K),(V \backslash K))$, can be defined by normalising the application of the normalised sample action to the query probability histogram,

$$
\left(\hat{Q}_{J} * T *(\hat{A} * M, V)\right)^{\wedge} \%(V \backslash K) \in \mathcal{A} \cap \mathcal{P}
$$

if the intersection of derived effective states is not empty, $(Q * T)^{\mathrm{F}} \cap(A * T)^{\mathrm{F}} \neq$ $\emptyset$. The normalisation is equivalent to assuming that the reduced sample probability histogram, $\hat{A} \% K$, is uniform,

$$
\hat{A} \% K=(\hat{A} \% K)^{\mathrm{FS}} \times\left\{1 /\left|(\hat{A} \% K)^{\mathrm{F}}\right|\right\} \in \mathcal{A} \cap \mathcal{P}
$$

The renormalisation means that neither (i) the expansion, $\hat{Q}_{J}=\hat{Q} *(J \backslash K)^{\mathrm{C} \wedge}$, nor (ii) the normalisations of the query or sample histograms, $\hat{Q}$ and $\hat{A}$, need be calculated, so the modelled transformed conditional product can be simplified to

$$
(Q * T * M * A)^{\wedge} \%(V \backslash K) \in \mathcal{A} \cap \mathcal{P}
$$

if $(Q * T)^{\mathrm{F}} \cap(A * T)^{\mathrm{F}} \neq \emptyset$.
The modelled transformed conditional product may be expressed in terms of the actual converse transform,

$$
Q * T * T^{\odot A} \%(V \backslash K) \in \mathcal{A} \cap \mathcal{P}
$$

where the actual converse transform is defined

$$
\begin{equation*}
T^{\odot A}:=\left(\sum_{(R, C) \in T^{-1}}\{R\}^{\mathrm{U}} *(A * C)^{\wedge}, V\right) \tag{2}
\end{equation*}
$$

where the normalisation is defined $\hat{A}=A /(A \% \emptyset)$ so that normalised zero histograms are empty, $\left(V^{\mathrm{CZ}}\right)^{\wedge}=\emptyset$.

If the effective sample reduction to underlying variables is cartesian, $(A \% K)^{\mathrm{F}}=$
$K^{\mathrm{C}}$, then the actual converse transform is conditional in the derived variables,

$$
\begin{equation*}
\operatorname{his}\left(T^{\odot A}\right)=\operatorname{his}\left(T^{\odot A}\right) /\left(\operatorname{his}\left(T^{\odot A}\right) \% W\right) \tag{3}
\end{equation*}
$$

because actual converse transform histogram reduction to derived variables is cartesian, $\operatorname{his}\left(T^{\odot A}\right) \% W=W^{\mathrm{C}}$. Note that, strictly speaking, this is only the case where the transform is non-overlapping (see section 'Overlapping transforms ${ }^{\text {‘ }}$ below).

In the case where the sample histogram is natural, $A=A * T * T^{\dagger}$, the actual converse equals the natural converse, $T^{\odot A}=T^{\dagger}$, and the query application simplifies to $Q * T * T^{\dagger} \%(V \backslash K)$, which does not depend on the sample, $A$, only on the model, $T$.

The relative entropy of the modelled transformed conditional product, $(Q *$ $T * M * A)^{\wedge} \%(V \backslash K) \in \mathcal{A} \cap \mathcal{P}$, with respect to the transformed conditional product, $\hat{Q} * T_{A}^{\prime}=\hat{Q} *(A /(A \% K),(V \backslash K)) \in \mathcal{A} \cap \mathcal{P}$, in case when the reduction of $A$ is as effective as $Q, Q^{\mathrm{F}} \leq(A \% K)^{\mathrm{F}}$, is

$$
\text { entropyRelative }(Q * A /(A \% K) \%(V \backslash K), Q * T * M * A \%(V \backslash K))
$$

or

$$
\text { entropyRelative }\left(Q * A /(A \% K) \%(V \backslash K), Q * T * T^{\odot A} \%(V \backslash K)\right)
$$

There is no need to stuff ineffective states because the modelled transformed conditional product is as effective as the transformed conditional product, $\left(Q * T * T^{\odot A}\right)^{\mathrm{F}} \geq(Q * A)^{\mathrm{F}}$.

The relative entropy is zero when the modelled transformed conditional product equals the transformed conditional product. This is the case, for example, for the self partition transform (see below), $T=V^{\mathrm{CS}\{ \} \mathrm{T}}$, or the full functional transform (see below), $T=\left\{\{v\}^{\mathrm{CS}\{ \} \mathrm{T}}: v \in V\right\}^{\mathrm{T}}$.

In the case where the transform is unary (see below), $T=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$, the modelled transformed conditional product is $\hat{A} \%(V \backslash K)$. This equals the transformed conditional product only if the histogram, $A$, is partially independent (see below), $\hat{A}=(\hat{A} \% K) *(\hat{A} \%(V \backslash K))$.

Let the difference between the sample variables and the query variables, $V \backslash K$, be called the label variables. If the histogram, $A$, is such that it is
causal between the query variables and the label variables, $\operatorname{split}\left(K, A^{\mathrm{FS}}\right) \in$ $K^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}$, then all queries consisting of one of the effective states have unique label state, $\forall Q \in(A \% K)^{\mathrm{FS}}\left(\mid\{Q\}^{\mathrm{U}} * A /(A \% K) \%\right.$ ( $V \backslash$ $K) \mid=1$ ), and so have zero transformed conditional product entropy, $\forall Q \in$ $(A \% K)^{\mathrm{FS}}\left(\operatorname{entropy}\left(\{Q\}^{\mathrm{U}} * A /(A \% K) \%(V \backslash K)\right)=0\right)$. In this case the relative entropy is the cross entropy, $-\ln \left(\left(\{Q\}^{\mathrm{U}} * T * T^{\odot A} \%(V \backslash K)\right)(R)\right)$, where $\{R\}=\left(\{Q\}^{\mathrm{U}} * A /(A \% K) \%(V \backslash K)\right)^{\mathrm{S}}$.

If the normalised histogram, $\hat{A} \in \mathcal{A} \cap \mathcal{P}$, is treated as a probability function of a single-state query, the expected entropy of the transformed conditional product is zero in the case of causal histogram,

$$
\sum_{Q \in(A \% K)^{\mathrm{FS}}} \operatorname{size}\left(\{Q\}^{\mathrm{U}} * \hat{A}\right) \times \operatorname{entropy}\left(\{Q\}^{\mathrm{U}} * A /(A \% K) \%(V \backslash K)\right)=0
$$

This may be compared to the expected entropy of the modelled transformed conditional product, or label entropy,

$$
\begin{aligned}
& \sum_{(R,) \in T^{-1}}(\hat{A} * T)_{R} \times \operatorname{entropy}\left(\{R\}^{\mathrm{U}} * T^{\odot A} \%(V \backslash K)\right) \\
= & \sum_{(R, C) \in T^{-1}}(\hat{A} * T)_{R} \times \operatorname{entropy}(A * C \%(V \backslash K))
\end{aligned}
$$

Let non-zero test histogram $B \in \mathcal{A}_{U}$ have variables equal to the sample variables, $\operatorname{vars}(B)=\operatorname{vars}(A)=V$, and be such that it is causal between the query variables and the label variables, split $\left(K, B^{\mathrm{FS}}\right) \in K^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}$. The test histogram implies a query probability histogram, $\hat{B} \% K \in \mathcal{A} \cap \mathcal{P}$.

Let $R \in V: \leftrightarrow: V_{R}$ be a mapping from the sample variables, $V$, to a disjoint reframed set, $V_{R}$, such that the reframe is literal, $\forall(v, w) \in R\left(U_{w}=U_{v}\right)$. The test histogram may be extended by dotting with the reframe,

$$
B_{R}=\{(S \cup \operatorname{reframe}(R, S), c):(S, c) \in B\} \in \mathcal{A}_{U}
$$

The reframe variables are disjoint, $V_{R} \cap V=\emptyset$, and so the extended test histogram has double the variables, $\left|\operatorname{vars}\left(B_{R}\right)\right|=2|V|$. The extended test histogram is still causal, $\operatorname{split}\left(K, B_{R}^{\mathrm{FS}}\right) \in K^{\mathrm{CS}} \rightarrow\left(V \backslash K \cup V_{R}\right)^{\mathrm{CS}}$.

Given the one functional transform $T=(M, W) \in \mathcal{T}_{U, f, 1}$, such that the reframe variables are disjoint with the derived variables, $V_{R} \cap W=\emptyset$, the modelled transformed conditional product for the test histogram, $B$, is
$\left(\hat{B}_{R} \%\left(K \cup V_{R}\right) *(J \backslash K)^{\mathrm{C} \wedge} * M \%\left(W \cup V_{R}\right) * M * \hat{A}\right)^{\wedge} \%\left(V \backslash K \cup V_{R}\right) \in \mathcal{A} \cap \mathcal{P}$

$$
\text { if }(B \% K * T)^{\mathrm{F}} \cap(A * T)^{\mathrm{F}} \neq \emptyset .
$$

This may be simplified to

$$
\left(B_{R} \%\left(K \cup V_{R}\right) * M \%\left(W \cup V_{R}\right) * M * A\right)^{\wedge} \%\left(V \backslash K \cup V_{R}\right) \in \mathcal{A} \cap \mathcal{P}
$$

The modelled label variables, $V \backslash K$, may be compared to the reframed test label variables, $V_{R} \backslash K_{R}$, for each $K \cong K_{R}$, to judge the accuracy of the model in terms of the test.

Note that in the case where an expansion is necessary, $J \backslash K \neq \emptyset$, the additional label variables, $J \backslash K$, necessarily contradict the reframed label variables, $J_{R} \backslash K_{R}$, unless they are all mono-valent. That is,

$$
\begin{aligned}
& \operatorname{split}\left(J \backslash K,\left(\hat { B } _ { R } \% ( K \cup V _ { R } ) * ( J \backslash K ) ^ { \mathrm { C } \wedge } \% \left(J_{R} \backslash\right.\right.\right.\left.\left.\left.K_{R} \cup J \backslash K\right)\right)^{\mathrm{FS}}\right) \notin \\
&(J \backslash K)^{\mathrm{CS}} \leftrightarrow\left(J_{R} \backslash K_{R}\right)^{\mathrm{CS}}
\end{aligned}
$$

where $\exists v \in J \backslash K\left(\left|U_{v}\right|>1\right)$.
In the case where no expansion is necessary, $J \backslash K=\emptyset$, and there is a single effective test state, $\left|B^{\mathrm{F}}\right|=1$, the modelled transformed conditional product is

$$
((B \% K) * T * M * A)^{\wedge} \%(V \backslash K) *\left(B_{R}^{\mathrm{F}} \% V_{R}\right) \in \mathcal{A} \cap \mathcal{P}
$$

### 3.5.4 Transform entropy

Now consider derived entropy. Let $T$ be a one functional transform, $T \in$ $\mathcal{T}_{U, \mathrm{f}, 1}$, having underlying variables $V=\operatorname{und}(T)$. Let $A$ be a non-zero histogram, $A \in \mathcal{A}_{U}$, in variables $V=\operatorname{vars}(A)$ having size $z=\operatorname{size}(A)>0$. The underlying volume is $v=\left|V^{\mathrm{C}}\right|$.

The normalised derived histogram $\hat{A} * T \in \mathcal{P}$ is a probability function,

$$
\begin{aligned}
\hat{A} * T & =\{(R, q / z):(R, q) \in A * T\} \\
& =\left\{(R, \operatorname{size}(A * C) / z):(R, C) \in T^{-1}\right\}
\end{aligned}
$$

In the case where the histogram is integral, $A \in \mathcal{A}_{\dot{i}}$, then a history $H=$ history $(\operatorname{trim}(A))$ is implied such that $z=|H|=\operatorname{size}(A)>0$. In this case the normalised derived histogram is $\hat{A} * T=\left\{(R,|D| / z):(R, D) \in(H * T)^{-1}\right\}$.

The normalised cartesian derived $\hat{V}^{\mathrm{C}} * T \in \mathcal{P}$ is a probability function,

$$
\begin{aligned}
\hat{V}^{\mathrm{C}} * T & =\left\{(R, q / v):(R, q) \in V^{\mathrm{C}} * T\right\} \\
& =\left\{(R,|C| / v):(R, C) \in T^{-1}\right\}
\end{aligned}
$$

The derived entropy or component size entropy is the negative derived histogram expected normalised derived histogram count logarithm,

$$
\operatorname{entropy}(A * T):=-\operatorname{expected}(\hat{A} * T)(\ln (\hat{A} * T))
$$

where $\ln A=\{(S, \ln c):(S, c) \in A, c>0\}$. The derived entropy is positive and less than or equal to the logarithm of the size, $0 \leq$ entropy $(A * T) \leq \ln z$.

Complementary to the derived entropy is the size expected component entropy,

```
entropyComponent(A,T) :=
expected (\hat{A}*T)({(R, entropy (A*C)): (R,C)\in\mp@subsup{T}{}{-1}})
```

or

$$
\text { entropyComponent }(A, T):=\sum_{(R, C) \in T^{-1}}(\hat{A} * T)_{R} \times \operatorname{entropy}(A * C)
$$

The size expected component entropy can be expressed in terms of the actual converse,

$$
\text { entropyComponent }(A, T)=\sum_{(R, \cdot) \in T^{-1}}(\hat{A} * T)_{R} \times \operatorname{entropy}\left(\{R\}^{\mathrm{U}} * T^{\odot A}\right)
$$

The component cardinality entropy is the negative cartesian derived expected normalised cartesian derived count logarithm,

$$
\operatorname{entropy}\left(V^{\mathrm{C}} * T\right):=-\operatorname{expected}\left(\hat{V}^{\mathrm{C}} * T\right)\left(\ln \left(\hat{V}^{\mathrm{C}} * T\right)\right)
$$

The cartesian derived entropy is positive and less than or equal to the logarithm of the volume, $0 \leq \operatorname{entropy}\left(V^{\mathrm{C}} * T\right) \leq \ln v$.

The cartesian derived derived sum entropy or component size cardinality sum entropy is

$$
\begin{aligned}
& \text { entropy }(A * T)+\operatorname{entropy}\left(V^{\mathrm{C}} * T\right):= \\
& \quad(-\operatorname{expected}(\hat{A} * T)(\ln (\hat{A} * T)))+\left(-\operatorname{expected}\left(\hat{V}^{\mathrm{C}} * T\right)\left(\ln \left(\hat{V}^{\mathrm{C}} * T\right)\right)\right)
\end{aligned}
$$

The component size cardinality cross entropy is the negative derived histogram expected normalised cartesian derived count logarithm,

$$
\text { entropyCross }\left(A * T, V^{\mathrm{C}} * T\right):=-\operatorname{expected}(\hat{A} * T)\left(\ln \left(\hat{V}^{\mathrm{C}} * T\right)\right)
$$

By Gibbs' inequality the component size cardinality cross entropy is greater than or equal to the derived entropy, entropy $\operatorname{Cross}\left(A * T, V^{\mathrm{C}} * T\right) \geq \operatorname{entropy}(A *$ $T)$.

The component cardinality size cross entropy is the negative cartesian derived expected normalised derived histogram count logarithm,

$$
\operatorname{entropyCross}\left(V^{\mathrm{C}} * T, A * T\right):=-\operatorname{expected}\left(\hat{V}^{\mathrm{C}} * T\right)(\ln (\hat{A} * T))
$$

The component cardinality size cross entropy is greater than or equal to the cartesian derived entropy, entropy $\operatorname{Cross}\left(V^{\mathrm{C}} * T, A * T\right) \geq \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)$.

The component size cardinality sum cross entropy is,

$$
\begin{aligned}
\operatorname{entropy}(A * T & \left.+V^{\mathrm{C}} * T\right):= \\
& \quad-\operatorname{expected}\left(\left(A * T+V^{\mathrm{C}} * T\right)^{\wedge}\right)\left(\ln \left(\left(A * T+V^{\mathrm{C}} * T\right)^{\wedge}\right)\right)
\end{aligned}
$$

The component size cardinality sum cross entropy is positive and less than or equal to the logarithm of the sum of the size and volume, $0 \leq \operatorname{entropy}(A *$ $\left.T+V^{\mathrm{C}} * T\right) \leq \ln (z+v)$.

In all cases the cross entropy is maximised when high size components are low cardinality components, $(\hat{A} * T)_{R} \gg\left(\hat{V}^{\mathrm{C}} * T\right)_{R}$ or $\operatorname{size}(A * C) / z \gg|C| / v$, and vice-versa, $(\hat{A} * T)_{R} \ll\left(\hat{V}^{\mathrm{C}} * T\right)_{R}$ or $\operatorname{size}(A * C) / z \ll|C| / v$.

The cross entropy is minimised when the normalised derived histogram equals the normalised cartesian derived, $\hat{A} * T=\hat{V}^{\mathrm{C}} * T$ or $\forall(R, C) \in T^{-1}$ (size $(A *$ $C) / z=|C| / v)$. In this case the cross entropy equals the corresponding component entropy.

The component size cardinality relative entropy is the component size cardinality cross entropy minus the component size entropy,

$$
\begin{aligned}
& \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right) \\
& \\
& :=\operatorname{expected}(\hat{A} * T)\left(\ln \frac{\hat{A} * T}{\hat{V}^{\mathrm{C}} * T}\right) \\
& \\
& =\operatorname{entropyCross}\left(A * T, V^{\mathrm{C}} * T\right)-\operatorname{entropy}(A * T)
\end{aligned}
$$

The component size cardinality relative entropy is positive, entropyRelative $(A *$ $\left.T, V^{\mathrm{C}} * T\right) \geq 0$.

The multinomial distribution, $Q_{\mathrm{m}, U}$, is described in section 'Multinomial distributions', below. The size scaled component size cardinality relative entropy approximates to the negative logarithm of the derived multinomial probability with respect to the cartesian derived,

$$
z \times \operatorname{entropyRelative}\left(A * T, V^{\mathrm{C}} * T\right) \approx-\ln \hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}} * T, z\right)(A * T)
$$

The component cardinality size relative entropy is the component cardinality size cross entropy minus the component cardinality entropy,

$$
\begin{aligned}
\operatorname{entropyRelative} & \left(V^{\mathrm{C}} * T, A * T\right) \\
& :=\operatorname{expected}\left(\hat{V}^{\mathrm{C}} * T\right)\left(\ln \frac{\hat{V}^{\mathrm{C}} * T}{\hat{A} * T}\right) \\
& =\operatorname{entropyCross}\left(V^{\mathrm{C}} * T, A * T\right)-\operatorname{entropy}\left(V^{\mathrm{C}} * T\right)
\end{aligned}
$$

The component cardinality size relative entropy is positive, entropyRelative $\left(V^{\mathrm{C}} *\right.$ $T, A * T) \geq 0$.

The volume scaled component cardinality size relative entropy approximates to the negative logarithm of the cartesian derived multinomial probability with respect to the derived,

$$
v \times \text { entropyRelative }\left(V^{\mathrm{C}} * T, A * T\right) \approx-\ln \hat{Q}_{\mathrm{m}, U}(A * T, v)\left(V^{\mathrm{C}} * T\right)
$$

where the derived is as effective as the cartesian derived, $(A * T)^{\mathrm{F}} \geq\left(V^{\mathrm{C}} *\right.$ $T)^{\mathrm{F}} \Longrightarrow\left|(A * T)^{\mathrm{F}}\right|=\left|T^{-1}\right|$.

The size-volume scaled component size cardinality sum relative entropy is the size-volume scaled component size cardinality sum cross entropy minus the size-volume scaled component size cardinality sum entropy,

$$
\begin{aligned}
(z+v) \times \operatorname{entropy}(A * T+ & \left.V^{\mathrm{C}} * T\right) \\
& -z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)
\end{aligned}
$$

The size-volume scaled component size cardinality sum relative entropy is positive, $(z+v) \times \operatorname{entropy}\left(A * T+V^{\mathrm{C}} * T\right)-z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} *\right.$ $T) \geq 0$. The size-volume scaled component size cardinality sum relative entropy is less than the size-volume scaled logarithm of the derived volume, $(z+v) \times \operatorname{entropy}\left(A * T+V^{\mathrm{C}} * T\right)-z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)<$ $(z+v) \ln w$.

In all cases the relative entropy is maximised when (a) the cross entropy is maximised and (b) the component entropy is minimised. The relative entropy is always positive by Gibbs' inequality, see Appendix 'Entropy and Gibbs' inequality', below. So the cross entropy is greater than or equal to the component entropy.

### 3.6 Functional definition sets

A functional definition set $F \in \mathcal{F}$ is a set of unit functional transforms subject to the constraint that derived variables may appear in only one transform. That is, the sets of derived variables are disjoint. Then $\mathcal{F} \subset \mathrm{P}\left(\mathcal{T}_{\mathrm{f}, \mathrm{U}}\right)$ where $\mathcal{T}_{\mathrm{f}, \mathrm{U}}=\mathcal{T}_{\mathrm{f}} \cap \mathcal{T}_{\mathrm{U}}$, and

$$
\forall F \in \mathcal{F} \forall(A, W),(B, X) \in F((A, W) \neq(B, X) \Longrightarrow W \cap X=\emptyset)
$$

Defining accessor functions, the domain of a functional definition set has a synonym histograms $\in \mathcal{F} \rightarrow \mathrm{P}(\mathcal{A})$

$$
\operatorname{histograms}(F):=\operatorname{dom}(F)=\{A:(A, W) \in F\}
$$

Define vars $\in \mathcal{F} \rightarrow \mathrm{P}(\mathcal{V})$

$$
\operatorname{vars}(F):=\bigcup\{\operatorname{vars}(A): A \in \operatorname{histograms}(F)\}
$$

Define accessors of a functional definition set such that its derived and underlying variables are disjoint. That is, derived $\in \mathcal{F} \rightarrow \mathrm{P}(\mathcal{V})$,

$$
\operatorname{derived}(F):=\bigcup_{T \in F} \operatorname{derived}(T) \backslash \bigcup_{T \in F} \operatorname{underlying}(T)
$$

And underlying $\in \mathcal{F} \rightarrow \mathrm{P}(\mathcal{V})$,

$$
\operatorname{underlying}(F):=\bigcup_{T \in F} \operatorname{underlying}(T) \backslash \bigcup_{T \in F} \operatorname{derived}(T)
$$

The underlying variables of a fud are sometimes called the substrate.
A functional definition set is a histogram expression which can be simplified to an equivalent transform, transform $\in \mathcal{F} \rightarrow \mathcal{T}_{\mathrm{f}, \mathrm{U}}$

$$
\operatorname{transform}(F):=\left(\prod \operatorname{histograms}(F) \%(\operatorname{der}(F) \cup \operatorname{und}(F)), \operatorname{der}(F)\right)
$$

where der $=$ derived and und $=$ underlying. Also, define $F^{\mathrm{T}}=\operatorname{transform}(F)$. The resultant equivalent transform is also a unit functional transform with the same derived and underlying variables, $\operatorname{der}\left(F^{\mathrm{T}}\right)=\operatorname{der}(F)$ and $\operatorname{und}\left(F^{\mathrm{T}}\right)=$ $\operatorname{und}(F)$.

In order to apply a functional definition set $F$ to a histogram $A$ apply the equivalent transform, $A * F^{\mathrm{T}}$. However, the evaluation of this histogram expression requires the computation of an intermediate histogram $\prod$ histograms $(F)$, with cardinality of nearly $\left|\operatorname{vars}(F)^{\mathrm{C}}\right|$, before the multiplication with $A$ and subsequent reduction to the derived variables, $\operatorname{der}(F)$, takes place. (See 'Computation of functional definition sets', below.) This cardinality may be much greater than that of the given histogram $|A|$. An alternative method of application, for example, is to navigate through the functional definition set reducing any non-derived variables as soon as possible. Define apply $\in \mathcal{F} \times \mathcal{A} \rightarrow \mathcal{A}$ as $\operatorname{apply}(F, A):=\operatorname{apply}(\operatorname{und}(F), \operatorname{der}(F), \operatorname{his}(F), A)$ where apply $\in \mathrm{P}(\mathcal{V}) \times \mathrm{P}(\mathcal{V}) \times \mathrm{P}(\mathcal{A}) \times \mathcal{A} \rightarrow \mathcal{A}$ is defined recursively as

$$
\begin{aligned}
& \operatorname{apply}(V, W, M, A):=\operatorname{if}(X \neq \emptyset, \operatorname{apply}(V, W, N, C), A \% W): \\
& \quad X=\{(|B|, B, Q)): D \in M, \operatorname{vars}(D) \cap(\operatorname{vars}(A) \cup V) \neq \emptyset \\
& \quad Q=M \backslash\{D\}, B=(A * D) \%(W \cup \bigcup\{\operatorname{vars}(E): E \in Q\})\}, \\
& \{(\cdot, C, N)\}=\operatorname{mind}\left(\operatorname{order}\left(D_{\mathbf{N} \times \mathcal{A} \times \mathcal{X}}, X\right)\right)
\end{aligned}
$$

The enumeration $D_{\mathbf{N} \times \mathcal{A} \times \mathcal{X}}$ orders by size, histogram and then arbitrarily, $D_{\mathbf{N} \times \mathcal{A} \times \mathcal{X}} \in \operatorname{enums}(\mathbf{N} \times \mathcal{A} \times \mathcal{X})$. The apply function assumes that the variables $V$ and $W$ are connected transitively via the variables of the histograms of the fud. Only those histograms that are in the closure of the union of variables $V$ and $\operatorname{vars}(A)$ are applied. In the case where there is no path from $V$ to $W$, the function returns $A \% W$. All of the histograms of the fud, $F$, are in the closure of the underlying, und $(F)$, so in the case where $V=\operatorname{und}(F)$ the application of the fud equals the application of the transform, $\operatorname{apply}(F, A)=A * F^{\mathrm{T}}$. Also there are other implementations depending on the computational constraints.

Following from the constraint on the derived variables define definitions $\in$ $\mathcal{F} \rightarrow\left(\mathcal{V} \rightarrow \mathcal{T}_{\mathrm{f}, \mathrm{U}}\right)$ as

$$
\text { definitions }(F):=\{(w,(A, W)):(A, W) \in F, w \in W\}
$$

The subset of the functional definition set which recursively contains all the underlying transforms for a given set of variables is defined depends $\in$ $\mathcal{F} \times \mathrm{P}(\mathcal{V}) \rightarrow \mathcal{F}$ as $\operatorname{depends}(F, W):=\operatorname{depends}(F, W, \emptyset)$ where depends $\in$ $\mathcal{F} \times \mathrm{P}(\mathcal{V}) \times \mathrm{P}(\mathcal{V}) \rightarrow \mathcal{F}$ is defined

$$
\begin{aligned}
& \operatorname{depends}(F, W, X):= \\
& \qquad \begin{array}{l}
\bigcup\{T\} \cup \operatorname{depends}(F, \operatorname{und}(T), X \cup\{w\}): \\
\qquad w \in W \cap \operatorname{dom}(\operatorname{def}(F)) \backslash X, T=\operatorname{def}(F)(w)\}
\end{array}
\end{aligned}
$$

where def $=$ definitions.

Fuds can contain both null transforms, $\operatorname{der}(T)=\emptyset$, and disjoint transforms, $\operatorname{und}(T)=\emptyset$, if the transforms are functional. Null transforms are always functional because there is only one derived state, $\emptyset$. Disjoint transforms are only functional if the derived states forms a singleton, $|\operatorname{std}(T)|=1$. This is the case, for example, when the derived variables are all mono-valent in the system $U,\left\{\left|U_{w}\right|: w \in \operatorname{der}(T)\right\}=\{1\}$.

A fud circularity in a functional definition set can occur where a defined variable $w$ appears in its own depends fud $w \in \operatorname{vars}(\operatorname{depends}(F,\{w\}) \backslash$ $\{$ definitions $(F)(w)\})$. Define circular $\in \mathcal{F} \rightarrow \mathbf{B}$ as

```
circular \((F)\) :=
    \(\exists w \in \operatorname{dom}(\operatorname{def}(F))(w \in \operatorname{vars}(\operatorname{depends}(F,\{w\}) \backslash\{\operatorname{def}(F)(w)\}))\)
```

A fud circularity cannot occur in the definition transform definitions $(F)(w)$ because the derived variables and underlying variables are disjoint. The fud circularity must be in a layer below.

Contradictions created by fud circularities can prevent the equivalent transform $F^{\mathrm{T}}$ from being one functional, $F^{\mathrm{T}} \notin \mathcal{T}_{U, \mathrm{f}, 1}$, even if the fud contains only one functional transforms, $F \in \mathrm{P}\left(\mathcal{T}_{U, \mathrm{f}, 1}\right)$.

The one functional definition set subset $\mathcal{F}_{U, 1} \subset \mathcal{F}$ in system $U$ is defined such that all transforms are one functional and the fud is not circular,

$$
\forall F \in \mathcal{F}_{U, 1}\left(F \in \mathrm{P}\left(\mathcal{T}_{U, \mathrm{f}, 1}\right) \wedge \neg \operatorname{circular}(F)\right)
$$

Thus the equivalent transform of a one functional definition set is a one functional transform, $\forall F \in \mathcal{F}_{U, 1}\left(F^{\mathrm{T}} \in \mathcal{T}_{U, f, 1}\right)$.

A one functional definition set $F \in \mathcal{F}_{U, 1}$ implies a one functional definition set $G \in \mathcal{F}_{U, 1}$ such that all the transforms in $G$ have a single derived variable, $\forall T \in G(|\operatorname{der}(T)|=1)$, and such that the equivalent transforms are equal, $G^{\mathrm{T}}=F^{\mathrm{T}}$. Define mono $\in \mathcal{F}_{U, 1} \rightarrow \mathcal{F}_{U, 1}$

$$
\operatorname{mono}(F):=\bigcup\{\{(X \%(\operatorname{vars}(X) \backslash W \cup\{w\}),\{w\}): w \in W\}:(X, W) \in F\}
$$

A non-circular functional definition set can be viewed as a tree of variables, $\operatorname{trees}(\mathcal{V})$. To construct the variables tree from the functional definition set,
define treeVariable $\in \mathcal{F} \rightarrow \operatorname{trees}(\mathcal{V})$ as treeVariable $(F):=\{(v, \operatorname{treev}(F, v, \emptyset)):$ $v \in \operatorname{der}(F)\}$. Define treev $\in \mathcal{F} \times \mathcal{V} \times \mathrm{P}(\mathcal{V}) \rightarrow \operatorname{trees}(\mathcal{V})$ as

$$
\begin{aligned}
& \operatorname{treev}(F, v, X):= \\
& \quad \operatorname{if}(v \in \operatorname{dom}(\operatorname{def}(F)) \\
& \quad\{(w, \operatorname{treev}(F, w, X \cup\{w\})): w \in \operatorname{und}(\operatorname{def}(F)(v)) \backslash X\}, \emptyset)
\end{aligned}
$$

Thus vars $(F)=$ elements $(\operatorname{treeVariable}(F))$.

Another tree is a tree of transforms. Define treeTransform $\in \mathcal{F} \rightarrow \operatorname{trees}\left(\mathcal{T}_{\mathrm{f}, \mathrm{U}}\right)$ as treeTransform $(F):=\{(T, \operatorname{treet}(F, T, \operatorname{und}(F))): v \in \operatorname{der}(F), T=\operatorname{def}(F)(v)\}$.
Define treet $\in \mathcal{F} \times \mathcal{T}_{\mathrm{f}, \mathrm{U}} \times \mathrm{P}(\mathcal{V}) \rightarrow \operatorname{trees}\left(\mathcal{T}_{\mathrm{f}, \mathrm{U}}\right)$ as

$$
\begin{aligned}
& \operatorname{treet}(F, T, X):= \\
& \quad\{(R, \operatorname{treet}(F, R, X \cup\{w\})): w \in \operatorname{und}(T) \backslash X, R=\operatorname{def}(F)(w)\}
\end{aligned}
$$

The depends-subset of a non-circular functional definition set could be defined

```
depends \((F, W):=\)
    \(\bigcup \operatorname{elements}(\operatorname{nodes}(\operatorname{tree} \operatorname{Transform}(F))(\operatorname{def}(F)(w))): w \in W \cap \operatorname{dom}(\operatorname{def}(F))\}\)
```

The layer in a non-circular functional definition set is the length of the longest path to the leaves from any of a given set of variables. Define layer $\in$ $\mathcal{F} \times \mathrm{P}(\mathcal{V}) \rightarrow \mathbf{N}$ as layer $(F, W):=\operatorname{layer}(F, W, \operatorname{und}(F))$, and layer $\in \mathcal{F} \times$ $\mathrm{P}(\mathcal{V}) \times \mathrm{P}(\mathcal{V}) \rightarrow \mathbf{N}$ as

$$
\begin{aligned}
& \operatorname{layer}(F, W, X):= \\
& \quad \operatorname{maxr}(\{(w, \operatorname{layer}(F, \operatorname{und}(T), X \cup\{w\})+1): \\
& \quad w \in W \cap \operatorname{dom}(\operatorname{def}(F)) \backslash X, T=\operatorname{def}(F)(w)\} \cup\{(\emptyset, 0)\})
\end{aligned}
$$

The layer can also be defined using generic tree semantics, $\operatorname{layer}(F, W):=$ $\operatorname{maxr}(\{(w,|L|): w \in W, L \in \operatorname{paths}(\operatorname{tree} \operatorname{Transform}(\operatorname{depends}(F,\{w\})))\})$.

The transforms of a non-circular fud $F \in \mathcal{F}$ can be arranged in a list of layer fuds $L \in \mathcal{L}(\mathrm{P}(F))$ such that each transform is in the highest layer of its derived variables, $L=\operatorname{inverse}(\{(T, \operatorname{layer}(F, \operatorname{der}(T))): T \in F\})$. The set of layer fuds partitions the fud, $\operatorname{set}(L) \in \mathrm{B}(F)$. The transforms in a layer fud depend only on transforms in lower layers, $\forall(i, G) \in L \forall T \in$ $G(\operatorname{depends}(F, \operatorname{der}(T)) \subseteq \bigcup \operatorname{set}(\operatorname{take}(i, L)))$.

A linear fud is a non-circular fud such that the underlying variables of the transforms in each layer fud are the derived variables of the layer fud immediately below, $\forall i \in\{2 \ldots|L|\}\left(\operatorname{und}\left(L_{i}\right) \subseteq \operatorname{der}\left(L_{i-1}\right)\right)$. Each of the layer fuds, $\operatorname{set}(L) \subset \mathrm{P}(F)$, can be combined into a single transform. Thus a linear fud may be represented as a list of transforms, $\left\{\left(i, G^{\mathrm{T}}\right):(i, G) \in L\right\} \in \mathcal{L}\left(\mathcal{T}_{\mathrm{f}, \mathrm{U}}\right)$.

The top transform, if it exists, is the transform in a fud that has the same derived variables as the fud, top $\in \mathcal{F} \rightarrow \mathcal{T}_{\mathrm{f}, \mathrm{U}}$

$$
\text { top }:=T
$$

where $\exists T \in F(\operatorname{der}(T)=\operatorname{der}(F))$.
A functional definition set is defined as non-overlapping if the underlying variables of the depends fuds of the derived variables are disjoint. Define overlap $\in \mathcal{F} \rightarrow \mathbf{B}$

$$
\begin{aligned}
& \operatorname{overlap}(F):= \\
& \qquad \exists v, w \in \operatorname{der}(F)(v \neq w \wedge(\operatorname{vars}(\operatorname{dep}(F,\{v\})) \cap \operatorname{vars}(\operatorname{dep}(F,\{w\})) \neq \emptyset))
\end{aligned}
$$

where dep $=$ depends. The empty fud is non-overlapping, $\neg \operatorname{overlap}(\emptyset)$. It can be determined if a fud is overlapping between any two layers by taking the subset of the transforms of the fud between the layers. If the fud is overlapping in a layer, then it must be overlapping in all layers below that down to the substrate. The function vars in the definition of overlap above could equally be replaced by und.

A non-overlapping fud $F$ can be viewed as the union of disjoint fuds, or a partition of depends fud components. Let $Q=\{\operatorname{depends}(F,\{w\}): w \in \operatorname{der}(F)\}$ then $F=\bigcup Q$ and overlap $(F)=(Q \notin \mathrm{~B}(F))$.

### 3.7 Partitions and partition variables

A partition is a partition of the cartesian set of states for some set of variables. The partition consists of component sets of states. The components are disjoint, but union together to equal the original cartesian set.

Define $\mathcal{R} \subset \mathrm{P}(\mathrm{P}(\mathcal{S}) \backslash\{\emptyset\})$ as the set of all partitions. Define vars $\in \mathcal{R} \rightarrow \mathrm{P}(\mathcal{V})$

$$
\operatorname{vars}(P):=\bigcup\{\operatorname{vars}(S): S \in \bigcup P\}
$$

The partitions are constrained

$$
\forall P \in \mathcal{R} \forall C \in P \forall S \in C(\operatorname{vars}(S)=\operatorname{vars}(P))
$$

and

$$
\forall P \in \mathcal{R} \forall C, D \in P(C \neq D \Longrightarrow C \cap D=\emptyset)
$$

That is, $P \in \mathrm{~B}(\bigcup P)$, where B is the partition function (see appendix). The empty partition, $\emptyset \in \mathcal{R}$, has no variables, $\operatorname{vars}(\emptyset)=\emptyset$. The scalar partition, which is the unary partition of the singleton set of empty state, $\{\{\emptyset\}\} \in \mathcal{R}$, has no variables, $\operatorname{vars}(\{\{\emptyset\}\})=\emptyset$.

A subset of the parents of a partition are those for which the cardinality of the partition is decremented. That is, partition $Q \in \mathcal{R}$ and parent $P \in$ parents $(Q)$ such that $|P|=|Q|-1$. Define decrements $\in \mathcal{R} \rightarrow \mathrm{P}(\mathcal{R})$ as

$$
\operatorname{decrements}(Q):=\{P: P \in \operatorname{parents}(Q),|P|=|Q|-1\}
$$

which can be constructed explicitly

$$
\operatorname{decrements}(Q)=\{Q \backslash\{C, D\} \cup\{C \cup D\}: C, D \in Q, C \neq D\}
$$

Thus $\forall Q \in \mathcal{R}$ (decrements $(Q) \subseteq \operatorname{parents}(Q)$ ). The cardinality of the decremented parent partition set is $|\operatorname{decrements}(Q)|=|Q|(|Q|-1) / 2$. The search tree initialised from the self partition finds all partitions in some variables $V$ in a system $U$, elements(search $\operatorname{Treer}\left(\mathcal{R}\right.$, decrements, $\left.\left.\left\{V^{\mathrm{CS}\{ \}}\right\}\right)\right)=\mathrm{B}\left(V^{\mathrm{CS}}\right)$. See appendix 'Search and optimisation' for a definition of the tree search.

In a particular system $U$ let $\mathcal{R}_{U} \subset \mathcal{R} \cap \mathrm{P}\left(\mathrm{P}\left(\mathcal{S}_{U}\right) \backslash\{\emptyset\}\right)$. $\mathcal{R}_{U}$ is additionally constrained

$$
\forall P \in \mathcal{R}_{U}(\bigcup P=\operatorname{cartesian}(U)(\operatorname{vars}(P)))
$$

The set of all partitions in system $U$ can be constructed explicitly

$$
\mathcal{R}_{U}=\bigcup\{\mathrm{B}(\operatorname{cartesian}(U)(W)): W \in \mathrm{P}(\operatorname{vars}(U))\}
$$

The empty partition is not in $\mathcal{R}_{U}, \emptyset \notin \mathcal{R}_{U}$. The scalar partition is in $\mathcal{R}_{U}$, $\left\{\emptyset^{C S}\right\}=\{\{\emptyset\}\} \in \mathcal{R}_{U}$.

A partition can be expanded to a superset of its variables by crossing with the cartesian states of the disjoint set of variables. Define $\operatorname{expand}(U) \in$ $\mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{R}_{U} \rightarrow \mathcal{R}_{U}$ as

$$
\operatorname{expand}(U)(V, P):=\left\{\left\{S \cup R: S \in C, R \in(V \backslash W)^{\mathrm{CS}}\right\}: C \in P\right\}
$$

where $W=\operatorname{vars}(P)$. Define shorthand $P^{V}:=\operatorname{expand}(U)(V, P)$. The variables of the expanded partition are the union $\operatorname{vars}\left(P^{V}\right)=\operatorname{vars}(P) \cup V$. The cardinality of the partition is unchanged by the expansion, $\left|P^{V}\right|=|P|$. The expansion of a scalar partition is the unary partition, $\left\{\emptyset^{\mathrm{CS}}\right\}^{V}=\left\{V^{\mathrm{CS}}\right\}$.

The converse operation is to contract a partition to the minimum subset of variables by removing any cartesian variables. Define contract $(U) \in \mathcal{R}_{U} \rightarrow$ $\mathcal{R}_{U}$ as

```
contract \((U)(P):=Q\) :
    \(\{Q\}=\operatorname{mind}\left(\left\{(R,|K|): K \subseteq V, R=\{\{S \% K: S \in C\}: C \in P\}, R^{V}=P\right\}\right)\)
```

where $V=\operatorname{vars}(P)$. Define shorthand $P^{\%}:=\operatorname{contract}(U)(P)$. The variables of the contracted partition are a subset $\operatorname{vars}\left(P^{\%}\right) \subseteq \operatorname{vars}(P)$. The cardinality of the partition is unchanged by the contraction, $\left|P^{\%}\right|=|P|$. There is always exactly one possible contraction, $\mid \min (\{(R,|K|): K \subseteq V, R=\{\{S \% K$ : $\left.\left.S \in C\}: C \in P\}, R^{V}=P\right\}\right) \mid=1$. A unary partition, $P=\operatorname{unary}\left(V^{\mathrm{CS}}\right)=$ $\left\{V^{\mathrm{CS}}\right\} \in \mathrm{R}_{U}$ which is such that $|P|=1$, contracts to the scalar partition, $P^{\%}=\left\{V^{\mathrm{CS}}\right\}^{\%}=\left\{\emptyset^{\mathrm{CS}}\right\}=\{\{\emptyset\}\}$.

Partition variables in system $U \in \mathcal{U}$ are defined such that the partition variable $P \in \operatorname{vars}(U)$ is itself a partition, $P \in \mathcal{R}_{U}$, and its values, $U_{P}$, are the components of this partition, $U_{P}=P$. That is, $\left(P, U_{P}\right)=(P, P) \in U$. If system $U^{\prime}$ contains all of its partition variables, $\forall P \in \mathcal{R}_{U^{\prime}}\left((P, P) \in U^{\prime}\right)$, then the system, $U^{\prime}$, must be infinite by recursive definition, $\left|U^{\prime}\right|=\infty$. Let function implied $\in \mathcal{U} \rightarrow \mathcal{U}$ be defined as

$$
\operatorname{implied}(U):=U \cup \operatorname{implied}\left(U \cup\left\{(P, P): P \in \mathcal{R}_{U}\right\}\right)
$$

The implied infinite system is $U^{\prime}=\operatorname{implied}(U)$.

Partitions can be thought of as partitions of the domains of histograms. Thus one functional transforms can be constructed having a single derived variable which is the partition variable of the partition of the given underlying variables in system $U$. Define transform $\in \bigcup\left\{\mathcal{R}_{U} \rightarrow \mathcal{T}_{U, \mathrm{f}, 1}: U \in \mathcal{U}\right\}$

$$
\operatorname{transform}(P):=(\{(S \cup\{(P, C)\}, 1): C \in P, S \in C\},\{P\})
$$

Define shorthand $P^{\mathrm{T}}:=$ transform $(P)$. These one functional transforms are called partition transforms.

The converse function partition $\in \bigcup\left\{\mathcal{T}_{U, \mathrm{f}, 1} \rightarrow \mathcal{R}_{U}: U \in \mathcal{U}\right\}$ recovers the partition from a given functional transform

$$
\operatorname{partition}(T):=\{\operatorname{states}(A): A \in \operatorname{ran}(\operatorname{inverse}(T))\}
$$

Define shorthand $T^{\mathrm{P}}:=\operatorname{partition}(T)$. The converse relationship obeys $\forall P \in$ $\mathcal{R}_{U}\left(P^{\mathrm{TP}}=P\right)$ in system $U$. Thus $P$ and $P^{\mathrm{T}}$ are isomorphic, $P \cong P^{\mathrm{T}}$.

A system partition $P \in \mathcal{R}_{U}$, which is non-empty, $P \neq \emptyset$, may be expanded using its partition transform, $P^{\mathrm{T}},\left(\operatorname{his}\left(P^{\mathrm{T}}\right) * V^{\mathrm{C}},\{P\}\right)^{\mathrm{P}}=P^{V}$, where his $=$ histogram. The application of an expanded partition transform $P^{V T}$ to a histogram $A$, where $V=\operatorname{vars}(A)$, forms a bijective map to the application of the partition transform $P^{\mathrm{T}}$, where $K=\operatorname{vars}(P)$ and $K \subset V$, $\exists Q \in A * P^{V \mathrm{~T}}: \leftrightarrow: A * P^{\mathrm{T}} \forall((S, c),(T, d)) \in Q(c=d)$. This is because there is a bijective map between the components of $P^{V}$ and $P$, and so $A * P^{V \mathrm{~T}}$ and $A * P^{\mathrm{T}}$ are non-literal reframes, reframe $\left(X, A * P^{V \mathrm{~T}}\right)=A * P^{\mathrm{T}}$ where $X=\left\{\left(P^{V},\left(P,\left\{\left(\left\{S \cup R: S \in C, R \in(V \backslash W)^{\mathrm{CS}}\right\}, C\right): C \in P\right\}\right)\right)\right\}$.

Define a function that returns the set of partition transforms for a set of partitions, creating a partition functional definition set, transforms $\in \bigcup\left\{\mathrm{P}\left(\mathcal{R}_{U}\right) \rightarrow\right.$ $\left.\mathcal{F}_{U, \mathrm{P}}: U \in \mathcal{U}\right\}$

$$
\operatorname{transforms}(Q):=\operatorname{map}(\operatorname{transform}, Q)
$$

The partition transforms form a subset of one functional transforms $\mathcal{T}_{U, \mathrm{P}} \subset$ $\mathcal{T}_{U, f, 1}$ which is defined

$$
\mathcal{T}_{U, \mathrm{P}}:=\left\{T: T \in \mathcal{T}_{U, \mathrm{f}, 1}, T^{\mathrm{PT}}=T\right\}=\left\{P^{\mathrm{T}}: P \in \mathcal{R}_{U}\right\}
$$

Partition transforms are such that $\forall T \in \mathcal{T}_{U, \mathrm{P}}\left(\operatorname{der}(T)=\left\{T^{\mathrm{P}}\right\}\right)$.
Similarly the partition functional definition sets is the subset of one functional definition sets which contain only partition transforms $\mathcal{F}_{U, \mathrm{P}} \subset \mathcal{F}_{U, 1}$, defined as

$$
\mathcal{F}_{U, \mathrm{P}}=\mathrm{P}\left(\mathcal{T}_{U, \mathrm{P}}\right)
$$

The definition constraint on derived variables of $f u d s$ is implied by definition because $\{(P,(X,\{P\})):(X,\{P\}) \in F\} \in \mathcal{V}_{U} \rightarrow \mathcal{T}_{U, \mathrm{P}}$ where $F \in \mathcal{F}_{U, \mathrm{P}}$, just as definitions $(F) \in(\operatorname{vars}(F) \backslash \operatorname{und}(F)) \rightarrow F$. Similarly there are no fud circularities in $F \in \mathcal{F}_{U, \mathrm{P}}$ by definition rather than by constraint. If there exists a top transform of a partition fud $F \in \mathcal{F}_{U, \mathrm{P}}, \operatorname{depends}(F, \operatorname{der}(\operatorname{top}(F)))=F$,
then there is only one derived variable, $|\operatorname{der}(\operatorname{top}(F))|=|\operatorname{der}(F)|=1$. All partition fuds are mono-variate in the derived variables of the transforms, $F=\operatorname{mono}(F)$.

The multi-partition transforms form a subset of one functional transforms $\mathcal{T}_{U, \mathrm{P} *} \subset \mathcal{T}_{U, \mathrm{f}, 1}$ which is defined as the set of transforms of single-layer partition fuds

$$
\begin{aligned}
\mathcal{T}_{U, \mathrm{P}^{*}} & :=\left\{F^{\mathrm{T}}: F \in \mathcal{F}_{U, \mathrm{P}}, \operatorname{layer}(F, \operatorname{der}(F))=1\right\} \\
& =\left\{F^{\mathrm{T}}: F \in \mathcal{F}_{U, \mathrm{P}},(\forall T \in F(\operatorname{und}(T) \subseteq \operatorname{und}(F))\}\right. \\
& =\left\{\left\{P^{\mathrm{T}}: P \in Q\right\}^{\mathrm{T}}: Q \subset \mathcal{R}_{U},\left(\forall P_{1}, P_{2} \in Q\left(P_{2} \notin \operatorname{vars}\left(P_{1}\right)\right)\right\}\right.
\end{aligned}
$$

The partition transforms is a subset of the multi-partition transforms, $\mathcal{T}_{U, \mathrm{P}} \subset$ $\mathcal{T}_{U, \mathrm{P}^{*}}$.

The multi-partition functional definition sets is the subset of one functional definition sets which contain only multi-partition transforms $\mathcal{F}_{U, \mathrm{P}^{*}} \subset \mathcal{F}_{U, 1}$, defined as

$$
\mathcal{F}_{U, \mathrm{P}^{*}}=\mathrm{P}\left(\mathcal{T}_{U, \mathrm{P}^{*}}\right)
$$

The partition fuds is a subset of the multi-partition fuds, $\mathcal{F}_{U, \mathrm{P}} \subset \mathcal{F}_{U, \mathrm{P} *}$.
Multi-partition transforms may be expanded to expanded multi-partition transforms. Define expand $(U, V) \in \mathcal{T}_{U, \mathrm{P}^{*}} \rightarrow \mathcal{T}_{U, \mathrm{P}^{*}}$ as $\operatorname{expand}(U, V)(T):=\left\{P^{V \mathrm{~T}}\right.$ : $P \in \operatorname{der}(T)\}^{\mathrm{T}}$. Define $T^{V}:=\operatorname{expand}(U, V)(T)$. A multi-partition fud $F \in \mathcal{F}_{U, \mathrm{P}^{*}}$ is said to be expanded if all of its multi-partition transforms are expanded, $\forall T \in F\left(T=T^{V}\right)$.

Multi-partition transforms may be contracted to contracted multi-partition transforms. Define contract $(U) \in \mathcal{T}_{U, \mathrm{P}^{*}} \rightarrow \mathcal{T}_{U, \mathrm{P}^{*}}$ as $\operatorname{contract}(U)(T):=$ $\left\{P^{\% \mathrm{~T}}: P \in \operatorname{der}(T)\right\}^{\mathrm{T}}$. Define $T^{\%}:=\operatorname{contract}(U)(T)$. A multi-partition fud $F \in \mathcal{F}_{U, \mathrm{P}^{*}}$ is said to be contracted if all of its multi-partition transforms are contracted, $\forall T \in F\left(T=T^{\%}\right)$.

Multi-partition transforms may be exploded to a partition fud. Define explode $\in$ $\bigcup\left\{\mathcal{T}_{U, \mathrm{P}^{*}} \rightarrow \mathcal{F}_{U, \mathrm{P}}: U \in \mathcal{U}\right\}$ as $\operatorname{explode}(T):=\left\{P^{\mathrm{T}}: P \in \operatorname{der}(T)\right\}$. A multi-partition fud may be exploded to a partition fud. Define explode $\in$ $\bigcup\left\{\mathcal{F}_{U, \mathrm{P}^{*}} \rightarrow \mathcal{F}_{U, \mathrm{P}}: U \in \mathcal{U}\right\}$ as $\operatorname{explode}(F):=\bigcup\{\operatorname{explode}(T): T \in F\}=$ $\left\{P^{\mathrm{T}}: T \in F, P \in \operatorname{der}(T)\right\}$.

### 3.8 Pointed partitions

The set of pointed partitions $\mathcal{R}_{*} \subset \mathcal{R} \times \mathrm{P}(\mathcal{S})$ are pairs of (i) partitions, and (ii) components of the partition, $\forall\left(P, C_{*}\right) \in \mathcal{R}_{*}\left(C_{*} \in P\right)$. The set of pointed partitions is defined

$$
\mathcal{R}_{*}=\left\{\left(P, C_{*}\right): P \in \mathcal{R}, C_{*} \in P\right\}
$$

Define vars $\in \mathcal{R}_{*} \rightarrow \mathrm{P}(\mathcal{V})$ as $\operatorname{vars}\left(\left(P, C_{*}\right)\right):=\operatorname{vars}(P)$. The partition of a pointed partition cannot be the empty partition, $\forall(P, \cdot) \in \mathcal{R}_{*}(P \neq \emptyset)$. The scalar pointed partition is $(\{\{\emptyset\}\},\{\emptyset\}) \in \mathcal{R}_{*}$. For any unary partition $P=\{C\} \in \mathcal{R}$ there is exactly one pointed partition, $(P, C) \in \mathcal{R}_{*}$.

Define transform $\in \mathcal{R}_{*} \rightarrow \mathcal{T}_{\mathrm{f}, \mathrm{U}}$ as transform $\left(\left(P, C_{*}\right)\right):=\operatorname{transform}(P)$. Define shorthand $P_{*}^{\mathrm{T}}:=\operatorname{transform}\left(P_{*}\right)$. There is no converse function in $\mathcal{T}_{\mathrm{f}} \rightarrow \mathcal{R}_{*}$ except in the case where the transform $T \in \mathcal{T}_{\mathrm{f}}$ maps to a unary partition, $|\operatorname{inverse}(T)|=1$. In this case the pointed partition is $\left(P, C_{*}\right)$ where $C_{*}=C^{\mathrm{S}},\{C\}=\operatorname{ran}(\operatorname{inverse}(T))$ and $P=\left\{C_{*}\right\}$.

The variables of a pointed partition $P_{*} \in \mathcal{R}_{*}$ are also known as the underlying variables because they equal the underlying variables of the pointed partition transform, $\operatorname{vars}\left(P_{*}\right)=\operatorname{und}\left(P_{*}^{\mathrm{T}}\right)$. The partition $P$ of the pointed partition, $(P, \cdot)=P_{*}$ is also known as the derived variable, $\{P\}=\operatorname{der}\left(P_{*}^{\mathrm{T}}\right)$.

The set of incremented pointed partitions of a pointed partition are those for which the cardinality of the point component is decremented and either (i) the cardinality of the partition is incremented, or (ii) the cardinality of one of the other components is incremented. That is, pointed partition $\left(P, C_{*}\right) \in \mathcal{R}_{*}$ and incremented pointed partition $\left(Q, D_{*}\right) \in \mathcal{R}_{*}$ are such that $\left|D_{*}\right|=\left|C_{*}\right|-1$ and either (i) $|Q|=|P|+1$, or (ii) $\exists C \in P \exists D \in Q(|D|=|C|+1)$. Define increments $\in \mathcal{R}_{*} \rightarrow \mathrm{P}\left(\mathcal{R}_{*}\right)$ as

```
increments \(\left(\left(P, C_{*}\right)\right):=\)
    \(\left\{\left(P \backslash\left\{C_{*}\right\} \cup\left\{D_{*}, D\right\}, D_{*}\right):\left|C_{*}\right|>1, S \in C_{*}\right.\),
        \(\left.D_{*}=C_{*} \backslash\{S\}, D=\{S\}\right\} \cup\)
\(\left\{\left(P \backslash\left\{C_{*}, C\right\} \cup\left\{D_{*}, D\right\}, D_{*}\right):\left|C_{*}\right|>1,|P|>1, S \in C_{*}, C \in P, C \neq C_{*}\right.\),
    \(\left.D_{*}=C_{*} \backslash\{S\}, D=C \cup\{S\}\right\}\)
```

The incremented pointed partitions cardinality is $\mid$ increments $\left(\left(P, C_{*}\right)\right) \mid=$ $\left|C_{*}\right||P|$ if $\left|C_{*}\right|>1$ otherwise $\left|\operatorname{increments}\left(\left(P, C_{*}\right)\right)\right|=0$. Let the search tree initialised from the unary partition of some variables $V$ in a system $U$ be

$$
Z_{+}=\operatorname{tree}\left(\operatorname{search} \operatorname{Treer}\left(\mathcal{R}_{*}, \text { increments, }\left\{\left(\left\{V^{\mathrm{CS}}\right\}, V^{\mathrm{CS}}\right)\right\}\right)\right)
$$

$Z_{+}$finds all partitions in variables $V$, $\operatorname{dom}\left(\operatorname{elements}\left(Z_{+}\right)\right)=\mathrm{B}\left(V^{\mathrm{CS}}\right)$. Compare to the search tree of decremented partitions initialised from the self partition,

$$
Z_{-}=\operatorname{tree}\left(\operatorname{search} \operatorname{Treer}\left(\mathcal{R}, \text { decrements, }\left\{V^{\mathrm{CS}\{ \}}\right\}\right)\right)
$$

which is also such that elements $\left(Z_{-}\right)=\mathrm{B}\left(V^{\mathrm{CS}}\right)$, but the increments and decrements are not converses of each other, $\left|\operatorname{nodes}\left(Z_{-}\right)\right|<\left|\operatorname{nodes}\left(Z_{+}\right)\right|$. The paths of the decrements tree are subsets of the paths of the increments tree, $\forall L_{-} \in \operatorname{paths}\left(Z_{-}\right) \exists L_{+} \in \operatorname{paths}\left(Z_{+}\right)\left(\operatorname{set}\left(L_{-}\right) \subset \operatorname{dom}\left(\operatorname{set}\left(L_{+}\right)\right)\right)$.

The subset singleton pointed partitions $\mathcal{R}_{*, \mathrm{~s}} \subset \mathcal{R}_{*}$ is defined $\mathcal{R}_{*, \mathrm{~s}}=\left\{\left(P, C_{*}\right)\right.$ : $\left.\left(P, C_{*}\right) \in \mathcal{R}_{*},\left|C_{*}\right|=1\right\}$. A pointed self partition, $\left(X^{\{ \}},\{x\}\right)$ where $x \in X$, is necessarily a singleton pointed partition.

The subset pointed binary partitions $\mathcal{R}_{*, \mathrm{~b}} \subset \mathcal{R}_{*}$ is defined $\mathcal{R}_{*, \mathrm{~b}}=\left\{\left(P, C_{*}\right)\right.$ : $\left.\left(P, C_{*}\right) \in \mathcal{R}_{*},|P|=2\right\}$. A pointed binary partition has a complement, $P_{*}^{\prime}=(\{A, B\}, B)$ where $P_{*}=(\{A, B\}, A)$. The complement is in the same variables, $\operatorname{vars}\left(P_{*}^{\prime}\right)=\operatorname{vars}\left(P_{*}\right)$.

There are logical operators on pointed binary partitions which derive a pointed binary partition from underlying pointed binary partitions. Let pointed binary partition $P_{*}=\left(P, C_{*}\right) \in \mathcal{R}_{*, \mathrm{~b}}$ be the pair of the binary partition variable, $P$ where $|P|=2$, and the point component, $C_{*} \in P$. So $P_{*} \in \mathcal{V} \times \mathcal{W}$ and $\left\{P_{*}\right\}$ is a state, $\left\{P_{*}\right\} \in \mathcal{S}$. In a system $U$ which contains the partition variable, $(P, P) \in U$, the cartesian states are $\{P\}^{\mathrm{CS}}=\left\{\left\{P_{*}\right\},\left\{P_{*}^{\prime}\right\}\right\}$ where $P_{*}^{\prime}$ is the complement of $P_{*}$. The only binary partition of the cartesian states equals the self partition, $\{P\}^{\mathrm{CS}\{ \}}=\left\{\left\{\left\{P_{*}\right\}\right\},\left\{\left\{P_{*}^{\prime}\right\}\right\}\right\} \in \mathcal{R}$. Define not $\in \mathcal{R}_{*, \mathrm{~b}} \rightarrow \mathcal{R}_{*, \mathrm{~b}}$ as

$$
\operatorname{not}\left(P_{*}\right):=\left(\left\{\left\{\left\{P_{*}\right\}\right\},\left\{\left\{P_{*}^{\prime}\right\}\right\}\right\},\left\{\left\{P_{*}^{\prime}\right\}\right\}\right)
$$

The underlying variable of the resultant pointed partition is the given partition variable, $\operatorname{vars}\left(\operatorname{not}\left(P_{*}\right)\right)=\{P\} \subset \mathcal{V} \cap \mathcal{R}$. The derived variable of the resultant pointed partition is the binary partition of the cartesian states, $\left\{\left\{\left\{P_{*}\right\}\right\},\left\{\left\{P_{*}^{\prime}\right\}\right\}\right\} \in \mathcal{V} \cap \mathcal{R}$.

Given two pointed binary partitions $P_{*}, R_{*} \in \mathcal{R}_{*, \mathrm{~b}}$ the cartesian states are $\{P, R\}^{\mathrm{CS}}=\left\{\left\{P_{*}, R_{*}\right\},\left\{P_{*}, R_{*}^{\prime}\right\},\left\{P_{*}^{\prime}, R_{*}\right\},\left\{P_{*}^{\prime}, R_{*}^{\prime}\right\}\right\}$, where $P_{*}^{\prime}$ and $R_{*}^{\prime}$ are the complements of $P_{*}$ and $R_{*}$. The and binary partition of the cartesian states is $\{X, Y\} \in \mathcal{R}$, where $X=\left\{\left\{P_{*}, R_{*}\right\}\right\}$ and $Y=\left\{\left\{P_{*}, R_{*}^{\prime}\right\},\left\{P_{*}^{\prime}, R_{*}\right\},\left\{P_{*}^{\prime}, R_{*}^{\prime}\right\}\right\}$.

The and pointed binary partition is $(\{X, Y\}, X) \in \mathcal{R}_{*, \mathrm{~b}}$. Define and $\in$ $\mathcal{R}_{*, \mathrm{~b}} \times \mathcal{R}_{*, \mathrm{~b}} \rightarrow \mathcal{R}_{*, \mathrm{~b}}$ as

$$
\operatorname{and}\left(P_{*}, R_{*}\right):=(\{X, Y\}, X)
$$

The underlying variables are the given partition variables, vars $\left(\operatorname{and}\left(P_{*}, R_{*}\right)\right)=$ $\{P, R\} \subset \mathcal{V} \cap \mathcal{R}$. The derived variable of the resultant pointed partition is the binary partition of the cartesian states, $\{X, Y\} \in \mathcal{V} \cap \mathcal{R}$.

Similarly, the or binary partition of the cartesian states is $\{A, B\} \in \mathcal{R}$, where $A=\left\{\left\{P_{*}, R_{*}\right\},\left\{P_{*}, R_{*}^{\prime}\right\},\left\{P_{*}^{\prime}, R_{*}\right\}\right\}$ and $B=\left\{\left\{P_{*}^{\prime}, R_{*}^{\prime}\right\}\right\}$. The or pointed binary partition is $(\{A, B\}, A) \in \mathcal{R}_{*, \mathrm{~b}}$. Define or $\in \mathcal{R}_{*, \mathrm{~b}} \times \mathcal{R}_{*, \mathrm{~b}} \rightarrow \mathcal{R}_{*, \mathrm{~b}}$

$$
\operatorname{or}\left(P_{*}, R_{*}\right):=(\{A, B\}, A)
$$

The underlying variables are the given partition variables, $\operatorname{vars}\left(\operatorname{or}\left(P_{*}, R_{*}\right)\right)=$ $\{P, R\} \subset \mathcal{V} \cap \mathcal{R}$. The derived variable of the resultant pointed partition is the binary partition of the cartesian states, $\{A, B\} \in \mathcal{V} \cap \mathcal{R}$.

The and and not operators result in singleton pointed binary partitions, $\operatorname{and}\left(P_{*}, R_{*}\right) \in \mathcal{R}_{*, \mathrm{~s}} \cap \mathcal{R}_{*, \mathrm{~b}}$ and $\operatorname{not}\left(P_{*}\right) \in \mathcal{R}_{*, \mathrm{~s}} \cap \mathcal{R}_{*, \mathrm{~b}}$, but the or operation does not.

The and and or binary operations can be extended to sets of pointed binary partitions. Define and $\in \mathrm{P}\left(\mathcal{R}_{*, \mathrm{~b}}\right) \rightarrow \mathcal{R}_{*, \mathrm{~b}}$ as

$$
\operatorname{and}\left(V_{*}\right):=\left(\left\{\left\{V_{*}\right\}, V^{\mathrm{CS}} \backslash\left\{V_{*}\right\}\right\},\left\{V_{*}\right\}\right)
$$

where $V=\left\{P:(P, \cdot) \in V_{*}\right\}$. The cartesian states, $V^{\mathrm{CS}}=\operatorname{cartesian}(U)(V)$, requires a system $U$ implied from the given partitions, $U=\{(P, P): P \in V\}$. Note that $V_{*} \in \mathcal{S}_{U}$. Define or $\in \mathrm{P}\left(\mathcal{R}_{*, \mathrm{~b}}\right) \rightarrow \mathcal{R}_{*, \mathrm{~b}}$

$$
\operatorname{or}\left(V_{*}\right):=\left(\left\{V^{\mathrm{CS}} \backslash\left\{V_{*}^{\prime}\right\},\left\{V_{*}^{\prime}\right\}\right\}, V^{\mathrm{CS}} \backslash\left\{V_{*}^{\prime}\right\}\right)
$$

where $V_{*}^{\prime}=\left\{P_{*}^{\prime}: P_{*} \in V_{*}\right\}$.
Given a tree of pointed binary partitions, $\operatorname{trees}\left(\mathcal{R}_{*, \mathrm{~b}}\right)$, a tree of inherited and operations can be derived. Define and $\in \operatorname{trees}\left(\mathcal{R}_{*, \mathrm{~b}}\right) \rightarrow \operatorname{trees}\left(\mathcal{R}_{*, \mathrm{~b}}\right)$ as

$$
\operatorname{and}(Z):=\left\{\left(P_{*}, \operatorname{and}\left(P_{*}, X\right)\right):\left(P_{*}, X\right) \in Z\right\}
$$

Define and $\in \mathcal{R}_{*, \mathrm{~b}} \times \operatorname{trees}\left(\mathcal{R}_{*, \mathrm{~b}}\right) \rightarrow \operatorname{trees}\left(\mathcal{R}_{*, \mathrm{~b}}\right)$ as

$$
\operatorname{and}\left(P_{*}, Z\right):=\left\{\left(M_{*}, \operatorname{and}\left(M_{*}, X\right)\right):\left(R_{*}, X\right) \in Z, M_{*}=\operatorname{and}\left(P_{*}, R_{*}\right)\right\}
$$

Let $F \in \mathcal{F}_{U, \mathrm{P}}$ be the fud of the given pointed binary partition tree $Z \in$ $\operatorname{trees}\left(\mathcal{R}_{*, \mathrm{~b}}\right)$ and its derived and tree, $\operatorname{and}(Z) \in \operatorname{trees}\left(\mathcal{R}_{*, \mathrm{~b}}\right)$. That is, $F=$ $\left\{P_{*}^{\mathrm{T}}: P_{*} \in \operatorname{elements}(Z) \cup\right.$ elements $\left.(\operatorname{and}(Z))\right\}$. The derived variables are the leaf partitions of the tree, $\operatorname{der}(F)=\operatorname{dom}(\operatorname{leaves}(\operatorname{and}(Z)))$. The underlying variables of the fud are the variables of the pointed partitions of the given $\operatorname{tree}, \operatorname{und}(F)=\bigcup\left\{\operatorname{vars}\left(P_{*}\right): P_{*} \in \operatorname{elements}(Z)\right\}$.

The set of pointed partitions in a system $U$ is $\mathcal{R}_{*, U}$. Pointed partitions can be expanded, expand $(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{R}_{*, U} \rightarrow \mathcal{R}_{*, U}$, and contracted, $\operatorname{contract}(U) \in \mathcal{R}_{*, U} \rightarrow \mathcal{R}_{*, U}$, such that $P_{*}^{\% V}=P_{*}$ where $V=\operatorname{vars}\left(P_{*}\right)$.

Given a variable $w \in \mathcal{V}_{U}$ in system $U$ and a pointed binary partition $P_{*} \in \mathcal{R}_{*, \mathrm{~b}}$, a nullable pointed partition can be derived which has values for each of the values of $w$ when the value of $P_{*}$ is the point component $C_{*}$, where $\left(P, C_{*}\right)=P_{*}$, and has a null value for any value of $w$ when the value of $P_{*}$ is the complement point component $C_{*}^{\prime}$, where $\left(P, C_{*}^{\prime}\right)=P_{*}^{\prime}$. Define nullable $(U) \in \mathcal{V}_{U} \times \mathcal{R}_{*, U, \mathrm{~b}} \rightarrow \mathcal{R}_{*, U}$ as

$$
\begin{aligned}
& \text { nullable }(U)\left(w, P_{*}\right):=\left(Q \cup\left\{D_{*}\right\}, D_{*}\right): \\
& \qquad=\left(\left\{\left\{P_{*}\right\}\right\}^{\mathrm{U}} *\{w\}^{\mathrm{C}}\right)^{\mathrm{S}\{ \}}, D_{*}=\left(\left\{\left\{P_{*}^{\prime}\right\}\right\}^{\mathrm{U}} *\{w\}^{\mathrm{C}}\right)^{\mathrm{S}}
\end{aligned}
$$

where (i) $P_{*}^{\prime}$ is the complement pointed partition of $P_{*}$, (ii) the non-null set of components $Q \subset \mathrm{P}\left(\{w, P\}^{\mathrm{CS}}\right)$ is a self partition, and (iii) $D_{*}$ is the null point component $D_{*} \in \mathrm{P}\left(\{w, P\}^{\mathrm{CS}}\right)$. The underlying variables are $\{w, P\} \subset \mathcal{V}$. The derived nullable variable is $Q \cup\left\{D_{*}\right\} \in \mathcal{V} \cap \mathcal{R}$. That is, $\operatorname{der}\left(\left(\operatorname{nullable}(U)\left(w, P_{*}\right)\right)^{\mathrm{T}}\right)=\left\{Q \cup\left\{D_{*}\right\}\right\}$. The point component, $D_{*}$, is the null value of the nullable variable, $D_{*} \in Q \cup\left\{D_{*}\right\}$. The resultant nullable pointed partition $\left(Q \cup\left\{D_{*}\right\}, D_{*}\right) \in \mathcal{R}_{*, U}$ is only a pointed binary partition if $w$ is mono-valent, $\left|U_{w}\right|=1 \Longrightarrow\left(Q \cup\left\{D_{*}\right\}, D_{*}\right) \in \mathcal{R}_{*, U, \mathrm{~b}}$. The cardinality of the values of the nullable variable is one greater than that of the given variable, $\left|Q \cup\left\{D_{*}\right\}\right|=\left|U_{w}\right|+1$. If the nullable variable is in the system, $Q \cup\left\{D_{*}\right\} \in \operatorname{vars}(U)$, then the volume is also incremented, $\left|\left\{Q \cup\left\{D_{*}\right\}\right\}^{\mathrm{C}}\right|=\left|\{w\}^{\mathrm{C}}\right|+1$.

### 3.9 Overlapping transforms

The derived variables of a transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ are non-overlapping if there exists an equivalent transform of a fud $F \in \mathcal{F}_{U, 1}$ which is non-overlapping, $\exists F \in \mathcal{F}_{U, 1}\left(\left(F^{\mathrm{T}}=T\right) \wedge \neg \operatorname{overlap}(F)\right)$. If the transform is non-overlapping, there exists at least one equivalent fud $F$ that weakly partitions the underlying variables, $\{\operatorname{und}(\operatorname{depends}(F,\{w\})): w \in W\} \in \mathrm{B}^{\prime}(V)$, where $W=\operatorname{der}(T)$,
$V=\operatorname{und}(T)$ and $\mathrm{B}^{\prime}$ is the weak partition function, $\mathrm{B}^{\prime}(V):=\mathrm{B}(V) \cup\{Y \cup$ $\{\emptyset\}: Y \in \mathrm{~B}(V)\}$ and $\mathrm{B}^{\prime}(\emptyset):=\{\{\emptyset\}\}$. If the transform, $T$, has plurivalent derived variables, $\exists w \in W\left(\left|(X \%\{w\})^{\mathrm{F}}\right|>1\right)$ where $(X, W)=T$, then there exists an equivalent fud $G$ having pluri-valent derived variables, $\operatorname{der}(G)=W^{\prime}$, where $W^{\prime}=\left\{w: w \in W,\left|(X \%\{w\})^{\mathrm{F}}\right|>1\right\}$, such that $G^{\mathrm{T}}=\left(\left(X \%\left(V \cup W^{\prime}\right)\right)^{\mathrm{F}}, W^{\prime}\right)$, that strongly partitions the underlying variables, $\left\{\operatorname{und}(\operatorname{depends}(G,\{w\})): w \in W^{\prime}\right\} \in \mathrm{B}(V)$. Mono-valent derived variables of the transform map to disjoint transform variables in the corresponding weakly partitioning $f u d$, $\operatorname{und}(R)=\emptyset$, where $R \in \operatorname{ran}(M)$ and $M \in W \cdot F$. Define overlap $\in \mathcal{T}_{\mathbf{U}} \rightarrow \mathbf{B}$ as

$$
\begin{aligned}
& \text { overlap }(T):=\neg\left(W^{\prime} \neq \emptyset \Longrightarrow\right. \\
& \left.\quad \exists Q \in \mathrm{~B}(V) \exists R \in W^{\prime} \cdot Q \forall(w, K) \in R\left(\left((X \%(K \cup\{w\}))^{\mathrm{F}},\{w\}\right) \in \mathcal{T}_{\mathrm{f}}\right)\right)
\end{aligned}
$$

where $V=\operatorname{und}(T),(X, W)=T$ and $W^{\prime}=\left\{w: w \in W,\left|(X \%\{w\})^{\mathrm{F}}\right|>1\right\}$. The empty transform is non-overlapping, $\neg \operatorname{overlap}((\emptyset, \emptyset))$. If the transform $T$ is non-overlapping, the corresponding non-overlapping fud is

$$
F=\left\{\left((X \%(K \cup\{w\}))^{\mathrm{F}},\{w\}\right):(w, K) \in R\right\} \in \mathcal{F}
$$

where $R=\{(w, \operatorname{und}(\operatorname{depends}(F,\{w\}))): w \in \operatorname{der}(T)\} \in W \rightarrow \mathrm{P}(V)$.

A one functional transform $T \in \mathcal{T}_{U, f, 1}$ is right total if and only if the transform is non-overlapping

$$
\neg \operatorname{overlap}(T) \Longleftrightarrow(X \% W)^{\mathrm{F}}=W^{\mathrm{C}}
$$

where $(X, W)=T$. For example, let $W \subset \mathrm{~B}\left(V^{\mathrm{CS}}\right)$ where $V=\operatorname{und}(T)$ and $W=\operatorname{der}(T)$.

The possible derived states are the effective derived states of the application of the transform to the cartesian, $\left(V^{\mathrm{C}} * T\right)^{\mathrm{FS}} \subseteq W^{\mathrm{CS}}$. The possible derived states is the domain of the transform inverse, $\left(V^{\mathrm{C}} * T\right)^{\mathrm{FS}}=$ $\operatorname{dom}\left(T^{-1}\right)=\operatorname{stateDeriveds}(T)$. The possible derived volume $w^{\prime}=\left|\left(V^{\mathrm{C}} * T\right)^{\mathrm{F}}\right|$ is the cardinality of the partition, $w^{\prime}=\left|T^{\mathrm{P}}\right|=\left|T^{-1}\right|$, and so is less than or equal to the derived volume, $w^{\prime} \leq w$, where $w=\left|W^{\mathrm{C}}\right|$. The possible derived volume equals the derived volume if and only if the transform is non-overlapped, $\neg \operatorname{overlap}(T) \Longleftrightarrow w^{\prime}=w$, because it is only in this case that the transform is right total, $\operatorname{dom}\left(T^{-1}\right)=(X \% W)^{\mathrm{FS}}=W^{\mathrm{CS}}$. If the transform is overlapping there are necessarily impossible derived states, $\operatorname{overlap}(T) \Longrightarrow W^{\mathrm{CS}} \backslash\left(V^{\mathrm{C}} * T\right)^{\mathrm{FS}} \neq \emptyset$. The possible derived volume is less than or equal to the underlying volume, $w^{\prime} \leq v$, where $v=\left|V^{\mathrm{C}}\right|$.

Derived variables $x, y \in W$ are said to be tautological if their partitions are equal, partition $((X \%(V \cup\{x\}),\{x\}))=\operatorname{partition}((X \%(V \cup\{y\}),\{y\}))$, where $(X, W)=T$ and $V=\operatorname{und}(T)$. A transform is tautologically overlapped if all of its derived variables are tautological. Define tautology $\in \mathcal{T}_{\mathrm{f}} \rightarrow \mathbf{B}$ as tautology $(T):=|\{\operatorname{partition}((X \%(V \cup\{w\}),\{w\})): w \in W\}|=1$. A tautology is always overlapped, $\forall T \in \mathcal{T}_{\mathrm{f}} \cap \mathcal{T}_{\mathrm{U}}$ (tautology $\left.(T) \Longrightarrow \operatorname{overlap}(T)\right)$.

A multi-partition transform $T \in \mathcal{T}_{U, \mathrm{P}^{*}}$ is overlapping if and only if the contracted transform is overlapping, overlap $(T) \Longleftrightarrow \operatorname{overlap}\left(T^{\%}\right)$. A contracted multi-partition transform is overlapping if and only if its explode fud is overlapping, $\operatorname{overlap}\left(T^{\%}\right) \Longleftrightarrow$ overlap $\left(\operatorname{explode}\left(T^{\%}\right)\right)$.

A multi-partition transform $T \in \mathcal{T}_{U, \mathrm{P}^{*}}$ represents a functional map between the underlying states and the derived states, $V^{\mathrm{CS}} \rightarrow W^{\mathrm{CS}}$, so the possible derived volume is at most the product of the cardinalities of the partitions, $w^{\prime}=\left|T^{\mathrm{P}}\right| \leq \prod_{P \in W}|P|=\left|W^{\mathrm{CS}}\right|$. If the transform is expanded, $W \subset \mathrm{~B}\left(V^{\mathrm{CS}}\right)$, the right total case requires that all of the components intersect, $\forall P, Q \in W \forall C \in P \forall D \in Q(C \cap D \neq \emptyset)$. This is true for non-overlapping transforms because the contracted partitions have disjoint variables, $\forall P_{1}, P_{2} \in W\left(P_{1} \neq P_{2} \Longrightarrow \operatorname{vars}\left(P_{1}^{\%}\right) \cap \operatorname{vars}\left(P_{2}^{\%}\right)=\emptyset\right)$.

A contracted multi-partition fud $F \in \mathcal{F}_{U, \mathrm{P}^{*}}$, where $\forall T \in F\left(T=T^{\%}\right)$, is recursively non-overlapping if the dependent exploded fud of each of its contracted multi-partition transforms is non-overlapping,

$$
\forall T \in F(\neg \operatorname{overlap}(\operatorname{depends}(\operatorname{explode}(F), \operatorname{der}(T))))
$$

### 3.10 Decompositions

The set of decompositions $\mathcal{D}$ is a subset of the trees of pairs of (i) states, $\mathcal{S}$, and (ii) unit functional transforms, $\mathcal{T}_{\mathrm{f}} \cap \mathcal{T}_{\mathrm{U}}$

$$
\mathcal{D} \subset \operatorname{trees}\left(\mathcal{S} \times \mathcal{T}_{\mathrm{f}, \mathrm{U}}\right)
$$

The set of decompositions is constrained such that the set of transforms forms a functional definition set,

$$
\forall D \in \mathcal{D}(\operatorname{ran}(\operatorname{elements}(D)) \in \mathcal{F})
$$

Define transforms $\in \mathcal{D} \rightarrow \mathcal{F}$ as transforms $(D):=\operatorname{ran}($ elements $(D))$. Define underlying $\in \mathcal{D} \rightarrow \mathrm{P}(\mathcal{V})$ as underlying $(D):=$ underlying $(\operatorname{transforms}(D))$.

The transforms form a fud, so the sets of derived variables are disjoint, $\forall(A, W),(B, X) \in G((A, W) \neq(B, X) \Longrightarrow W \cap X=\emptyset)$, where $G=$ transforms $(D)$.

There are some additional constraints on decompositions. First, no underlying variable of a transform in the decomposition can be a derived variable in another transform

$$
\forall D \in \mathcal{D}(\bigcup\{\operatorname{und}(T): T \in \operatorname{transforms}(D)\}=\operatorname{underlying}(D))
$$

where und $=$ underlying. That is, the fud is single layer, $\operatorname{layer}(G, \operatorname{der}(G))=1$ or $\forall T \in G(\operatorname{und}(T) \subseteq \operatorname{und}(G))$. So the derived variables of a transform do not intersect with the variables of any other, $\forall T_{1}, T_{2} \in G\left(T_{1} \neq T_{2} \Longrightarrow\right.$ $\left.\operatorname{der}\left(T_{1}\right) \cap \operatorname{vars}\left(T_{2}\right)=\emptyset\right)$, where $G=\operatorname{transforms}(D)$.

Second, the states of the root pairs are empty states

$$
\forall D \in \mathcal{D}(\operatorname{dom}(\operatorname{roots}(D))=\{\emptyset\})
$$

Third, each of the states in child pairs are states of the derived variables of the parent transform

$$
\forall D \in \mathcal{D} \forall((\cdot, T),(S, \cdot)) \in \operatorname{steps}(D)(S \in \operatorname{std}(T))
$$

where std $=$ stateDeriveds $=$ dom $\circ$ inverse. The set of states need not be all of the derived states, but only a subset or empty, $\forall((\cdot, T), E) \in$ $\operatorname{nodes}(D)(\operatorname{dom}(\operatorname{dom}(E)) \subseteq \operatorname{std}(T))$.

The empty decomposition consists of the empty transform, $\{((\emptyset,(\emptyset, \emptyset)), \emptyset)\} \in$ D.

The application of a decomposition to a histogram is a tree of contingent applications of the transforms. Define apply $\in \mathcal{D} \times \mathcal{A} \rightarrow \operatorname{trees}(\mathcal{S} \times \mathcal{A})$ as $\operatorname{apply}(D, A):=\operatorname{apply}(D, \operatorname{vars}(A), A)$ where apply $\in \mathcal{D} \times \mathrm{P}(\mathcal{V}) \times \mathcal{A} \rightarrow$ $\operatorname{trees}(\mathcal{S} \times \mathcal{A})$ is

$$
\begin{aligned}
& \operatorname{apply}(D, V, A):= \\
& \qquad \begin{array}{l}
\{(S, B \% W), \operatorname{apply}(E, V, B)):((S,(X, W)), E) \in D \\
\left.B=A *\{S\}^{\mathrm{U}} * X \%(V \cup W)\right\}
\end{array}
\end{aligned}
$$

Define shorthand $A * D=\operatorname{apply}(D, A)$.

The application of a decomposition, $D$, to a histogram, $A$, can be contingently constrained by a query histogram $Q \in \mathcal{A}$ to produce a tree of subsets of the given histogram, $A$. Define query $\in \mathcal{D} \times \mathcal{A} \times \mathcal{A} \rightarrow \operatorname{trees}(\mathcal{S} \times \mathcal{A})$ as query $(D, A, Q):=$ query $(D, \operatorname{vars}(A), A, Q)$ where query $\in \mathcal{D} \times \mathrm{P}(\mathcal{V}) \times \mathcal{A} \times$ $\mathcal{A} \rightarrow \operatorname{trees}(\mathcal{S} \times \mathcal{A})$ is

$$
\begin{aligned}
& \text { query }(D, V, A, Q):= \\
& \qquad \begin{aligned}
&\{((S, B \% V), \text { query }(E, V, B, R)):((S,(X, W)), E) \in D \\
& R=Q *\{S\}^{\mathrm{U}} * X \%(V \cup W), \operatorname{size}(R)>0, \\
&\left.B=A *\{S\}^{\mathrm{U}} * X *(R \% W) \%(V \cup W)\right\}
\end{aligned}
\end{aligned}
$$

In the case where the query variables are a superset of the decomposition's underlying variables, $\operatorname{vars}(Q) \supseteq \operatorname{und}(D)$, and the query has a single effective state, $\left|Q^{\mathrm{F}}\right|=1$, the resultant tree has a single path, $\mid$ paths $($ query $(D, A, Q)) \mid=$ 1.

A decomposition $D \in \mathcal{D}$ is distinct if the elements are a functional map of states to transforms, elements $(D) \in \mathcal{S} \rightarrow \mathcal{T}$. In fact, a less strict definition is all that is necessary, $\forall E \in\{D\} \cup \operatorname{ran}(\operatorname{nodes}(D))(\operatorname{dom}(E) \in \mathcal{S} \rightarrow \mathcal{T})$. The subset of distinct decompositions, $\mathcal{D}_{\mathrm{d}} \subset \mathcal{D}$ is defined $\mathcal{D}_{\mathrm{d}}=\{D: D \in$ $\left.\mathcal{D}, \operatorname{dom}(D) \in \mathcal{S} \rightarrow \mathcal{T}, \operatorname{ran}(D) \subset \mathcal{D}_{\mathrm{d}}\right\}$. The distinct decompositions allow the same transform to be in more than one path with different ancestors, $\exists D \in \mathcal{D}_{\mathrm{d}}($ flip $($ elements $(D)) \notin \mathcal{T} \rightarrow \mathcal{S})$. The function on trees of pairs, distinct $\in \operatorname{trees}(\mathcal{X} \times \mathcal{Y}) \rightarrow \mathrm{P}(\operatorname{trees}(\mathcal{X} \times \mathcal{Y}))$, described in appendix 'Trees', returns the set of distinct decomposition trees as distinct $\in \operatorname{trees}(\mathcal{S} \times \mathcal{T}) \rightarrow$ $\mathrm{P}(\operatorname{trees}(\mathcal{S} \times \mathcal{T}))$

$$
\begin{aligned}
& \operatorname{distinct}(D):= \\
& \qquad \begin{aligned}
&\{H: H \subseteq\{((S, T), G):((S, T), E) \in D, G \in \operatorname{distinct}(E)\}, \\
&\operatorname{dom}(H) \in \operatorname{dom}(\operatorname{dom}(D)): \rightarrow \operatorname{ran}(\operatorname{dom}(D))\}
\end{aligned}
\end{aligned}
$$

where $\operatorname{distinct}(\emptyset):=\{\emptyset\}$. Given a decomposition, $D \in \mathcal{D}$, the function returns a set of distinct decompositions, $\operatorname{distinct}(D) \in \mathrm{P}\left(\mathcal{D}_{\mathrm{d}}\right)$, because $(\mathcal{D} \rightarrow$ $\left.\mathrm{P}\left(\mathcal{D}_{\mathrm{d}}\right)\right) \subset(\operatorname{trees}(\mathcal{S} \times \mathcal{T}) \rightarrow \mathrm{P}(\operatorname{trees}(\mathcal{S} \times \mathcal{T})))$. A distinct decomposition $D \in \mathcal{D}_{\mathrm{d}}$ has singleton roots, $\operatorname{roots}(D)=\{(\emptyset, \cdot)\}$.

The subset of decompositions $\mathcal{D}_{U} \subset \mathcal{D}$ in a system $U$ is a subset of the trees of pairs of (i) states, $\mathcal{S}_{U}$, and (ii) one functional transforms, $\mathcal{T}_{U, \mathrm{f}, 1}$

$$
\mathcal{D}_{U}=\mathcal{D} \cap \operatorname{trees}\left(\mathcal{S}_{U} \times \mathcal{T}_{U, \mathrm{f}, 1}\right)
$$

If a decomposition is distinct there exists an inversion of the decomposition, $\operatorname{trees}\left(\mathcal{S}_{U} \times \mathcal{T}_{U, \mathrm{f}, 1}\right) \rightarrow \operatorname{trees}\left(\mathcal{T}_{U, \mathrm{f}, 1} \times \mathcal{S}_{U}\right)$, from pairs of transforms and their parent transform's derived states to pairs of transforms and their own derived states. The inversion is such that the derived states of the transforms are completed where they correspond to non-empty components of the partition of the underlying variables of the decomposition. That is, the decomposition completed states are possible states of the transform. Define application $(U) \in$ $\mathcal{D}_{\mathrm{d}, U} \rightarrow \operatorname{trees}\left(\mathcal{T}_{U, \mathrm{f}, 1} \times \mathcal{S}_{U}\right)$ as application $(U)(D):=\operatorname{app}(U)(D, \emptyset, \emptyset, \emptyset)$ where $\operatorname{app}(U) \in \operatorname{trees}\left(\mathcal{S}_{U} \times \mathcal{T}_{U, \mathrm{f}, 1}\right) \times \mathcal{S}_{U} \times \mathcal{S}_{U} \times \mathcal{F}_{U, 1} \rightarrow \operatorname{trees}\left(\mathcal{T}_{U, \mathrm{f}, 1} \times \mathcal{S}_{U}\right)$ is

$$
\begin{aligned}
& \operatorname{app}(U)(D, Q, R, F):= \\
& \quad\{((T, S), \operatorname{app}(U)(E, S, R \cup S, F \cup\{T\})):((P, T), E) \in D, P=Q, \\
& \left.\quad S \in \operatorname{dom}(\operatorname{dom}(E)), R \cup S \in \operatorname{std}\left((F \cup\{T\})^{\mathrm{T}}\right)\right\} \\
& \cup \quad\{((T, S), \emptyset):((P, T), E) \in D, P=Q, \\
& \left.\quad S \in \operatorname{der}(T)^{\mathrm{CS}} \backslash \operatorname{dom}(\operatorname{dom}(E)), R \cup S \in \operatorname{std}\left((F \cup\{T\})^{\mathrm{T}}\right)\right\}
\end{aligned}
$$

The computation of the set of derived states, $\operatorname{std}\left((F \cup\{T\})^{\mathrm{T}}\right) \subset \mathcal{S}$, in an implementation of this definition may be impracticable if the volume of the intermediate transform, $(F \cup\{T\})^{\mathrm{T}}$, is too large. An equivalent definition may be given in terms of the application of the fud, constrained to contain the disjoint transform of the ancestor state, $\left(\{R\}^{\mathrm{U}}\right.$, $\left.\operatorname{vars}(R)\right)$, to a unit scalar, $\operatorname{states}\left(\operatorname{apply}\left(F \cup\left\{T,\left(\{R\}^{\mathrm{U}}, \operatorname{vars}(R)\right)\right\}, \operatorname{scalar}(1)\right)\right) \subset \operatorname{std}\left((F \cup\{T\})^{\mathrm{T}}\right)$. That is,

$$
\begin{aligned}
& \operatorname{app}(U)(D, Q, R, F):= \\
& \quad\{((T, S), \operatorname{app}(U)(E, S, R \cup S, F \cup\{T\})):((P, T), E) \in D, P=Q, \\
& \quad S \in \operatorname{dom}(\operatorname{dom}(E)), W=\operatorname{vars}(R) \cup \operatorname{vars}(S), \\
& \\
& \left.\quad X=\operatorname{his}(F \cup\{T\}) \cup\left\{\{R\}^{\mathrm{U}},\{S\}^{\mathrm{U}}\right\}, R \cup S \in \operatorname{apply}\left(V, W, X, Z_{1}\right)^{\mathrm{S}}\right\} \\
& \cup\{((T, S), \emptyset):((P, T), E) \in D, P=Q, \\
& \\
& \quad S \in \operatorname{der}(T)^{\mathrm{CS}} \backslash \operatorname{dom}(\operatorname{dom}(E)), W=\operatorname{vars}(R) \cup \operatorname{vars}(S), \\
& \\
& \left.\quad X=\operatorname{his}(F \cup\{T\}) \cup\left\{\{R\}^{\mathrm{U}},\{S\}^{\mathrm{U}}\right\}, R \cup S \in \operatorname{apply}\left(V, W, X, Z_{1}\right)^{\mathrm{S}}\right\}
\end{aligned}
$$

where $V=\operatorname{und}(D)$ and $Z_{1}=\operatorname{scalar}(1)$.
The application tree $D^{*}=\operatorname{application}(U)(D)$ is defined only for distinct decompositions, $D \in \mathcal{D}_{\mathrm{d}, U}$. The application tree is such that only one transform appears in the roots,

$$
\forall E^{*} \in\left\{D^{*}\right\} \cup \operatorname{ran}\left(\operatorname{nodes}\left(D^{*}\right)\right)\left(\left|\operatorname{dom}\left(\operatorname{dom}\left(E^{*}\right)\right)\right|=1\right)
$$

The elements of the application tree are pairs of the transforms and their possible derived states, elements $\left(D^{*}\right) \subseteq \bigcup\{\{T\} \times \operatorname{std}(T): T \in \operatorname{transforms}(D)\}$,
where $\operatorname{std}(T)=\operatorname{dom}\left(T^{-1}\right)=\left(V^{\mathrm{C}} * T\right)^{\mathrm{FS}}$. Impossible derived states, $W^{\mathrm{CS}} \backslash$ $\operatorname{std}(T)$, where $W=\operatorname{der}(T)$, that exist if the transform is overlapped, $\neg \operatorname{overlap}(T)$, are excluded.

The application tree is constructed by concatenating the derived state $S$ of the transform $T$ to the accumulated derived state $R$ of the ancestors, $R \cup S$. Similarly the transform $T$ is concatenated to the accumulated functional definition set $F$ of the ancestors, $G=F \cup\{T\}$. Application trees exclude contradictions, $R \cup S \notin \mathcal{S}$, because these unions of states are not in the possible derived states of the accumulated functional definition set, $\operatorname{std}\left(G^{\mathrm{T}}\right) \subset \mathcal{S}$. The exclusion of contradictions occurs if the same derived variable appears more than once in a path. That is, if the same transform appears more than once. Multiple transforms in the same path are necessarily redundant because the application children have the same derived state. If the transform of the accumulated fud is overlapping, overlap $\left(G^{\mathrm{T}}\right)$, then it is not right total, $X \% W \neq W^{\mathrm{C}}$ where $(X, W)=G^{\mathrm{T}}$, and hence some of the cartesian derived states are excluded because they are impossible. In this case the set of possible derived states is a proper subset, $\operatorname{std}\left(G^{\mathrm{T}}\right) \subset W^{\mathrm{CS}}$.

The converse function that restores the distinct decomposition given the application is defined decomp $\in \operatorname{trees}(\mathcal{T} \times \mathcal{S}) \rightarrow \mathcal{D}$ as $\operatorname{decomp}\left(D^{*}\right):=$ $\operatorname{decomp}\left(\emptyset, D^{*}\right)$ where decomp $\in \mathcal{S} \times \operatorname{trees}(\mathcal{T} \times \mathcal{S}) \rightarrow \mathcal{D}$ is

$$
\begin{aligned}
& \operatorname{decomp}\left(R, D^{*}\right):= \\
& \qquad\left\{\left((R, T), \bigcup\left\{\operatorname{decomp}\left(S, E^{*}\right):\left((\cdot, S), E^{*}\right) \in D^{*}\right\}\right): T \in \operatorname{dom}\left(\operatorname{dom}\left(D^{*}\right)\right)\right\}
\end{aligned}
$$

A well behaved decomposition is equal to the converse of the application, decomp $(\operatorname{application}(U)(D))=D$. A well behaved decomposition is such that the set of its transforms equals that of its application, $\operatorname{transforms}(D)=$ dom (elements $\left.\left(D^{*}\right)\right)$. Let the set of well behaved decompositions in system $U$ be defined $\mathcal{D}_{\mathrm{w}, U}=\left\{D: D \in \mathcal{D}_{\mathrm{d}, U}\right.$, decomp(application $\left.\left.(U)(D)\right)=D\right\}$. The empty decomposition is not well behaved, $\{((\emptyset,(\emptyset, \emptyset)), \emptyset)\} \notin \mathcal{D}_{\mathrm{w}, U}$.

There are a couple of functions on paths in the application tree. Define transforms $\in \mathcal{L}\left(\mathcal{T}_{\mathrm{f}} \times \mathcal{S}\right) \rightarrow \mathcal{F}$ as transforms $(L):=\operatorname{dom}(\operatorname{set}(L))$. Define state $\in \mathcal{L}\left(\mathcal{T}_{\mathrm{f}} \times \mathcal{S}\right) \rightarrow \mathrm{P}(\mathcal{V} \times \mathcal{W})$ as state $(L):=\bigcup \operatorname{ran}(\operatorname{set}(L))$. The pair is sometimes expressed $(F, S)=(\operatorname{trn}(L), \operatorname{st}(L))$ where $\operatorname{trn}=$ transforms and st $=$ state.

The simple partition of a decomposition is $G^{\mathrm{TP}}$ where $G=\operatorname{transforms}(D)$. $G$ is the union of the transforms of the decomposition. However, the sim-
ple partition does not correspond to the purpose of decompositions which is to represent contingent application of child transforms. That is, the transforms of paths in a decomposition application tree are unioned into functional definition sets and applied to histograms separately, $A * F$ where $F=\operatorname{transforms}(L)$ and $L \in \operatorname{paths}\left(D^{*}\right)$.

The partition of a well behaved distinct decomposition is derived from the paths of the decomposition application. Define partition $(U) \in \mathcal{D}_{\mathrm{w}, U} \rightarrow \mathcal{R}_{U}$ as
$\operatorname{partition}(U)(D):=\left\{\left(\operatorname{his}\left(G^{\mathrm{T}}\right) *\{S\}^{\mathrm{U}} \% V\right)^{\mathrm{S}}: L \in \operatorname{paths}\left(D^{*}\right), S=\operatorname{state}(L)\right\}$
where $D^{*}=\operatorname{application}(U)(D), V=\operatorname{und}(D)$, and $G=\operatorname{transforms}(D)$. An equivalent definition in terms of a more tractable navigated fud application is

$$
\begin{aligned}
& \operatorname{partition}(U)(D):= \\
& \quad\left\{\operatorname{apply}\left(V, V, \operatorname{his}(F) \cup\left\{V^{\mathrm{C}},\{S\}^{\mathrm{U}}\right\}, Z_{1}\right)^{\mathrm{S}}:\right. \\
& \left.\quad L \in \operatorname{paths}\left(D^{*}\right),(F, S)=(\operatorname{trn}(L), \operatorname{st}(L))\right\}
\end{aligned}
$$

Define shorthand $D^{\mathrm{P}}=\operatorname{partition}(U)(D)$. The partition variables are the underlying variables of the decomposition, $\operatorname{vars}\left(D^{\mathrm{P}}\right)=\operatorname{und}(D)$. The union of non-empty components is a partition because each of the unions of the one functional transforms in the initial sub-paths of the decomposition is a one functional definition set and therefore a partition, $\forall L \in \operatorname{subpaths}(D) \diamond F=$ transforms $(L)\left(F^{\mathrm{TP}} \in \mathcal{R}_{U}\right)$. If the distinct decomposition consists only of a root transform, elements $(D)=\operatorname{roots}(D)=\{(\emptyset, T)\}$, then the partition is simply that of the transform, $D^{\mathrm{P}}=T^{\mathrm{P}}$. The decomposition partition is a parent partition of the simple partition, parent $\left(D^{\mathrm{P}}, G^{\mathrm{TP}}\right)$ where $G=\operatorname{transforms}(D)$. Hence of the cardinality of the simple partition is greater than or equal to that of the partition, $\left|G^{\mathrm{TP}}\right| \geq\left|D^{\mathrm{P}}\right|$.

A tree of components can be mapped cumulatively from the application tree. Define component $(U, V) \in \mathcal{L}\left(\mathcal{T}_{U, \mathrm{f}, 1} \times \mathcal{S}_{U}\right) \rightarrow \mathrm{P}\left(V^{\mathrm{CS}}\right)$ for some variables $V \subset \mathcal{V}_{U}$ as

$$
\operatorname{component}(U, V)(L):=\left(\operatorname{inverse}\left(F^{\mathrm{T}}\right)(S) * V^{\mathrm{C}}\right)^{\mathrm{S}}
$$

where $F=\operatorname{transforms}(L)$ and $S=\operatorname{state}(L)$. An equivalent definition in terms of fud application is

$$
\text { component }(U, V)(L):=\operatorname{apply}\left(V, V, \operatorname{his}(F) \cup\left\{V^{\mathrm{C}},\{S\}^{\mathrm{U}}\right\}, Z_{1}\right)^{\mathrm{S}}
$$

Define components $(U) \in \mathcal{D}_{\mathrm{d}, U} \rightarrow \operatorname{trees}\left(\mathrm{P}\left(V^{\mathrm{CS}}\right)\right)$ as

$$
\operatorname{components}(U)(D):=\operatorname{mapAccum}\left(\operatorname{component}(U, V), D^{*}\right)
$$

where $D^{*}=\operatorname{application}(U)(D)$ and $V=\operatorname{und}(D)$. In this definition, the inverse component is expanded by multiplication with $V^{\mathrm{C}}$.

The decomposition partition can also be defined in terms of the accumulated path fuds

$$
\operatorname{partition}(U)(D):=\left\{\operatorname{component}(U, V)(L): L \in \operatorname{paths}\left(D^{*}\right)\right\}
$$

or from the components tree leaves

$$
\operatorname{partition}(U)(D):=\operatorname{leaves}(\operatorname{components}(U)(D))
$$

The child components of the components tree are subsets of their parent components, $\forall\left(C_{1}, C_{2}\right) \in \operatorname{step}(Y)\left(C_{2} \subseteq C_{1}\right)$ where $Y=\operatorname{components}(U)(D)$. Each component of the components tree exists at a unique place, $\left\{\left(L_{|L|}, L\right)\right.$ : $L \in \operatorname{subpaths}(Y)\} \in \mathrm{P}\left(V^{\mathrm{CS}}\right) \rightarrow \mathcal{L}\left(\mathrm{P}\left(V^{\mathrm{CS}}\right)\right)$.

A well behaved distinct decomposition $D \in \mathcal{D}_{\mathrm{w}, U}$ in system $U$ contains a variable symmetry if $\exists(L, T),(M, R) \in Q((L \neq M) \wedge(\operatorname{der}(T) \cap \operatorname{der}(R) \neq \emptyset))$ where $Q=\left\{(L, T):\left(L, E^{*}\right) \in \operatorname{places}\left(D^{*}\right), T \in \operatorname{dom}\left(\operatorname{dom}\left(E^{*}\right)\right)\right\} \in \mathcal{L}\left(\mathcal{T}_{\mathrm{f}} \times\right.$ $\mathcal{S}) \rightarrow \mathcal{T}_{\mathrm{f}}$ and $D^{*}=\operatorname{application}(U)(D)$. The transforms of the decomposition form a fud which implies that the derived variables are uniquely defined. Therefore a variable symmetry is also a transform symmetry. That is, more strictly, $\exists(L, T),(M, R) \in Q((L \neq M) \wedge(T=R))$.

In the still stricter case of $\exists\left(L, E^{*}\right),\left(M, G^{*}\right) \in \operatorname{places}\left(D^{*}\right)\left((L \neq M) \wedge\left(E^{*}=\right.\right.$ $\left.G^{*} \neq \emptyset\right)$ ) then $D$ contains an application symmetry. In this case there is a bijection between the child components of $L,\left\{\operatorname{inverse}\left(F^{\mathrm{T}}\right)(S): N \in\right.$ $\left.\operatorname{paths}\left(E^{*}\right), P=\operatorname{concat}(L, N),(F, S)=(\operatorname{trn}(P), \operatorname{st}(P))\right\}$ and the child components of $M$.

If the same non-root transform symmetry, $T \neq T_{\mathrm{r}}$ where $\left\{\left(\emptyset, T_{\mathrm{r}}\right)\right\}=\operatorname{roots}(D)$, exists in all paths, $\forall L \in \operatorname{paths}(D)(T \in \operatorname{dom}(\operatorname{set}(L)))$, then the decomposition has a non-contingent symmetry. If the non-contingent symmetry, $T$, is also an application symmetry everywhere, the decomposition could be broken into two distinct decompositions at the non-contingent symmetry.

If it is the case that each node in a well behaved distinct decomposition $D \in$
$\mathcal{D}_{\mathrm{w}, U}$ has a single transform, $\forall E \in\{D\} \cup \operatorname{ran}(\operatorname{nodes}(D))(|\operatorname{ran}(\operatorname{dom}(E))|=1)$ then $D$ is completely symmetrical and there is a unique path of transforms, $|\{\{(i, T):(i,(\cdot, T)) \in L\}: L \in \operatorname{paths}(D)\}|=1$. In this case the partition equals the simple partition, $D^{\mathrm{P}}=G^{\mathrm{TP}}$ where $G=\operatorname{transforms}(D)$.

A decomposition application tree $D^{*}$ that has at least two children per node, $\forall E^{*} \in\left\{D^{*}\right\} \cup \operatorname{ran}\left(\operatorname{nodes}\left(D^{*}\right)\right)\left(E^{*} \neq \emptyset \Longrightarrow\left|E^{*}\right| \geq 2\right)$, has a depth that is limited by the cardinality of the self-partition of the underlying variables $V$ which is the underlying volume, $\left|V^{\mathrm{CS}\{ \}}\right|=\left|V^{\mathrm{C}}\right|$. That is, $\operatorname{depth}\left(D^{*}\right) \leq$ $\operatorname{ceil}\left(\log _{2}\left(\left|V^{\mathrm{C}}\right|\right)\right)$.

A contingent tree of pairs of components and transforms can be mapped cumulatively from a decomposition $D \in \mathcal{D}$. Define contingent $\in \mathcal{L}\left(\mathcal{S} \times \mathcal{T}_{\mathfrak{f}}\right) \rightarrow$ $\mathcal{A} \times \mathcal{T}_{\mathrm{f}}$ as

$$
\begin{aligned}
& \operatorname{contingent}(L):=\left(\operatorname{inverse}\left(F^{\mathrm{T}}\right)(S), T\right): \\
& \quad(\cdot, T)=L_{|L|}, F=\operatorname{ran}\left(\operatorname{set}\left(L_{\{1 \ldots|L|-1\}}\right)\right), S=\bigcup \operatorname{dom}(\operatorname{set}(L))
\end{aligned}
$$

where contingent $(\{(1,(\cdot, T))\}):=(\operatorname{scalar}(1), T)$. An equivalent definition in terms of fud application is

$$
\operatorname{contingent}(L):=\left(\operatorname{apply}\left(V, V, \operatorname{his}(F) \cup\left\{\{S\}^{\mathrm{U}}\right\}, Z_{1}\right)^{\mathrm{F}}, T\right)
$$

Define contingents $\in \mathcal{D} \rightarrow \operatorname{trees}\left(\mathcal{A} \times \mathcal{T}_{\mathrm{f}}\right)$ as

$$
\operatorname{contingents}(D):=\text { mapAccum(contingent, } D)
$$

In this definition, the inverse component, inverse $\left(F^{\mathrm{T}}\right)(S)$, is not expanded. The places of the application tree, $D^{*}$, are related to the contingent tree,

$$
\begin{aligned}
& \left\{\left(\operatorname{inverse}\left(F^{\mathrm{T}}\right)(S), T\right):\right. \\
& \left.\left(L, E^{*}\right) \in \operatorname{places}\left(D^{*}\right),(F, S)=(\operatorname{trn}(L), \operatorname{st}(L)), T \in \operatorname{dom}\left(\operatorname{dom}\left(E^{*}\right)\right)\right\} \\
\subseteq & \operatorname{elements}(\operatorname{contingents}(D))
\end{aligned}
$$

The application tree of the decomposition $D$ applied to histogram $A$, is related to the contingent tree,

$$
\{B:(\cdot, B) \in \operatorname{elements}(A * D)\}=\{A * C * T:(C, T) \in \operatorname{cont}(D)\}
$$

where $\operatorname{cont}(D)=\operatorname{elements}(\operatorname{contingents}(D))$.

The definition of the partition, $D^{\mathrm{P}}$, of a well behaved distinct decomposition $D \in \mathcal{D}_{\mathrm{w}, U}$ implies a transform, $D^{\mathrm{PT}}$, which is mono-variate in the derived variables, $\left|\operatorname{der}\left(D^{\mathrm{PT}}\right)\right|=1$, like any partition transform. A crown transform can be derived from a well behaved distinct decomposition's application. First, a transform slice tree is constructed which consists of singleton pointed binary partitions. Define sliceTransforms $(U) \in \mathcal{D}_{\mathrm{w}, U} \rightarrow \operatorname{trees}\left(\mathcal{R}_{*, U, \mathrm{~s}, \mathrm{~b}}\right)$ as

$$
\text { sliceTransforms }(U)(D):=\operatorname{map}\left(\operatorname{slice}(U), D^{*}\right)
$$

where $D^{*}=\operatorname{application}(U)(D)$ and slice $(U) \in\left(\mathcal{T}_{U, \mathrm{f}, 1} \times \mathcal{S}_{U}\right) \rightarrow \mathcal{R}_{*, U, \mathrm{~s}, \mathrm{~b}}$ is defined as

$$
\operatorname{slice}(U)((T, S)):=\left(\left\{\{S\}, \operatorname{der}(T)^{\mathrm{CS}} \backslash\{S\}\right\},\{S\}\right)
$$

The same transform may appear more than once in the decomposition. Thus there may be fewer transform slices than the places in the application tree, $\mid$ elements(sliceTransforms $(U)(D))\left|\leq\left|\operatorname{places}\left(D^{*}\right)\right|\right.$.

Second, the contingent slice tree is constructed by inheriting a logical and operation on the underlying transform slice and the parent contingent slice. Like the transform slices, the contingent slices are singleton pointed binary partitions. Define sliceContingents $(U) \in \mathcal{D}_{\mathrm{w}, U} \rightarrow \operatorname{trees}\left(\mathcal{R}_{*, U, \mathrm{~s}, \mathrm{~b}}\right)$ as

$$
\text { sliceContingents }(U)(D):=\operatorname{and}(\text { sliceTransforms }(U)(D))
$$

where the and binary operation on pointed binary partition trees is defined above as and $\in \operatorname{trees}\left(\mathcal{R}_{*, \mathrm{~b}}\right) \rightarrow \operatorname{trees}\left(\mathcal{R}_{*, \mathrm{~s}, \mathrm{~b}}\right)$ as

$$
\operatorname{and}(Z):=\left\{\left(P_{*}, \operatorname{and}\left(P_{*}, X\right)\right):\left(P_{*}, X\right) \in Z\right\}
$$

Define and $\in \mathcal{R}_{*, \mathrm{~b}} \times \operatorname{trees}\left(\mathcal{R}_{*, \mathrm{~b}}\right) \rightarrow \operatorname{trees}\left(\mathcal{R}_{*, \mathrm{~s}, \mathrm{~b}}\right)$ as

$$
\operatorname{and}\left(P_{*}, Z\right):=\left\{\left(M_{*}, \operatorname{and}\left(M_{*}, X\right)\right):\left(R_{*}, X\right) \in Z, M_{*}=\operatorname{and}\left(P_{*}, R_{*}\right)\right\}
$$

Let the set $N$ of slice partitions be $N=$ elements(sliceTransforms $(U)(D)) \cup$ elements(sliceContingents $(U)(D)$ ). The point component $C_{*}$ of the transform and contingent slices, $\left(\left\{C_{*}, C_{*}^{\prime}\right\}, C_{*}\right) \in N$, is called the in-slice component. The complement point component $C_{*}^{\prime}$ is called the out-slice component.

The slices fud is the set of transforms of the union of (i) the transform slices and (ii) the contingent slices. Define slices $(U) \in \mathcal{D}_{\mathrm{w}, U} \rightarrow \mathcal{F}_{U, 1}$ as

$$
\begin{aligned}
& \operatorname{slices}(U)(D):= \\
& \quad\left\{P_{*}^{\mathrm{T}}: P_{*} \in \operatorname{elements}(\operatorname{sliceTransforms}(U)(D)) \cup\right. \\
& \quad \text { elements }(\text { sliceContingents }(U)(D))\}
\end{aligned}
$$

The underlying variables of the slices fud, slices $(U)(D)$, equals the derived variables of the well behaved decomposition transforms, $\operatorname{und}(H)=\operatorname{der}(G)$ where $G=\operatorname{transforms}(D)$ and $H=\operatorname{slices}(U)(D)$.

The transforms in the slices fud have underlying volumes no greater than the largest derived volume of the decomposition transforms, $\operatorname{maxr}\left(\left\{\left(T,\left|V^{\mathrm{C}}\right|\right)\right.\right.$ : $T \in \operatorname{slices}(U)(D), V=\operatorname{und}(T)\}=\operatorname{maxr}\left(\left\{\left(R,\left|W^{\mathrm{C}}\right|\right): R \in G, W=\right.\right.$ $\operatorname{der}(T)\}$ where $G=\operatorname{transforms}(D)$. If the slice transforms were instead constructed from the accumulated fud $F$ and state $S$ of each path $L$ in the application tree $D^{*},\left\{\left\{\{S\}, \operatorname{der}\left(F^{\mathrm{T}}\right)^{\mathrm{CS}} \backslash\{S\}\right\}^{\mathrm{T}}: L \in \operatorname{paths}\left(D^{*}\right),(F, S)=\right.$ (transforms $(L)$, state $(L))\}$, there would be no need for a tree of contingent slices but the maximum underlying volume would be as large as the derived volume of the largest accumulated path fud, $\operatorname{maxr}\left(\left\{\left(L,\left|W^{\mathrm{C}}\right|\right): L \in\right.\right.$ $\left.\operatorname{paths}\left(D^{*}\right), F=\operatorname{transforms}(L), W=\operatorname{der}(F)\right\}$.

The crown transform is transform of the union of (i) the transforms fud and (ii) the slices fud, of a well behaved distinct decomposition. Define transformCrown $(U) \in \mathcal{D}_{\mathrm{w}, U} \rightarrow \mathcal{T}_{U, \mathrm{f}, 1}$ as

$$
\operatorname{transformCrown}(U)(D):=(G \cup H)^{\mathrm{T}}
$$

where $G=\operatorname{transforms}(D)$ and $H=\operatorname{slices}(U)(D)$. The underlying variables of the crown transform equals the underlying variables of the decomposition, $\operatorname{und}(T)=\operatorname{und}(D)$ where $T=\operatorname{transformCrown}(U)(D)$. The crown transform is such that crown $(X \% W)$ is true, where $(X, W)=T$. Another way of stating this is $\operatorname{crown}\left(V^{\mathrm{C}} * T\right)$, where $V=\operatorname{und}(D)$. The partition of the crown transform equals the decomposition partition, $T^{\mathrm{P}}=D^{\mathrm{P}}$. However the converse does not hold, $T \neq D^{\mathrm{PT}}$ because the crown transform is necessarily pluri-variate in its derived variables, $|\operatorname{der}(T)|>1$.

The transforms of the slices fud $H=\operatorname{slices}(U)(D) \in \mathcal{F}$ are derived from singleton pointed binary partitions, $\mathcal{R}_{*, \mathrm{~s}, \mathrm{~b}}$, but lose the knowledge of the in-slice point component because there is no converse function for transform $\in \mathcal{R}_{*} \rightarrow$ $\mathcal{T}_{\mathfrak{f}, \mathrm{U}}$. However, because both the transform and contingent slices are singleton pointed partitions, the in-slice derived state $S$ can be identified by the cardinality of its component, $\mid$ inverse $(T)(S) \mid=1$ where $T \in H$, or $S=\{(P, C)\}$ where $P=T^{\mathrm{P}}, C \in P$ and $|C|=1$. Of course, in the case of a decomposition with a root transform, $T \in \operatorname{ran}(\operatorname{roots}(D))$, which has only two derived states, $\left|\operatorname{der}(T)^{\mathrm{CS}}\right|=2$, both the in-slice and out-slice state has singleton components. An alternative is to create slice variables explicitly, for example defined for each sub-path in the application tree, subpaths $\left(D^{*}\right) \subset \mathcal{V}$. Each of these slice
variables would have well-known values, for example $\{$ in, out $\} \subset \mathcal{W}$. The inslice derived states of the transforms containing the explicitly defined slice variables could then be easily identified without relying on the cardinality.

A set of nullable pointed partitions can be derived from the contingent slice pointed partition tree, sliceContingents $(U)(D) \in \operatorname{trees}\left(\mathcal{R}_{*, U, \mathrm{~s}, \mathrm{~b}}\right)$. First, obtain the or pointed binary partition of the set of parent contingent slice partitions for each derived variable of the transforms of the decomposition. Define $\operatorname{varsSliceAlternates}(U) \in \mathcal{D}_{\mathrm{w}, U} \rightarrow \mathrm{P}\left(\mathcal{V}_{U} \times \mathcal{R}_{*, U, \mathrm{~s}, \mathrm{~b}}\right)$ as

$$
\begin{aligned}
& \text { varsSliceAlternates }(U)(D):= \\
& \quad\{(w, \text { or }(N)):(w, N) \in \text { inverse }(\text { slicesVars }(U)(D))\}
\end{aligned}
$$

where $\operatorname{slices} \operatorname{Vars}(U) \in \mathcal{D}_{\mathrm{w}, U} \rightarrow \mathrm{P}\left(\mathcal{R}_{*, U, \mathrm{~s}, \mathrm{~b}} \times \mathcal{V}_{U}\right)$ is defined as

$$
\begin{aligned}
& \text { slicesVars }(U)(D):= \\
& \qquad\left\{\left(P_{*}, w\right):\left(P_{*}, Q_{*}\right) \in \operatorname{steps}(\text { sliceContingents }(U)(D)),\right. \\
& \left.\quad(P, \cdot)=P_{*},\{P, X\}=\operatorname{vars}\left(Q_{*}\right), w \in \operatorname{vars}(X)\right\}
\end{aligned}
$$

where the n -ary or operation on a set of pointed binary partitions, or $\in$ $\mathrm{P}\left(\mathcal{R}_{*, \mathrm{~b}}\right) \rightarrow \mathcal{R}_{*, \mathrm{~b}}$, is defined above. If there are symmetries for variable $w \in \operatorname{der}\left(G^{\mathrm{T}}\right)$, where $G=\operatorname{transforms}(D)$, then the cardinality of the slices corresponding to $w$ is greater than one, $\mid$ inverse $(\operatorname{slicesVars}(U)(D))(w) \mid>1$, and the alternate slice will have more than one underlying contingent slice, $|\operatorname{vars}(\operatorname{varsSliceAlternates}(U)(D)(w))|>1$.

Then, obtain the nullable pointed partition of the derived variable and the or pointed binary partition of the alternate slices of the decomposition. Define nullables $(U) \in \mathcal{D}_{\mathrm{w}, U} \rightarrow \mathrm{P}\left(\mathcal{R}_{*, U}\right)$ as

$$
\begin{aligned}
& \text { nullables }(U)(D):= \\
& \quad\left\{\operatorname{nullable}(U)\left(w, P_{*}\right):\left(w, P_{*}\right) \in \operatorname{varsSliceAlternates}(U)(D)\right\}
\end{aligned}
$$

where nullable $(U) \in \mathcal{V}_{U} \times \mathcal{R}_{*, U, \mathrm{~b}} \rightarrow \mathcal{R}_{*, U}$ is defined above.
The nullable fud is the union of (i) full functional self partition transforms of the variables of the root transform, (ii) the non-leaf transform slice transforms, (iii) the non-leaf contingent slice transforms, (iv) the alternate slice transforms, and (v) the nullable transforms, of a distinct decomposition. De-
fine nullable $(U) \in \mathcal{D}_{\mathrm{w}, U} \rightarrow \mathcal{F}_{U, 1}$ as

$$
\begin{aligned}
& \text { nullable }(U)(D):= \\
& \qquad\left\{\{w\}{ }^{\mathrm{CS}\{ \} \mathrm{T}}: T \in \operatorname{ran}(\operatorname{roots}(D)), w \in \operatorname{der}(T)\right\} \cup \\
& \left\{P_{*}^{\mathrm{T}}: P_{*} \in \operatorname{nonleaves}(\operatorname{sliceTransforms}(U)(D)) \cup\right. \\
& \quad \text { nonleaves }(\text { sliceContingents }(U)(D)) \cup \\
& \quad \text { ran }(\operatorname{varsSliceAlternates}(U)(D)) \cup \\
& \quad \text { nullables }(U)(D)\}
\end{aligned}
$$

where nonleaves $(Z)=\operatorname{elements}(Z) \backslash \operatorname{leaves}(Z)$.
The nullable transform of a well behaved distinct decomposition is the transform of the union of (i) the transforms fud and (ii) the nullable fud. Define transform $(U) \in \mathcal{D}_{\mathrm{w}, U} \rightarrow \mathcal{T}_{U, \mathrm{f}, 1}$ as

$$
\operatorname{transform}(U)(D):=D^{\mathrm{FT}}
$$

where $D^{\mathrm{F}}:=\operatorname{transforms}(D) \cup$ nullable $(U)(D)$. Define shorthand $D^{\mathrm{T}}:=$ transform $(U)(D)=D^{\mathrm{FT}}$. The underlying variables of the nullable transform equals the underlying variables of the decomposition, $\operatorname{und}\left(D^{\mathrm{T}}\right)=\operatorname{und}(D)$. The partition of the nullable transform equals the decomposition partition, $D^{\mathrm{TP}}=D^{\mathrm{P}}$. However the converse does not hold, $D^{\mathrm{T}} \neq D^{\mathrm{PT}}$ because the nullable transform is necessarily pluri-variate in its derived variables, $\left|\operatorname{der}\left(D^{\mathrm{T}}\right)\right|>1$, unless it trivially consists of nothing but a mono-variate root transform, $|\operatorname{der}(T)|=1$ where $\{(\emptyset, T)\}=D$.

The function originals $(U) \in \mathcal{D}_{\mathrm{w}, U} \rightarrow\left(\mathcal{V}_{U} \rightarrow \mathcal{V}_{U}\right)$ recovers the map from the nullable derived variables to the root and transform derived variables

$$
\begin{aligned}
& \text { originals }(U)(D):= \\
& \quad\left\{\left(\{w\}^{\mathrm{CS}\{ \}}, w\right): T \in \operatorname{ran}(\operatorname{roots}(D)), w \in \operatorname{der}(T)\right\} \cup \\
& \quad\{(P, w): P \in \operatorname{dom}(\operatorname{nullables}(U)(D)),\{w\}=\operatorname{vars}(P) \cap \operatorname{der}(G)\}
\end{aligned}
$$

where $G=\operatorname{transforms}(D)$. So originals $(U)(D) \in \operatorname{der}\left(D^{\mathrm{T}}\right) \rightarrow \operatorname{der}(G)$. If it is the case that none of the root transform derived variables of a well behaved decomposition $D \in \mathcal{D}_{\mathrm{w}, U}$ are symmetrical, $\operatorname{der}(T) \cap \operatorname{der}(G \backslash\{T\})=\emptyset$ where $\{T\}=\operatorname{ran}(\operatorname{roots}(D))$, then the mapping is a bijection, originals $(U)(D) \in$ $\operatorname{der}\left(D^{\mathrm{T}}\right) \leftrightarrow \operatorname{der}(G)$.

The full functional self partition transforms, $\left\{\{w\}^{\operatorname{CS}\{ \} \mathrm{T}}: w \in W_{\mathrm{r}}\right\}$, of the derived variables $W_{\mathrm{r}}=\operatorname{der}\left(T_{\mathrm{r}}\right)$ of the root transform $T_{\mathrm{r}} \in \operatorname{ran}(\operatorname{roots}(D))$, are
transforms, $\left\{P^{\mathrm{T}}: P \in N_{\mathrm{r}}\right\}$, of the root frame variables $N_{\mathrm{r}}=\left\{\{w\}^{\mathrm{CS}\{ \}}: w \in\right.$ $\left.W_{\mathrm{r}}\right\}$. The use of root frame variables, $N_{\mathrm{r}}$, in the nullable fud, nullable $(U)(D)$, is necessary to ensure that the derived variables of the root transform, $W_{\mathrm{r}}$, are indirectly represented in the derived variables of the nullable transform. This is because the root transform derived variables, $W_{\mathrm{r}}$, are underlying variables of the slice transforms,

$$
\left.W_{\mathrm{r}} \subseteq \operatorname{und}\left(\left\{P_{*}^{\mathrm{T}}: P_{*} \in \text { elements(sliceTransforms }(U)(D)\right)\right\}\right)
$$

and so are hidden in the nullable fud, $W_{\mathrm{r}} \cap \operatorname{der}(\operatorname{nullable}(U)(D))=\emptyset$, and hence cannot be in the derived variables of the nullable transform, $W_{\mathrm{r}} \cap$ $\operatorname{der}\left(D^{\mathrm{T}}\right)=\emptyset$. Instead, the root frame variables are in the derived variables of the nullable transform, $N_{\mathrm{r}} \subseteq \operatorname{der}\left(D^{\mathrm{T}}\right)$.

If the decomposition consists solely of a root transform $T_{\mathrm{r}}$ where $\left\{\left(\left(\emptyset, T_{\mathrm{r}}\right), \emptyset\right)\right\}=$ $D$ then the nullable transform is a value full functional transform of the root transform. That is, the nullable transform is a reframe transform. In this case, the partition of the nullable transform equals the partition of $T_{\mathrm{r}}$, $D^{\mathrm{TP}}=T_{\mathrm{r}}^{\mathrm{P}}$, and the volume of the derived variables of the nullable transform equals the volume of the derived variables of $T_{\mathrm{r}},\left|\operatorname{der}\left(D^{\mathrm{T}}\right)^{\mathrm{C}}\right|=\left|\operatorname{der}\left(T_{\mathrm{r}}\right)^{\mathrm{C}}\right|$.

If the decomposition contains nullable variables, nullables $(U)(D) \neq \emptyset$, then the volume of the derived variables of the nullable transform is greater than the volume of the derived variables of the transforms, $\left|\operatorname{der}\left(D^{\mathrm{T}}\right)^{\mathrm{C}}\right|>$ $\left|\operatorname{der}(G)^{\mathrm{C}}\right|$. This is because the nullable variables have an additional null value with respect to their corresponding originating variable, $\exists(w, v) \in$ originals $(U)(D)\left(\left|U_{w}\right|=\left|U_{v}\right|+1\right)$.

The application of the transform of a well behaved distinct decomposition $D$ to the cartesian of the underlying decomposition variables $\operatorname{und}(D)=$ $V \subset \mathcal{V}_{U}$, followed by the reduction to the root frame variables, form a completely effective histogram if the root transform is non-overlapping. Let $\left\{T_{\mathrm{r}}\right\}=\operatorname{ran}(\operatorname{roots}(D)), \neg \operatorname{overlap}\left(T_{\mathrm{r}}\right)$ and $N_{\mathrm{r}}=\left\{\{w\}^{\mathrm{CS}\{ \}}: w \in \operatorname{der}\left(T_{\mathrm{r}}\right)\right\}$ where $D \in \mathcal{D}_{\mathrm{w}, U}$ and $\operatorname{und}(D)=V$. Then $\left(V^{\mathrm{C}} * T_{\mathrm{r}}\right)^{\mathrm{F}}=W_{\mathrm{r}}^{\mathrm{C}}$ where $W_{\mathrm{r}}=\operatorname{der}\left(T_{\mathrm{r}}\right)$ and

$$
\left(V^{\mathrm{C}} * D^{\mathrm{T}} \% N_{\mathrm{r}}\right)^{\mathrm{F}}=N_{\mathrm{r}}^{\mathrm{C}}
$$

If the decomposition contains nullable variables then the decomposition transform is overlapping,

$$
\text { nullables }(U)(D) \neq \emptyset \Longrightarrow \operatorname{overlap}\left(D^{\mathrm{T}}\right)
$$

This is because the nullable variables depend via alternate, contingent and transform slice variables on ancestor transform derived variables, which themselves have dependent variables in the nullable fud derived variables. Let $F=\operatorname{nullable}(U)(D)$, then $\forall n \in \operatorname{dom}(\operatorname{nullables}(U)(D)) \exists u \in \operatorname{der}(F)((u \neq$ $n) \wedge(\operatorname{und}(\operatorname{depends}(F,\{u\})) \cap \operatorname{und}(\operatorname{depends}(F,\{n\})) \neq \emptyset))$. The transform is necessarily overlapping whatever symmetries exist because of the additional null value of the nullable variables. The null value exists even if none of the possible derived states are null. In particular, all nullable variables depend on the root transform derived variables, $\forall n \in \operatorname{dom}(\operatorname{nullables}(U)(D))\left(\operatorname{der}\left(T_{\mathrm{r}}\right) \subset\right.$ $\operatorname{und}(\operatorname{depends}(F,\{n\})))$.

In the case where there are nullable variables, nullables $(U)(D) \neq \emptyset$, and the transforms are also all mono-derived-variate transforms, $\forall T \in G(|\operatorname{der}(T)|=$ $1)$, the application to the cartesian is skeletal, skeleton $\left(V^{\mathrm{C}} * D^{\mathrm{T}}\right)$, and any non-singleton subset of the decomposition derived variables is contingent and overlapping

$$
\forall J \subseteq \operatorname{der}\left(D^{\mathrm{T}}\right)\left(|J|>1 \Longrightarrow\left(V^{\mathrm{C}} * D^{\mathrm{T}} \% J\right)^{\mathrm{F}} \neq J^{\mathrm{C}}\right)
$$

The application of an overlapping decomposition transform, $\operatorname{overlap}\left(D^{\mathrm{T}}\right)$, to the cartesian is incompletely effective, $\left(V^{\mathrm{C}} * D^{\mathrm{T}}\right)^{\mathrm{F}}<N^{\mathrm{C}}$ where $N=\operatorname{der}\left(D^{\mathrm{T}}\right)$. That is, the possible derived volume $w^{\prime}=\left|\left(V^{\mathrm{C}} * D^{\mathrm{T}}\right)^{\mathrm{F}}\right|=\left|D^{\mathrm{P}}\right|=\left|\left(D^{\mathrm{T}}\right)^{-1}\right|$ is less the derived volume, $w^{\prime}<w$, where $w=\left|N^{\mathrm{C}}\right|$. The possible derived volume, $w^{\prime}$, may be calculated from the contingent possible derived volumes of the decomposition's transforms,

$$
\begin{aligned}
w^{\prime} & =\left|\left(V^{\mathrm{C}} * T_{\mathrm{r}}\right)^{\mathrm{F}}\right|+\sum\left(\left|(C * T)^{\mathrm{F}}\right|-1:(C, T) \in \operatorname{cont}(D),(C, T) \neq\left(V^{\mathrm{C}}, T_{\mathrm{r}}\right)\right) \\
& =\sum\left(\left|(C * T)^{\mathrm{F}}\right|:(C, T) \in \operatorname{cont}(D)\right)+1-|\operatorname{cont}(D)|
\end{aligned}
$$

where cont $=$ elements o contingents. The possible derived volume, $w^{\prime}$, is bounded by the possible derived volumes of the individual transforms,

$$
\begin{aligned}
w^{\prime} & \leq\left|T_{\mathrm{r}}^{-1}\right|+\sum_{T \in G, T \neq T_{\mathrm{r}}}\left(\left|T^{-1}\right|-1\right) \\
& =\sum_{T \in G}\left(\left|T^{-1}\right|\right)+1-|G|
\end{aligned}
$$

where there are no transform symmetries, $|\operatorname{nodes}(D)|=|G|$. In the case where all transforms are non-overlapping, $\forall T \in G(\neg \operatorname{overlap}(T))$, the possible
derived volume is bounded

$$
\begin{aligned}
w^{\prime} & \leq\left|W_{\mathrm{r}}^{\mathrm{C}}\right|+\sum_{T \in G, T \neq T_{\mathrm{r}}}\left(\left|W_{T}^{\mathrm{C}}\right|-1\right) \\
& =\sum_{T \in G}\left(\left|W_{T}^{\mathrm{C}}\right|\right)+1-|G|
\end{aligned}
$$

This calculation is only an upper bound for the possible derived volume, $w^{\prime}$, because it ignores overlaps between transforms in the same path, whether the transforms themselves are overlapping or not. Let $\left(C_{1}, T_{1}\right),\left(C_{2}, T_{2}\right) \in$ cont $(D)$ such that $T_{1} \neq T_{2}, C_{1} \supset C_{2}, ~ \neg \operatorname{overlap}\left(T_{1}\right)$ and $\neg \operatorname{overlap}\left(T_{2}\right)$. Then $\operatorname{overlap}\left(\left\{T_{1}, T_{2}\right\}\right) \Longrightarrow\left|\left(\left\{T_{1}, T_{2}\right\}\right)^{-1}\right|<\left|T_{1}^{-1}\right|\left|T_{2}^{-1}\right|=\left|\operatorname{der}\left(\left\{T_{1}, T_{2}\right\}\right)^{\mathrm{C}}\right|$, and $\operatorname{overlap}\left(\left\{T_{1}, T_{2}\right\}\right) \Longrightarrow\left|\left(C_{1} * T_{1}\right)^{\mathrm{F}}\right|+\left|\left(C_{2} * T_{2}\right)^{\mathrm{F}}\right| \leq\left|\left(C_{1} * T_{1}\right)^{\mathrm{F}}\right|+\mid\left(C_{1} *\right.$ $\left.T_{2}\right)^{\mathrm{F}} \mid$. This is more obvious when viewed in terms of the accumulated states and fuds of subpaths of the decomposition. Let $L \in \operatorname{paths}(D), L_{2} \in$ $\operatorname{subpaths}(L), L_{1} \in \operatorname{subpaths}\left(L_{2}\right)$, such that (i) $\left(F_{1}, R_{1}\right)=\left(\operatorname{trn}\left(L_{1}\right), \operatorname{st}\left(L_{1}\right)\right)$ and $\operatorname{his}\left(F_{1}\right) *\left\{R_{1}\right\}^{\mathrm{U}} \% V=C_{1}$, and (ii) $\left(F_{2}, R_{2}\right)=\left(\operatorname{trn}\left(L_{2}\right), \operatorname{st}\left(L_{2}\right)\right)$ and $\operatorname{his}\left(F_{2}\right) *\left\{R_{2}\right\}^{U} \% V=C_{2}$. Then $\left\{T_{1}, T_{2}\right\} \subseteq F_{2}$ and overlap $\left(F_{2}\right)$.

The reduced application of the nullables of a non-root transform $T$ form a pivot histogram. Let $Y=\left\{P_{*}: P_{*} \in \operatorname{nullables}(U)(D), \operatorname{vars}\left(P_{*}\right) \cap \operatorname{der}(T) \neq \emptyset\right\}$ where $T \in G \backslash\left\{T_{\mathrm{r}}\right\}$ and $G=\operatorname{transforms}(D)$

$$
\operatorname{pivot}\left(V^{\mathrm{C}} * D^{\mathrm{T}} \% \operatorname{dom}(Y)\right)
$$

The nullable variables are $\operatorname{dom}(Y)=\operatorname{ran}(\operatorname{filter}(\operatorname{der}(T), \operatorname{flip}(\operatorname{originals}(U)(D))))$. The pivot state is the out-slice or null state, $Y \in \mathcal{S}_{U}$.

A pair of nullable variables taken from different non-root transforms form an axial histogram when applied to the cartesian $V^{\mathrm{C}}$. Let $P_{1 *}, P_{2 *} \in \operatorname{nullables}(U)(D)$ such that originals $(U)(D)\left(P_{1}\right) \in \operatorname{der}\left(T_{1}\right)$, originals $(U)(D)\left(P_{2}\right) \in \operatorname{der}\left(T_{2}\right)$, $T_{1}, T_{2} \in G \backslash\left\{T_{\mathrm{r}}\right\}$ and $T_{1} \neq T_{2}$, then

$$
\operatorname{axial}\left(V^{\mathrm{C}} * D^{\mathrm{T}} \%\left\{P_{1}, P_{2}\right\}\right)
$$

If the transforms are on different paths, $M_{T_{1}} \neq M_{T_{2}}$ where $M=\{(T$, first $\circ$ $\left.L): L \in \operatorname{paths}\left(D^{*}\right), T \in \operatorname{dom}(\operatorname{set}(L))\right\}$, where first $((x, \cdot))=x$, then the pivot corresponds to the null state, $Y=\left\{P_{1_{*}}, P_{2 *}\right\} \in \mathcal{S}_{U}$, where both nullable variables are in their out-slices. If the transforms are the only children of the root transform, $M_{T_{1}}(2)=T_{1}, M_{T_{2}}(2)=T_{2}$ and $\left|\left\{L_{\{1 \ldots 2\}}: L \in \operatorname{paths}\left(D^{*}\right)\right\}\right|=2$, then the pivot state is zero, $\left(V^{\mathrm{C}} * D^{\mathrm{T}} *\{Y\}^{\mathrm{U}}\right)^{\mathrm{F}}=\emptyset$, because the out-slices are exclusive. Consider the case where the transforms each appear once on
the same path $L=M_{T_{1}}=M_{T_{2}}$. Let the ancestor transform be $T_{1}$ and the descendant transform be $T_{2}$, where flip $(L)\left(T_{1}\right)<\operatorname{flip}(L)\left(T_{2}\right)$. The pivot state corresponds to an in-slice non-null value of the ancestor variable $P_{1}$ and an out-slice null value of the descendant variable $P_{2}$. That is, the pivot state is one of $\left\{\left\{\left(P_{1}, C\right), P_{2 *}\right\}: C \in P_{1},\left(P_{1}, C\right) \neq P_{1 *}\right\} \subset \mathcal{S}_{U}$.

Thus the reduced transformed cartesian of a selection of the derived variables $K \subset N$ originating bijectively, $K \leftrightarrow G$, forms a skeletal histogram. Let $\operatorname{trans}(D)=\{(w, T): T \in G, w \in \operatorname{der}(T)\}$, then $\operatorname{trans}(D) \circ \operatorname{originals}(U)(D) \in$ $N \rightarrow G$ and

$$
\begin{aligned}
& \forall Q \subseteq \operatorname{trans}(D) \circ \operatorname{originals}(U)(D) \\
& \qquad\left(Q \in N \leftrightarrow G \Longrightarrow \operatorname{skeletal}\left(V^{\mathrm{C}} * D^{\mathrm{T}} \% \operatorname{dom}(Q)\right)\right.
\end{aligned}
$$

A functional transform $T \in \mathcal{T}_{\mathrm{f}}$ has a set of reduced transforms with respect to a histogram $A \in \mathcal{A}$, where $\operatorname{vars}(A)=$ underlying $(T)$. Section 'Transform, Action and Function histograms', above, defines the function reductions $\in \mathcal{A} \times \mathcal{T}_{\mathrm{f}} \rightarrow \mathrm{P}\left(\mathcal{T}_{\mathrm{f}}\right)$ such that $\forall T^{\prime} \in \operatorname{reductions}(A, T)(\{\operatorname{trim}(A * C)$ : $\left.\left.(\cdot, C) \in \operatorname{inverse}\left(T^{\prime}\right)\right\}=\{\operatorname{trim}(A * C):(\cdot, C) \in \operatorname{inverse}(T)\}\right)$. The nullable transform of a decomposition has reductions, reductions $\left(A, D^{\mathrm{T}}\right)$, but note that only the nullable variables of the nullable transform are reduced. The underlying transforms, transforms $(D)$, are not reduced. However, a decomposition can also be contingently reduced to a set of distinct decompositions. Define reductions $\in \mathcal{A} \times \mathcal{D} \rightarrow \mathrm{P}(\mathcal{D})$ as reductions $(A, D):=$ distinct(reductions $(A, \emptyset, \emptyset, D))$ where reductions $\in \mathcal{A} \times \mathcal{F} \times \mathcal{S} \times \mathcal{D} \rightarrow \mathcal{D}$ is

$$
\begin{aligned}
& \text { reductions }(A, F, R, D):= \\
& \quad\{((Q, X), G):((S, T), E) \in D, Q=S \% \operatorname{der}(F), \\
& \quad X \in \operatorname{reductions}\left(A * \operatorname{inverse}\left(F^{\mathrm{T}}\right)(R \cup Q), T\right), \\
& \quad G=\operatorname{reductions}(A, F \cup\{X\}, R \cup Q, E)\}
\end{aligned}
$$

The intersection with the nullable transform reductions contains the nullable transform, $D^{\mathrm{T}} \in\left\{E^{\mathrm{T}}: E \in \operatorname{reductions}(A, D)\right\} \cap \operatorname{reductions}\left(A, D^{\mathrm{T}}\right)$. The cardinality of the nullable transform reductions is greater than or equal to the cardinality of the contingent reduction decomposition nullable transforms, $\mid$ reductions $\left(A, D^{\mathrm{T}}\right)\left|\geq\left|\left\{E^{\mathrm{T}}: E \in \operatorname{reductions}(A, D)\right\}\right|\right.$.

If it is the case that all of the transforms of a decomposition are contingently diagonalised with respect to the histogram,

$$
\forall B \in \operatorname{ran}(\operatorname{elements}(A * D))(\operatorname{diagonal}(B))
$$

or

$$
\forall(C, T) \in \operatorname{elements}(\operatorname{contingents}(D))(\operatorname{diagonal}(A * C * T))
$$

then there must exist a contingent reduction decomposition nullable transform that is skeletal,

$$
\exists D^{\prime} \in \operatorname{reductions}(A, D)\left(\operatorname{skeletal}\left(A * D^{\prime \mathrm{T}}\right)\right)
$$

That is, the reduction to any two derived variables of the derived histogram of the nullable transform of the contingent reduction, $D^{\prime}$, is linear or axial

$$
\forall P_{1}, P_{2} \in \operatorname{der}\left(D^{\prime \mathrm{T}}\right)\left(\operatorname{line}\left(A * D^{\prime \mathrm{T}} \%\left\{P_{1}, P_{2}\right\}\right) \vee \operatorname{axial}\left(A * D^{\prime \mathrm{T}} \%\left\{P_{1}, P_{2}\right\}\right)\right)
$$

Also, there must exist a reduction nullable transform that is skeletal,

$$
\exists T \in \operatorname{reductions}\left(A, D^{\mathrm{T}}\right)(\operatorname{skeletal}(A * T))
$$

A skeletal contingent reduction decomposition, $D^{\prime}$, of a contingently diagonalised decomposition, $D$, implies a tree of derived variables $Z=\operatorname{map}\left(\mathrm{vr}, D^{\prime}\right) \in$ $\operatorname{trees}\left(\operatorname{der}\left(D^{\prime \mathrm{T}}\right)\right)$ where $\operatorname{vr}((\cdot, T)):=x$ and $\{x\}=\operatorname{der}(T)$. The reduction to any two of these derived variables, $B=A * D^{\prime \mathrm{T}} \%\left\{P_{1}, P_{2}\right\}$ where $\left\{P_{1}, P_{2}\right\} \subseteq$ elements $(Z)$, is linear or axial, line $(B) \vee \operatorname{axial}(B)$. If axial, the pivot state is $X=\bigcup\left\{S \cap T: S, T \in B^{\mathrm{FS}}\right\} \in\left\{P_{1}, P_{2}\right\}^{\mathrm{CS}}$. If one of the variables is a descendant of the other, $\exists L \in \operatorname{paths}(Z)\left(P_{1} \neq P_{2} \wedge\left\{P_{1}, P_{2}\right\} \subseteq \operatorname{set}(L)\right)$, then the descendant, $P_{2}$, has the null value in the pivot state, $P_{2 *} \in X$, where $P_{2 *} \in$ nullables $(U)\left(D^{\prime}\right)$ and $\operatorname{flip}(L)\left(P_{2}\right)>\operatorname{flip}(L)\left(P_{1}\right)$. In this case a non-root ancestor, $P_{1} \notin \operatorname{roots}(Z)$, has a non-null value, $P_{1 *} \notin X$, where $P_{1 *} \in \operatorname{nullables}(U)\left(D^{\prime}\right)$. The pivot state, $X$, is therefore not the ancestor out-slice state, $X \neq Y$, where the out-slice or null state is $Y=\left\{P_{1 *}, P_{2 *}\right\}$. If the variables are not ancestor-descendant, $P_{1} \neq P_{2} \wedge P_{1} \in \operatorname{set}(L) \wedge P_{2} \in$ $\operatorname{set}(M) \Longrightarrow L \neq M$ where $L, M \in \operatorname{paths}(Z)$, then both are necessarily null-valued in the pivot state. That is, the pivot state is the out-slice/null state, $X=Y$. The count of the pivot state, $B_{X}$, depends on how closely related the pair of variables is. If $P_{1}$ is an immediate parent of $P_{2}$, then the pivot state is zero, $\left(P_{1}, P_{2}\right) \in \operatorname{steps}(Z) \Longrightarrow B_{X}=0$. Note, however, that the out-slice count, $B_{Y}$, is not necessarily zero. If $P_{1}$ and $P_{2}$ are the only siblings of the root variable then the pivot state/out-slice is zero, $\left\{\left(\cdot,\left\{\left(P_{1}, \cdot\right),\left(P_{2}, \cdot\right)\right\}\right)\right\}=Z \Longrightarrow B_{X}=B_{Y}=0$. If the pair are, for example, in different leaves, $P_{1} \neq P_{2} \wedge\left\{P_{1}, P_{2}\right\} \subseteq$ leaves $(Z)$, then the pivot/out-slice count, $B_{X}=B_{Y}$, will vary as the depth of the tree, $\operatorname{depth}(Z)$. The more distant the pair, the more the axial resembles a singleton.

Given a one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ and a histogram $A \in \mathcal{A}$, where $\operatorname{vars}(A)=\operatorname{underlying}(T)$, a set of well behaved decompositions $H \subset \mathcal{D}_{\mathrm{w}, U}$, where $\forall D \in H(\operatorname{und}(D)=\operatorname{vars}(A))$, may be inferred such that the nullable transforms of the decompositions correspond to the given transform. That is, the application of the nullable transforms of the decompositions to the given histogram are non-literal reframes of the application of the given transform, $\forall D \in H \exists X \in \operatorname{der}(T) \leftrightarrow\left(\operatorname{der}\left(D^{\mathrm{T}}\right) \times(\mathcal{W} \leftrightarrow \mathcal{W})\right)\left(A * D^{\mathrm{T}}=\right.$ $\operatorname{reframe}(X, A * T))$. The inferred decompositions contains at least a decomposition consisting of a reframe transform of the given transform as the root transform, $\left\{\left(\left(\emptyset,\left\{\{w\}^{\mathrm{Cs}\{ \} \mathrm{T}}: w \in \operatorname{der}(T)\right\}^{\mathrm{T}}\right), \emptyset\right)\right\} \in H$.

Let the subset of the given derived variables $K \subset \operatorname{der}(T)$ correspond to the non-root transforms of an inferred decomposition $D \in H$. Let the null state be $R \in K^{\mathrm{CS}}$. Consider the case where a partition of the null state $M \in \mathrm{~B}(R)$ exists such that the reduction of the application of the given transform to the variables of a component $P \in M \subset \mathcal{S}$ forms a pivoted histogram, $\forall P \in M$ ( $\operatorname{pivot}(A * T \% \operatorname{vars}(P))$ ), such that the component, $P$, is the pivot state, $\forall P \in M \forall S \in(A * T \% \operatorname{vars}(P))^{\mathrm{FS}}(S \neq P \Longrightarrow S \cap P=$ $\emptyset)$. Then a decomposition $D \in H$ exists such that the reframe mapping $X \in \operatorname{der}(T) \leftrightarrow\left(\operatorname{der}\left(D^{\mathrm{T}}\right) \times(\mathcal{W} \leftrightarrow \mathcal{W})\right)$ is constrained such that the point components of the nullable pointed partition variables correspond to the null values in the values map, $\forall(v,((Q, C), W)) \in X(v \in K \quad \Longrightarrow \quad((Q, C) \in$ nullables $\left.(U)(D)) \wedge\left(\left(M_{v}, C\right) \in W\right)\right)$.

In the case where two components of the null state partition $P_{1}, P_{2} \in M$, where $P_{1} \neq P_{2}$, are such that the reduction to the union of their variables is also a pivoted histogram, $\operatorname{pivot}\left(A * T \%\left(\operatorname{vars}\left(P_{1}\right) \cup \operatorname{vars}\left(P_{2}\right)\right)\right)$, such that the pivot state is $P_{1} \cup P_{2}$, then the corresponding non-root transforms, $T_{1}, T_{2} \in \operatorname{transforms}(D)$, of an inferred decomposition, $D \in H$, must be on different paths. That is, there exists no path in which the transforms are in an ancestor-descendant relation, $\forall L \in \operatorname{paths}(D)\left(T_{1} \notin \operatorname{ran}(\operatorname{set}(L)) \vee T_{2} \notin\right.$ $\operatorname{ran}(\operatorname{set}(L)))$.

A non-empty sub-decomposition $E \in \mathcal{D}$ of non-empty decomposition $D \in$ $\mathcal{D}$ is a subtree $E \in \operatorname{subtrees}(D) \backslash\{\emptyset\}$. The underlying variables of $E$ are a subset of the underlying variables of $D, \operatorname{und}(E) \subseteq \operatorname{und}(D)$. If $D$ is in system $U, D \in \mathcal{D}_{U}$, then $E$ is in system $U, E \in \mathcal{D}_{U}$.

If $D$ is distinct, $D \in \mathcal{D}_{\mathrm{d}}$, then $E$ is distinct, $E \in \mathcal{D}_{\mathrm{d}}$. Both decompositions share the same root transform, $\operatorname{roots}(E)=\operatorname{roots}(D)=\left\{\left(\emptyset, T_{\mathrm{r}}\right)\right\}$. The
expanded partition of $E$ is a parent partition of $D$, $\operatorname{parent}\left(E^{\mathrm{P} V}, D^{\mathrm{P}}\right)$ where $V=\operatorname{und}(D)$. The components tree of $E$ is a subtree of the components tree of $D$, components $(U)(E) \in \operatorname{subtrees}($ components $(U)(D))$. If there are no symmetries between the transforms of $E$, transforms $(E)$, and the disjoint transforms, transforms $(D) \backslash$ transforms $(E)$, then the nullable fud of $E$ is a subset of the nullable fud of $D$, nullable $(U)(E) \subseteq$ nullable $(U)(D)$. In this case, the application of the decomposition $D$ to histogram $A \in \mathcal{A}$, having variables $V$, reduces to the application of the decomposition $E, A * D^{\mathrm{T}} \% \operatorname{der}\left(E^{\mathrm{T}}\right)=A * E^{\mathrm{T}}$.

Let non-zero sample histogram $A \in \mathcal{A}_{U}$ have non-empty variables $V=$ $\operatorname{vars}(A) \neq \emptyset$. The normalisation is a probability histogram, $\hat{A} \in \mathcal{A} \cap \mathcal{P}$. Let non-zero query histogram $Q \in \mathcal{A}_{U}$ have variables $K=\operatorname{vars}(Q)$ that are a subset of the sample variables, $K \subseteq V$. The normalisation of the query histogram is a probability histogram, $\hat{Q} \in \mathcal{A} \cap \mathcal{P}$. The difference between the sample variables and the query variables, $V \backslash K$, is called the set of label variables. As discussed above in section 'Transforms', given a one functional transform $T=(M, W) \in \mathcal{T}_{U, f, 1}$, having underlying variables $J=\operatorname{und}(T)$, the model analog of the transformed conditional product, $\hat{Q} * T_{A}^{\prime}=\hat{Q} *$ $(A /(A \% K),(V \backslash K)) \in \mathcal{A} \cap \mathcal{P}^{\prime}$, is the renormalisation of the application of the normalised sample action, $(T,(\hat{A} * M, V))$, to the expanded query probability histogram, $\hat{Q}_{J}=\hat{Q} *(J \backslash K)^{\mathrm{C} \wedge} \in \mathcal{A} \cap \mathcal{P}$,

$$
\left(\hat{Q}_{J} * T *(\hat{A} * M, V)\right)^{\wedge} \%(V \backslash K) \in \mathcal{A} \cap \mathcal{P}
$$

or

$$
\hat{Q}_{J} * T * T^{\odot A} \%(V \backslash K) \in \mathcal{A} \cap \mathcal{P}
$$

if the intersection of derived effective states is not empty, $(Q * T)^{\mathrm{F}} \cap(A * T)^{\mathrm{F}} \neq$ $\emptyset$.

The modelled transformed conditional product can be computed for a well behaved decomposition $D \in \mathcal{D}_{\mathrm{w}, U}$ by constructing the nullable transform, $D^{\mathrm{T}}$,

$$
\left(\hat{Q}_{J} * D^{\mathrm{T}} *\left(\hat{A} * \operatorname{his}\left(D^{\mathrm{T}}\right), V\right)\right)^{\wedge} \%(V \backslash K) \in \mathcal{A} \cap \mathcal{P}
$$

where his $=$ histogram. However, in some cases the computation of the nullable transform, $D^{\mathrm{T}}$, may be impracticable. In these cases the query function, query $\in \mathcal{D} \times \mathcal{A} \times \mathcal{A} \rightarrow \operatorname{trees}(\mathcal{S} \times \mathcal{A})$, may sometimes be used instead. If (i) the set of query variables is a superset of the set of decomposition underlying variables, $K \supseteq J$, where $J=\operatorname{und}(D)$, (ii) the query histogram is an effective singleton, $\left|Q^{\mathrm{F}}\right|=1$, and (iii) the intersection of derived effective states is not empty, $R \in\left(A * D^{\mathrm{T}}\right)^{\mathrm{FS}}$, where $\{R\}=\left(Q * D^{\mathrm{T}}\right)^{\mathrm{F}}$, then

$$
\left(\hat{Q}_{J} * D^{\mathrm{T}} *\left(\hat{A} * \operatorname{his}\left(D^{\mathrm{T}}\right), V\right)\right)^{\wedge} \%(V \backslash K)=\hat{N} \%(V \backslash K)
$$

where

$$
\{N\}=\operatorname{leaves}(\text { query }(D, A, Q))
$$

In this case of effective singleton query, $\left|Q^{\mathrm{F}}\right|=1$, the query tree has a single path, $|\operatorname{paths}(q u e r y(D, A, Q))|=1$, and hence a single leaf element, $\mid$ leaves(query $(D, A, Q)) \mid=1$. If the intersection of derived effective states is not empty, $R \in\left(A * D^{\mathrm{T}}\right)^{\mathrm{FS}}$, then the last histogram in the path is not empty, $\operatorname{size}\left(L_{|L|}\right)>0$, where $\{L\}=\operatorname{paths}($ query $(D, A, Q))$, and so the leaf histogram, $N=L_{|L|}$, is not empty, $\operatorname{size}(N)>0$.

If, however, the intersection of derived effective states is empty, $R \notin(A *$ $\left.D^{\mathrm{T}}\right)^{\mathrm{FS}}$, because of over-fitting, it may be that some ancestor slice is not empty. That is, sometimes there exists $\left(C_{1}, T_{1}\right),\left(C_{2}, T_{2}\right) \in \operatorname{cont}(D)$ such that $C_{1} \supset C_{2}, \operatorname{size}\left(Q * C_{2}\right)>0, \operatorname{size}\left(A * C_{2}\right)=0$, but $\operatorname{size}\left(A * C_{1}\right)>0$. The ancestor slice is the last of the non-empty filtered path. Let $L^{\prime}=\operatorname{filter}(\{(P, \operatorname{size}(P)>$ 0) : $P \in \operatorname{set}(L)\}, L)$, then $N=L_{\left|L^{\prime}\right|}^{\prime}$, if $\left|L^{\prime}\right| \neq 0$.

If the filtered path is empty, $\left|L^{\prime}\right|=0$, then the query is an ineffective derived state of the root transform, $R \notin\left(A * T_{\mathrm{r}}\right)^{\mathrm{FS}}$, where $\{R\}=\left(Q * T_{\mathrm{r}}\right)^{\mathrm{FS}}$ and $\left\{\left(\left(\emptyset, T_{\mathrm{r}}\right), \emptyset\right)\right\}=D$. In this case the best best guess is simply $\hat{A} \%(V \backslash K)$.

The set of functional definition set decompositions $\mathcal{D}_{\mathrm{F}}$ is a subset of the trees of pairs of (i) states, $\mathcal{S}$, and (ii) functional definition sets, $\mathcal{F}$

$$
\mathcal{D}_{\mathrm{F}} \subset \operatorname{trees}(\mathcal{S} \times \mathcal{F})
$$

The set of fud decompositions is constrained such that the derived variables of the transforms in the fuds are each uniquely defined

$$
\forall D \in \mathcal{D}_{\mathrm{F}}(\bigcup\{\operatorname{def}(F): F \in \operatorname{fuds}(D)\} \in \mathcal{V} \rightarrow \mathcal{T})
$$

where def $=$ definitions and fuds $\in \mathcal{D}_{\mathrm{F}} \rightarrow \mathrm{P}(\mathcal{F})$ is defined as fuds $(D):=$ $\operatorname{ran}($ elements $(D)$ ). In other words, if in fud decomposition $D$ fuds $F, G \in$ fuds $(D)$ share a defined variable $w \in \operatorname{dom}(\operatorname{def}(F)) \cap \operatorname{dom}(\operatorname{def}(G))$ then the definition is the same in each, $\operatorname{def}(F)(w)=\operatorname{def}(G)(w)$. This also allows the same fud to appear more than once in a fud decomposition tree. The union of the fuds is therefore a fud,

$$
\forall D \in \mathcal{D}_{\mathrm{F}}(\bigcup \operatorname{ran}(\operatorname{elements}(D)) \in \mathcal{F})
$$

Define fud $\in \mathcal{D}_{\mathrm{F}} \rightarrow \mathcal{F}$ as fud $(D):=\bigcup$ fuds $(D)$. Define underlying $\in \mathcal{D}_{\mathrm{F}} \rightarrow$ $\mathrm{P}(\mathcal{V})$ as underlying $(D):=$ underlying $($ fud $(D))$.

There are some additional constraints on fud decompositions. First, no underlying variable of a fud in the decomposition can be a defined variable in another fud

$$
\forall D \in \mathcal{D}_{\mathrm{F}}(\bigcup\{\operatorname{und}(F): F \in \operatorname{fuds}(D)\}=\text { underlying }(D))
$$

where und $=$ underlying. So only the underlying variables of a fud can intersect with the underlying variables of any other, $\forall F_{1}, F_{2} \in \operatorname{fuds}(D)\left(\operatorname{vars}\left(F_{1}\right) \backslash\right.$ $\left.\operatorname{und}\left(F_{1}\right) \cap \operatorname{und}\left(F_{2}\right)=\emptyset\right)$.

Second, the states of the root pairs are empty states

$$
\forall D \in \mathcal{D}_{\mathrm{F}}(\operatorname{dom}(\operatorname{roots}(D))=\{\emptyset\})
$$

Third, each of the states in child pairs are states of the derived variables of the parent fud

$$
\forall D \in \mathcal{D}_{\mathrm{F}} \forall((\cdot, F),(S, \cdot)) \in \operatorname{steps}(D)\left(S \in \operatorname{std}\left(F^{\mathrm{T}}\right)\right)
$$

where std $=$ stateDeriveds.
The empty fud decomposition consists of the empty fud, $\{((\emptyset, \emptyset), \emptyset)\} \in \mathcal{D}_{\mathrm{F}}$.

A fud decomposition $D \in \mathcal{D}_{\mathrm{F}}$ may be converted to a transform decomposition if the sets of derived variables of the fuds are disjoint, $\left(\forall F_{1}, F_{2} \in\right.$ fuds $\left.(D)\left(F_{1} \neq F_{2} \Longrightarrow \operatorname{der}\left(F_{1}\right) \cap \operatorname{der}\left(F_{2}\right)=\emptyset\right)\right) \Longrightarrow \operatorname{map}($ transform, $D) \in$ $\mathcal{D}$, where transform $\in(\mathcal{S} \times \mathcal{F}) \rightarrow\left(\mathcal{S} \times \mathcal{T}_{\mathrm{f}, \mathrm{U}}\right)$ is defined transform $((S, F)):=$ $\left(S, F^{\mathrm{T}}\right)$. Define shorthand $D^{\mathrm{D}}:=\operatorname{map}($ transform, $D)$.

There is no constraint on converting a transform decomposition to a fud decomposition, $\forall D \in \mathcal{D}\left(\operatorname{map}(f u d, D) \in \mathcal{D}_{\mathrm{F}}\right)$, where fud $\in\left(\mathcal{S} \times \mathcal{T}_{\mathrm{f}, \mathrm{U}}\right) \rightarrow(\mathcal{S} \times \mathcal{F})$ is defined $\operatorname{fud}((S, T)):=(S,\{T\})$.

The application of a fud decomposition to a histogram is a tree of contingent applications of the fuds. Define apply $\in \mathcal{D}_{\mathrm{F}} \times \mathcal{A} \rightarrow \operatorname{trees}(\mathcal{S} \times \mathcal{A})$ as $\operatorname{apply}(D, A):=\operatorname{apply}(D, \operatorname{vars}(A), A)$ where apply $\in \mathcal{D}_{\mathrm{F}} \times \mathrm{P}(\mathcal{V}) \times \mathcal{A} \rightarrow$ $\operatorname{trees}(\mathcal{S} \times \mathcal{A})$ is

$$
\begin{aligned}
& \operatorname{apply}(D, V, A):= \\
& \qquad \begin{array}{c}
\{((S, B \% W), \operatorname{apply}(E, V, B)):((S, F), E) \in D, W=\operatorname{der}(F), \\
\left.B=\operatorname{apply}\left(V, V \cup W, \operatorname{his}(F) \cup\left\{\{S\}^{\mathrm{U}}\right\}, A\right)\right\}
\end{array}
\end{aligned}
$$

where his $=$ histograms. Define shorthand $A * D=\operatorname{apply}(D, A)$. The application of a fud decomposition to a histogram equals the application of the corresponding transform decomposition to a histogram, $A * D=A * D^{\mathrm{D}}$.

The subset of fud decompositions $\mathcal{D}_{\mathrm{F}, U} \subset \mathcal{D}_{\mathrm{F}}$ in a system $U$ is a subset of the trees of pairs of (i) states, $\mathcal{S}_{U}$, and (ii) one functional definition sets, $\mathcal{F}_{U, 1}$

$$
\mathcal{D}_{\mathrm{F}, U}=\mathcal{D}_{\mathrm{F}} \cap \operatorname{trees}\left(\mathcal{S}_{U} \times \mathcal{F}_{U, 1}\right)
$$

The fuds of a system fud decomposition are non-circular, $\forall D \in \mathcal{D}_{\mathrm{F}, U} \forall F \in$ fuds $(D)(\neg \operatorname{circular}(F))$.

A further subset is the set of system fud decompositions where the fuds are partition fuds. Define the partition fud decompositions

$$
\mathcal{D}_{\mathrm{F}, U, \mathrm{P}}=\mathcal{D}_{\mathrm{F}} \cap \operatorname{trees}\left(\mathcal{S}_{U^{\prime}} \times \mathcal{F}_{U, \mathrm{P}}\right)
$$

where the finite system $U^{\prime}$ is defined $U^{\prime}=\left\{(P, P): F \in \mathcal{F}_{U, \mathrm{P}}, P \in\right.$ $\operatorname{dom}(\operatorname{def}(F))\} \cup U$.

A contingent tree of pairs of components and fuds can be mapped cumulatively from a fud decomposition $D \in \mathcal{D}_{\mathrm{F}}$. Define contingent $\in \mathcal{L}(\mathcal{S} \times \mathcal{F}) \rightarrow$ $\mathcal{A} \times \mathcal{F}$ as

$$
\begin{aligned}
& \text { contingent }(L):=\left(\operatorname{inverse}\left(G^{\mathrm{T}}\right)(S), F\right): \\
& \qquad(\cdot, F)=L_{|L|}, G=\bigcup \operatorname{ran}\left(\operatorname{set}\left(L_{\{1 \ldots|L|-1\}}\right)\right), S=\bigcup \operatorname{dom}(\operatorname{set}(L))
\end{aligned}
$$

contingent $(\{(1,(\cdot, F))\}):=(\operatorname{scalar}(1), F)$. Define contingents $\in \mathcal{D}_{\mathrm{F}} \rightarrow \operatorname{trees}(\mathcal{A} \times$ $\mathcal{F}$ ) as

$$
\operatorname{contingents}(D):=\text { mapAccum(contingent, } D)
$$

The subset distinct fud decompositions $\mathcal{D}_{\mathrm{F}, \mathrm{d}} \subset \mathcal{D}_{\mathrm{F}}$ is defined $\mathcal{D}_{\mathrm{F}, \mathrm{d}}=\mathcal{D}_{\mathrm{F}} \cap$ $\left((\mathcal{S} \rightarrow \mathcal{F}) \rightarrow \mathcal{D}_{\mathrm{F}, \mathrm{d}}\right)$. Define partition $(U) \in \mathcal{D}_{\mathrm{F}, \mathrm{d}, U} \rightarrow \mathcal{R}_{U}$ as

$$
\operatorname{partition}(U)(D):=\operatorname{partition}(U)\left(D^{\mathrm{D}}\right)
$$

The well behaved distinct fud decompositions is a subset of the distinct fud decompositions, $\mathcal{D}_{\mathrm{F}, \mathrm{w}, U} \subset \mathcal{D}_{\mathrm{F}, \mathrm{d}, U}$. A fud decomposition is well behaved if its transform decomposition is well behaved, $\forall D \in \mathcal{D}_{\mathrm{F}, \mathrm{w}, U}\left(D^{\mathrm{D}} \in \mathcal{D}_{\mathrm{w}, U}\right)$. Define transform $(U) \in \mathcal{D}_{\mathrm{F}, \mathrm{w}, U} \rightarrow \mathcal{T}_{U, \mathrm{f}, 1}$ as

$$
\operatorname{transform}(U)(D):=D^{\mathrm{FT}}
$$

where $D^{\mathrm{F}}:=\operatorname{fud}(D) \cup$ nullable $(U)\left(D^{\mathrm{D}}\right)$.

A well behaved distinct fud decomposition $D \in \mathcal{D}_{\mathrm{F}, \mathrm{w}, U}$ in system $U$ contains a variable symmetry if $\exists(L, T),(M, R) \in Q((L \neq M) \wedge(\operatorname{der}(T) \cap \operatorname{der}(R) \neq \emptyset))$ where $Q=\left\{(L, T):(L, E) \in \operatorname{places}\left(D^{\mathrm{D} *}\right), T \in \operatorname{dom}(\operatorname{dom}(E))\right\} \in \mathcal{L}\left(\mathcal{T}_{\mathrm{f}} \times\right.$ $\mathcal{S}) \rightarrow \mathcal{T}_{\mathrm{f}}$ and $D^{\mathrm{D} *}=\operatorname{application}(U)\left(D^{\mathrm{D}}\right)$. If all of the derived variables are equal the variable symmetry is also a fud symmetry. That is, more strictly, $\exists(L, T),(M, R) \in Q((L \neq M) \wedge(T=R))$.

### 3.11 Substrate structures

Consider the partition functional definition set $F_{U, V} \in \mathcal{F}_{U, \mathrm{P}}$ of all possible partition transforms of the cartesian set of states of some substrate set of underlying variables $V$ in system $U$,

$$
F_{U, V}=\operatorname{transforms}(\mathrm{B}(\operatorname{cartesian}(U)(V)))
$$

$F_{U, V}$ is called the base functional definition set of $V$ in system $U$. It may be more concisely defined $F_{U, V}=\left\{P^{\mathrm{T}}: P \in \mathrm{~B}\left(V^{\mathrm{CS}}\right)\right\}$. The base fud, $F_{U, V}$, contains all its partition variables in one layer, $\left|\operatorname{der}\left(F_{U, V}\right)\right|=\left|F_{U, V}\right|$. All of the partition variables are expanded, $\forall P \in \operatorname{der}\left(F_{U, V}\right)(\operatorname{vars}(P)=V)$ and $\forall T \in F_{U, V}(\operatorname{und}(T)=V) . F_{U, V}$ has cardinality

$$
\left|F_{U, V}\right|=|\mathrm{B}(\operatorname{cartesian}(U)(V))|=|\mathrm{B}(\{1 \ldots y\})|=\operatorname{bell}(y)
$$

where the volume $y=\left|V^{\mathrm{C}}\right|$. The function bell $\in \mathbf{N}_{>0} \rightarrow \mathbf{N}_{>0}$ is Bell's number which is factorial, bell $\in \mathrm{O}\left(\left\{\left(n, n^{n}\right): n \in \mathbf{R}_{>0}\right\}\right)$. The cardinality of the base functional definition set is finite, though because it is of factorial complexity in the volume, it is impracticable in some cases. For example, if the variables $V$ have the same valency $d$ having a regular volume $y=d^{n}$, where dimension $n=|V|$, then for four bi-valent variables the Bell's number is $\operatorname{bell}\left(2^{4}\right)=10480142147$. Similarly for two quad-valent variables, $\operatorname{bell}\left(4^{2}\right)=10480142147$. For three tri-valent variables, $\operatorname{bell}\left(3^{3}\right)=545717047936059989389$.

The base functional definition set, $F_{U, \emptyset}$, of empty substrate, $\emptyset$, is a singleton containing only the unary scalar partition transform, $F_{U, \emptyset}=\left\{P^{\mathrm{T}}: P \in\right.$ $\left.\mathrm{B}\left(\emptyset^{\mathrm{CS}}\right)\right\}=\left\{\left(\{\{(R,\{\emptyset\})\}\}^{\mathrm{U}},\{R\}\right)\right\}$ where $R=\operatorname{unary}\left(\emptyset^{\mathrm{CS}}\right)=\left\{\emptyset^{\mathrm{CS}}\right\}=\{\{\emptyset\}\}$.

The base fud contains the unary partition transform, $R^{\mathrm{T}}=\left(\left\{S \cup\left\{\left(R, V^{\mathrm{CS}}\right)\right\}\right.\right.$ : $\left.\left.S \in V^{\mathrm{CS}}\right\}^{\mathrm{U}},\{R\}\right) \in F_{U, V}=\left\{P^{\mathrm{T}}: P \in \mathrm{~B}\left(V^{\mathrm{CS}}\right)\right\}$, where $R$ is the unary partition, $R=\operatorname{unary}\left(V^{\mathrm{CS}}\right)=\left\{V^{\mathrm{CS}}\right\} \in \mathrm{B}\left(V^{\mathrm{CS}}\right)$. The corresponding contracted unary partition transform is the unary scalar partition transform, $R^{\% \mathrm{~T}}=\left(\left\{\left\{\left(R^{\%},\{\emptyset\}\right)\right\}\right\}^{\mathrm{U}},\left\{R^{\%}\right\}\right)$ where $R^{\%}=\left\{\emptyset^{\mathrm{CS}}\right\}=\{\{\emptyset\}\}$.

The base fud contains the self partition transform, $Q^{\mathrm{T}}=(\{S \cup\{(Q,\{S\})\}$ : $\left.\left.S \in V^{\mathrm{CS}}\right\}^{\mathrm{U}},\{Q\}\right) \in F_{U, V}=\left\{P^{\mathrm{T}}: P \in \mathrm{~B}\left(V^{\mathrm{CS}}\right)\right\}$, which corresponds to the self partition $Q=\operatorname{self}\left(V^{\mathrm{CS}}\right)=V^{\mathrm{CS}\{ \}}=\left\{\{S\}: S \in V^{\mathrm{CS}}\right\} \in \mathrm{B}\left(V^{\mathrm{CS}}\right)$.

Given a set of substrate variables $V \subset \mathcal{V}_{U}$ in system $U$, let the set $\mathcal{T}_{U, V} \subset$ $\mathcal{T}_{U, \mathrm{P}^{*}}$ be the set of multi-partition transforms that are the equivalent transforms of fud subsets of the base functional definition set, $F_{U, V}$, of substrate V

$$
\mathcal{T}_{U, V}=\{\operatorname{transform}(F): F \subseteq \operatorname{transforms}(\mathrm{~B}(\operatorname{cartesian}(U)(V)))\}
$$

or more succinctly $\mathcal{T}_{U, V}=\left\{F^{\mathrm{T}}: F \subseteq F_{U, V}\right\}$. This finite set is called the substrate transforms set on variables $V$. Constrain the system $U$ such that it contains all of the partition variables in the transforms, $\bigcup\{\operatorname{der}(T): T \in$ $\left.\mathcal{T}_{U, V}\right\} \subset \operatorname{vars}(U) . \mathcal{T}_{U, V}$ can also be rewritten in various ways

$$
\begin{aligned}
\mathcal{T}_{U, V} & =\left\{F^{\mathrm{T}}: F \subseteq\left\{P^{\mathrm{T}}: P \in \mathrm{~B}\left(V^{\mathrm{CS}}\right)\right\}\right\} \\
& =\left\{\left\{P^{\mathrm{T}}: P \in X\right\}^{\mathrm{T}}: X \subseteq \mathrm{~B}\left(V^{\mathrm{CS}}\right)\right\} \\
& =\left\{\left\{\left\{A^{\mathrm{S}}: A \in M\right\}^{\mathrm{T}}: M \in Y\right\}^{\mathrm{T}}: Y \subseteq \mathrm{~B}\left(V^{\mathrm{C}}\right)\right\}
\end{aligned}
$$

The substrate transforms set can also be defined in terms of expanded partitions, $\mathcal{T}_{U, V}=\left\{F^{\mathrm{T}}: F \subseteq\left\{P^{V \mathrm{~T}}: K \subseteq V, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}\right\}$.

Let $y$ be the volume of the substrate, $y=\left|V^{\mathrm{C}}\right|$. The cardinality of the substrate transforms set is $\left|\mathcal{T}_{U, V}\right|=2^{\operatorname{bell}(y)}$. A large practicable volume is the bi-valent bi-variate case $y=2^{2}$ where $\left|\mathcal{T}_{U, V}\right|=2^{15}=32768$. The next volume is the 5 -valent mono-variate case, $y=5^{1}$, where $\left|\mathcal{T}_{U, V}\right|=2^{52}=$ 4503599627370496.

The substrate transforms set contains the empty transform, $(\emptyset, \emptyset) \in \mathcal{T}_{U, V}$. The empty transform is the equivalent transform of the empty fud, $(\emptyset, \emptyset)=$ $\emptyset^{\mathrm{T}}$. It is the only element of the substrate transforms set which has no derived variables, $|\operatorname{der}((\emptyset, \emptyset))|=0$. It is the only element which has underlying variables not equal to $V, \operatorname{und}((\emptyset, \emptyset))=\emptyset \neq V$.

The substrate transforms set contains the unary partition transform, $\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in$ $\mathcal{T}_{U, V}$, and the self partition transform, $V^{\mathrm{CS}\{ \} \mathrm{T}} \in \mathcal{T}_{U, V}$.

The substrate transforms set contains the value full functional transform, $\left\{\{v\}^{\operatorname{CS}\{ \} V \mathrm{~T}}: v \in V\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V}$. This transform is the only value full functional transform of the substrate variables in the substrate transforms set.

The derived states, $(X \% W)^{\mathrm{S}}=\left\{\{v\}^{\mathrm{CS}\{ \} V}: v \in V\right\}^{\mathrm{CS}}$, are reframed underlying states, $(X \% V)^{\mathrm{S}}=V^{\mathrm{CS}}$, where $(X, W)=\left\{\{v\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: v \in V\right\}^{\mathrm{T}}$. That is, $\exists Q \in V \cdot W \forall(v, w) \in Q\left(\operatorname{split}\left(\{v\},(X \%\{v, w\})^{\mathrm{S}}\right) \in\{v\}^{\mathrm{CS}} \leftrightarrow\{w\}^{\mathrm{CS}}\right)$.

The substrate transforms set contains the base fud transform, $F_{U, V}^{\mathrm{T}} \in \mathcal{T}_{U, V}$.
The substrate transforms set is a superset of the base fud, $F_{U, V} \subset \mathcal{T}_{U, V}$. The subset of substrate transforms, having non-empty substrate variables, $V \neq \emptyset$, that are mono-variate in the derived variables equals the base fud, $\left\{T: T \in \mathcal{T}_{U, V},|\operatorname{der}(T)|=1\right\}=F_{U, V}$. The substrate transforms set contains the unary partition transform, $R^{\mathrm{T}} \in \mathcal{T}_{U, V}$ where $R=\left\{V^{\mathrm{CS}}\right\}$. The subset of the substrate transforms set which contains the unary partition, $\left\{T: T \in \mathcal{T}_{U, V},\left\{V^{\mathrm{CS}}\right\} \in \operatorname{der}(T)\right\}$, has a complement of the same cardinality, $\left\{T: T \in \mathcal{T}_{U, V},\left\{V^{\mathrm{CS}}\right\} \in \operatorname{der}(T)\right\} \leftrightarrow\left\{T: T \in \mathcal{T}_{U, V},\left\{V^{\mathrm{CS}}\right\} \notin \operatorname{der}(T)\right\}$. The empty transform, $(\emptyset, \emptyset)$, complements the unary partition transform, $R^{\mathrm{T}}$.

A substrate partition-set $N \in \mathrm{P}\left(\mathcal{R}_{U}\right)$ in variables $V$ is constrained to be such that each of the partitions in the partition-set has variables which are a subset of $V, \forall P \in N(\operatorname{vars}(P) \subseteq V)$. Define the substrate partition-sets set

$$
\mathcal{N}_{U, V}=\mathrm{P}\left(\left\{P: K \subseteq V, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}\right)
$$

The cardinality of the substrate partition-sets set is

$$
\left|\mathcal{N}_{U, V}\right|=2^{c}: c=\sum_{K \subseteq V} \operatorname{bell}\left(\left|K^{\mathrm{CS}}\right|\right)
$$

This is bounded

$$
2^{\operatorname{bell}(y)} \leq\left|\mathcal{N}_{U, V}\right| \leq 2^{2^{n} \operatorname{bell}(y)}
$$

where $y=\left|V^{\mathrm{CS}}\right|$. In the case of regular variables $V$, having valency $\{d\}=$ $\left\{\left|U_{w}\right|: w \in V\right\}$ and dimension $n=|V|$, the cardinality is

$$
\left|\mathcal{N}_{U, V}\right|=2^{c}: c=\sum_{k \in\{0 \ldots n\}}\binom{n}{k} \operatorname{bell}\left(d^{k}\right)
$$

A substrate partition-set $N \in \mathcal{N}_{U, V}$ maps to a multi-partition transform, $\left\{P^{\mathrm{T}}: P \in N\right\}^{\mathrm{T}} \in \mathcal{T}_{U, \mathrm{P}^{*}}$. A substrate partition-set $N \in \mathcal{N}_{U, V}$ maps to a substrate transforms set by expanding the partitions to $V,\left\{P^{V \mathrm{~T}}: P \in N\right\}^{\mathrm{T}} \in$ $\mathcal{T}_{U, V}$. The empty partition-set, $\emptyset \in \mathcal{N}_{U, V}$, expands to the empty transform, $(\emptyset, \emptyset) \in \mathcal{T}_{U, V}$. A converse function maps a substrate transform $T \in \mathcal{T}_{U, V}$
to a contracted partition-set, $\left\{P^{\%}: P \in \operatorname{der}(T)\right\} \in \mathcal{N}_{U, V}$. The substrate transforms set can therefore be defined in terms of substrate partition-sets,

$$
\mathcal{T}_{U, V}=\left\{\left\{P^{V \mathrm{~T}}: P \in N\right\}^{\mathrm{T}}: N \in \mathcal{N}_{U, V}\right\}=\left\{\left\{P^{\mathrm{T}}: P \in N\right\}^{\mathrm{TV}}: N \in \mathcal{N}_{U, V}\right\}
$$

Define transform $\in \bigcup\left\{\mathrm{P}\left(\mathcal{R}_{U}\right) \rightarrow \mathcal{T}_{U, \mathrm{P}^{*}}: U \in \mathcal{U}\right\}$ as

$$
\operatorname{transform}(N):=\left\{P^{\mathrm{T}}: P \in N\right\}^{\mathrm{T}}
$$

and shorthand $N^{\mathrm{T}}:=\operatorname{transform}(N)$. Then the substrate transforms set is defined $\mathcal{T}_{U, V}=\left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V}\right\}$.

Define the converse function that constructs a substrate partition-set given a one functional transform, partitionset $\in \bigcup\left\{\mathcal{T}_{U, f, 1} \rightarrow \mathrm{P}\left(\mathcal{R}_{U}\right): U \in \mathcal{U}\right\}$

$$
\operatorname{partitionset}(T):=\left\{(X \%(V \cup\{w\}),\{w\})^{\mathrm{P}}: w \in W\right\}
$$

where $W=\operatorname{der}(T), V=\operatorname{und}(T)$ and $X=\operatorname{his}(T)$.
Similarly a substrate pointed partition-set $N \in \mathrm{P}\left(\mathcal{R}_{*, U}\right)$ in variables $V$ is constrained to be such that each of the pointed partitions has variables which are a subset of $V, \forall P_{*} \in N\left(\operatorname{vars}\left(P_{*}\right) \subseteq V\right)$. A substrate pointed partition-set is also constrained such that the partitions are unique, $|\operatorname{dom}(N)|=|N|$. Define the substrate pointed partition-sets set

$$
\mathcal{N}_{*, U, V}=\mathrm{P}\left(\left\{\left(P, C_{*}\right): K \subseteq V, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right), C_{*} \in P\right\}\right) \cap\left(\mathcal{R}_{U} \rightarrow \mathrm{P}\left(\mathcal{S}_{U}\right)\right)
$$

A substrate pointed partition-set $N \in \mathcal{N}_{*, U, V}$ maps to a substrate transform by expanding the partitions to $V,\left\{P^{V \mathrm{~T}}:(P, \cdot) \in N\right\} \in \mathcal{T}_{U, V}$. The point component is forgotten. This is no converse function to map a substrate transform $T \in \mathcal{T}_{U, V}$ to a substrate pointed partition-set except in the case where the contractions are unary partitions, $\forall P \in \operatorname{der}(T)\left(\left|P^{\%}\right|=1\right)$. In this case the substrate pointed partition-set is $\left\{\left(P^{\%}, C_{*}\right): P \in \operatorname{der}(T),\left\{C_{*}\right\}=\right.$ $\left.P^{\%}\right\} \in \mathcal{N}_{U, V}$.

Consider the set of all the flattened expanded partition transforms generated from a one functional definition set. Define flatten $\in \mathcal{F} \rightarrow \mathcal{F}$
flatten $(F):=$

$$
\left\{(X \%(V \cup W), W)^{\mathrm{PT}}: T \in F, W=\operatorname{der}(T)\right\}: V=\operatorname{und}(F), X=\prod \operatorname{his}(F)
$$

where his $=$ histograms, und $=$ underlying and der $=$ derived. If $F \in \mathcal{F}_{U, 1}$ then flatten $(F)$ is a subset of the base fud, flatten $(F) \subseteq F_{U, V} \in \mathcal{F}_{U, \mathrm{P}}$. All
of the partition transforms are expanded, $\forall T \in$ flatten $(F)\left(T^{\mathrm{P}}=T^{\mathrm{PV}}\right)$, where $V=\operatorname{und}(F)$. The flatten function uses a similar method to that used to create the equivalent transform by taking the product, $X$, of all the histograms in the fud. The flattened fud can also be defined in terms of the equivalent transform of the depends functional definition set where the system $U$ is given. The resultant partitions are expanded to the substrate of underlying variables of the fud

$$
\begin{aligned}
\text { flatten }(F) & =\left\{G^{\mathrm{TPVT}}: T \in F, G=\operatorname{depends}(F, \operatorname{der}(T))\right\} \\
& \subseteq\left\{G^{\mathrm{TPVT}}: G \subseteq F, \operatorname{und}(G) \subseteq V\right\}
\end{aligned}
$$

where $V=\operatorname{und}(F)$. The flattened fud is not equal to the given fud unless the fud is a subset of the base fud, $F \cap F_{U, V} \neq F \Longrightarrow \operatorname{flatten}(F) \neq F$.

Another special case of a partition functional definition set, $F \in \mathcal{F}_{U, \mathrm{P}}$, that consists only of partition transforms is the power functional definition set. This set is constructed from a substrate $V$ in a system $U$ by partitioning the cartesian of all subsets of $V$, and recursing on the union of the set of newly derived variables and the underlying variables. The power functional definition set excludes partition circularities because each of its transforms is constrained such that none is equivalent to an element of the flattened fud of its underlying transforms in the depends functional definition set. Define $\operatorname{power}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \mathcal{F}_{U, \mathrm{P}}$

$$
\operatorname{power}(U)(V):=\operatorname{power}(U)(V, \emptyset)
$$

Define power $(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{F}_{U, \mathrm{P}} \rightarrow \mathcal{F}_{U, \mathrm{P}}$

$$
\begin{aligned}
& \operatorname{power}(U)(V, F):= \\
& \quad \operatorname{if}(G=\emptyset, F, \operatorname{power}(U)(V, F \cup G)): \\
& \quad G=\{T: K \subseteq \operatorname{vars}(F) \cup V, H=\operatorname{depends}(F, K), \\
& \left.\quad T \in F_{U, K} \backslash F,(H \cup\{T\})^{\mathrm{TPT}} \notin \operatorname{flatten}(H)\right\}
\end{aligned}
$$

The power fud contains as subsets all possible non-circular layered partition fuds on the given substrate $V$ or subset of the substrate. Let $G_{U, V}=$ power $(U)(V)$. The power fud is a superset of the power fuds of subsets of the substrate, $\forall K \subseteq V\left(\operatorname{power}(U)(K) \subseteq G_{U, V}\right)$. The power fud is a superset of the base fud, $F_{U, V} \subset G_{U, V}$. Also the base fud is equal to flattened fud of the power fud, $F_{U, V}=\operatorname{flatten}\left(G_{U, V}\right)=\left\{T: T \in G_{U, V}, \operatorname{und}(T)=V\right\} \subset$ $G_{U, V}$. The power fud of a non-empty set of substrate variables, $V \neq \emptyset$, excludes partition circularities and so has a finite depth or number of layers,
$\operatorname{layer}\left(G_{U, V}, \operatorname{der}\left(G_{U, V}\right)\right)=\left|\mathrm{B}\left(V^{\mathrm{CS}}\right)\right|+1=\operatorname{bell}(y)+1$ where substrate volume $y=\left|V^{\mathrm{CS}}\right|$. The depth of the power fud is therefore greater than the cardinality of its base fud and flattened fud. The base fud is a subset of the first layer subset, $F_{U, V}=\left\{P^{\mathrm{T}}: P \in \mathrm{~B}\left(V^{\mathrm{CS}}\right)\right\} \subset\left\{T: T \in G_{U, V}, \operatorname{und}(T) \subseteq V\right\} \subset G_{U, V}$, where the first layer subset is $\left\{T: T \in G_{U, V}, \operatorname{und}(T) \subseteq V\right\}=\{M: M \subset$ $\left.G_{U, V}, \operatorname{und}(M) \subseteq V, \operatorname{layer}(M, \operatorname{der}(M))=1\right\}=\left\{P^{\mathrm{T}}: K \subseteq V, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}$. The cardinality of the first layer subset is the width of the bottom layer, therefore the cardinality of the power fud of a non-empty set of substrate variables is greater than twice the cardinality of non-powerset base fud, $\left|G_{U, V}\right|>2 \operatorname{bell}(y)$. Thus the power fud is less practicable than the base fud. See appendix 'Cardinality of the power functional definition set'.

Given a set of substrate variables $V \subset \mathcal{V}_{U}$ in system $U$, let the set $\mathcal{F}_{U, V} \subset$ $\mathcal{F}_{U, \mathrm{P}}$ be the set of all subsets of the power fud having underlying variables equal to or a subset of $V$

$$
\mathcal{F}_{U, V}=\{F: F \subseteq \operatorname{power}(U)(V), \quad \operatorname{und}(F) \subseteq V\}
$$

This finite set is called the substrate fuds set on variables $V$. Constrain the system $U$ such that it contains all of the partition variables in the transforms of the fuds, $\bigcup\left\{\operatorname{der}(T): F \in \mathcal{F}_{U, V}, T \in F\right\} \subset \operatorname{vars}(U)$. The substrate fuds set can also be defined in terms of the variables in the power fud, $\mathcal{F}_{U, V}=\left\{\operatorname{depends}\left(G_{U, V}, X\right): X \subseteq \operatorname{vars}\left(G_{U, V}\right)\right\}$ where $G_{U, V}=\operatorname{power}(U)(V)$. The substrate fuds set can also be defined in terms of the transforms in the power fud, $\mathcal{F}_{U, V}=\left\{\bigcup\left\{\operatorname{depends}\left(G_{U, V}, \operatorname{der}(T)\right): T \in F\right\}: F \subseteq G_{U, V}\right\}$. Thus the cardinality of the substrate fuds set is such that $\left|\mathcal{F}_{U, V}\right| \leq 2^{\left|G_{U, V}\right|}$. The substrate fuds set contains the empty fud, $\emptyset \in \mathcal{F}_{U, V}$. The substrate fuds set is a superset of the powerset of the base fud, $\mathrm{P}\left(F_{U, V}\right) \subset \mathcal{F}_{U, V}$.

The consistent one functional definition sets $\mathcal{F}_{U, 1, \mathrm{x}} \subset \mathcal{F}_{U, 1}$ is the subset of one functional definition sets that do not contain circularities or contradictions or duplicates. All consistent one functional definition sets, $F \in \mathcal{F}_{U, 1, \mathrm{x}}$ having underlying variables $V$, und $(F)=V$, have an equivalence class defined by a member of the substrate fuds set, $E \in \mathcal{F}_{U, V}$. That is, fud $F$ and substrate fud $E$ form a pair in a surjective functional map $Z,(F, E) \in Z \in \mathcal{F}_{U, 1, \mathrm{x}, V} \rightarrow$ $\mathcal{F}_{U, V}$ where $\mathcal{F}_{U, 1, \mathrm{x}, V}=\left\{F: F \in \mathcal{F}_{U, 1, \mathrm{x}}, \operatorname{und}(F)=V\right\}$. Each $F$ implies $G=\operatorname{mono}(F) \in \mathcal{F}_{U, 1}$ which is the one functional definition set that is monovariate in its derived variables in each transform, $\forall T \in G(|\operatorname{der}(G)|=1)$, such that $G^{\mathrm{T}}=F^{\mathrm{T}}$. There exists exactly one non-literal frame variables mapping $X$ in system $U$ such that $\exists X \subset\{(v,(w, W)): Q \in(\operatorname{vars}(F) \backslash V)$. $\left.(\operatorname{vars}(E) \backslash V),(v, w) \in Q, W \in U_{v} \cdot U_{w}\right\}\left(X \in \mathcal{V}_{U} \leftrightarrow\left(\mathcal{V}_{U} \times\left(\mathcal{W}_{U} \leftrightarrow \mathcal{W}_{U}\right)\right)\right)$
such that $\operatorname{reframe}(X, G)$ is defined and $\operatorname{reframe}(X, G)=E$. The existence of a mapping between the transforms, $G \leftrightarrow E$, implies that the cardinalities are equal, $|G|=|E|$. The cardinalities of the underlying variables are equal, $\exists M \in G \leftrightarrow E \forall\left(T, T^{\prime}\right) \in M\left(|\operatorname{und}(T)|=\left|\operatorname{und}\left(T^{\prime}\right)\right|\right)$. The number of layers are equal layer $(F, \operatorname{der}(F))=\operatorname{layer}(E, \operatorname{der}(E))$. Thus the possibly infinite set $\mathcal{F}_{U, 1, \mathrm{x}}$ is partitioned into sets of fuds, $\mathcal{F}_{U, 1, \mathrm{x}, V}$, having the same underlying variables, $V, \bigcup\left\{\mathcal{F}_{U, 1, \mathrm{x}, V}: F \in \mathcal{F}_{U, 1, \mathrm{x}}, V=\operatorname{und}(F)\right\}=\mathcal{F}_{U, 1, \mathrm{x}}$. Then these possibly infinite sets are partitioned into equivalence classes by finite substrate fuds sets, $\mathcal{F}_{U, 1, \mathrm{x}, V} \rightarrow \mathcal{F}_{U, V}$.

The substrate transforms set, $\mathcal{T}_{U, V}$, and substrate fuds set, $\mathcal{F}_{U, V}$, in substrate variables $V$ in system $U$ are closely related. Each substrate transform $T \in$ $\mathcal{T}_{U, V}$ can be exploded to a substrate fud, explode $(T)=\left\{P^{\mathrm{T}}: P \in \operatorname{der}(T)\right\}=$ $\{(\operatorname{his}(T) \%(V \cup\{P\}),\{P\}): P \in \operatorname{der}(T)\} \in \mathcal{F}_{U, V}$. A similar explode exists for contracted partitions, $\operatorname{explode}\left(T^{\%}\right)=\left\{P^{\% \mathrm{~T}}: P \in \operatorname{der}(T)\right\} \in \mathcal{F}_{U, V}$. The subset of substrate transforms that are mono-variate in the derived variables form singleton substrate fuds, $\left\{\{T\}: T \in \mathcal{T}_{U, V},|\operatorname{der}(T)|=1\right\} \subset \mathcal{F}_{U, V}$. The substrate transforms set is equal to the set of expanded equivalent transforms of the substrate fud set

$$
\mathcal{T}_{U, V}=\left\{\left\{G^{\mathrm{TPVT}}: w \in \operatorname{der}(F), G=\operatorname{depends}(F,\{w\})\right\}^{\mathrm{T}}: F \in \mathcal{F}_{U, V}\right\}
$$

Thus there exists a functional surjection $\mathcal{F}_{U, V} \rightarrow \mathcal{T}_{U, V}$. Each partition $P \in$ $\mathrm{B}\left(V^{\mathrm{CS}}\right)$ forms an equivalence class for non-empty substrate transforms. Each substrate transform $T \in \mathcal{T}_{U, V}$ forms an equivalence class for a substrate fud $E \in \mathcal{F}_{U, V}$ which in turn forms an equivalence class for a consistent one fud $F \in \mathcal{F}_{U, 1, \mathrm{x}}$ where $\operatorname{und}(F)=V$

$$
\mathcal{F}_{U, 1, \mathbf{x}, V} \rightarrow \mathcal{F}_{U, V} \rightarrow \mathcal{T}_{U, V} \rightarrow\left(F_{U, V} \cup\{(\emptyset, \emptyset)\}\right) \leftrightarrow\left(\mathrm{B}\left(V^{\mathrm{CS}}\right) \cup\{\emptyset\}\right)
$$

The empty consistent fud, $\emptyset \in \mathcal{F}_{U, 1, \mathrm{x}, V}$, maps to the empty fud, $\emptyset \in \mathcal{F}_{U, V}$, thence to the empty transform, $(\emptyset, \emptyset) \in \mathcal{T}_{U, V}$, and thence to the empty partition $\emptyset \in\left(\mathrm{B}\left(V^{\mathrm{CS}}\right) \cup\{\emptyset\}\right)$.

The substrate decompositions set $\mathcal{D}_{U, V} \subset \operatorname{trees}(\mathcal{S} \times \mathcal{T})$ is the subset of distinct decompositions, $\mathcal{D}_{\mathrm{d}}$, such that the transforms are in the substrate transforms set, $\mathcal{T}_{U, V}$, and no transform appears more than once in any path

$$
\begin{aligned}
& \mathcal{D}_{U, V}=\left\{D: D \in \mathcal{D}_{\mathrm{d}}, \operatorname{transforms}(D) \subseteq \mathcal{T}_{U, V},\right. \\
& \quad \forall L \in \operatorname{paths}(D)(\operatorname{maxr}(\operatorname{count}(\{(T, i):(i,(\cdot, T)) \in L\}))=1)\}
\end{aligned}
$$

The substrate decompositions set, $\mathcal{D}_{U, V}$, is finite because $\mathcal{T}_{U, V}$ is finite. The depth of the tree of a substrate decomposition $D \in \mathcal{D}_{U, V}$ is less than or equal
to the cardinality of the substrate transforms set, $\operatorname{depth}(D) \leq\left|\mathcal{T}_{U, V}\right|$. Note that if the constraint on the paths were relaxed to be maxr $(\operatorname{count}(\operatorname{flip}(L)))=$ 1 , the maximum depth would be much greater but the depth of the decomposition application tree, $D^{*}$, would still be limited, $\operatorname{depth}\left(D^{*}\right) \leq\left|\mathcal{T}_{U, V}\right|$.

The substrate decompositions set, $\mathcal{D}_{U, V}$, can be created explicitly from the power decomposition. Define power $(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathcal{S}_{U} \times \mathcal{T}_{U}\right)$ as

$$
\operatorname{power}(U)(V):=\left\{((\emptyset, T), \operatorname{power}(U)(V, T,\{T\})): T \in \mathcal{T}_{U, V}\right\}
$$

where power $(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{T}_{U, \mathrm{f}, 1} \times \mathcal{F}_{U, 1} \rightarrow \operatorname{trees}\left(\mathcal{S}_{U} \times \mathcal{T}_{U}\right)$ is defined as

$$
\begin{aligned}
& \operatorname{power}(U)(V, T, F):= \\
& \quad\left\{((S, R), \operatorname{power}(U)(V, R, F \cup\{R\})): S \in \operatorname{std}(T), R \in \mathcal{T}_{U, V}, R \notin F\right\} \cup \\
& \quad\left\{((S, R), \emptyset): S \in \operatorname{std}(T), R \in \mathcal{T}_{U, V}, R \notin F\right\}
\end{aligned}
$$

where std $=$ stateDeriveds. Then the substrate decompositions set is the set of distinct decompositions in the power decompositions such that the transforms form a fud,

$$
\begin{aligned}
& \mathcal{D}_{U, V}=\{D: D \in \operatorname{distinct}(\operatorname{power}(U)(V)), \\
& \quad \forall(A, W),(B, X) \in \operatorname{transforms}(D)((A, W) \neq(B, X) \Longrightarrow W \cap X=\emptyset)\}
\end{aligned}
$$

The substrate decompositions set, $\mathcal{D}_{U, V}$, maps to $\mathcal{T}_{U, V}$ in several ways. First, a substrate decomposition $D \in \mathcal{D}_{U, V}$ has a partition, $D^{\mathrm{P}} \in \mathrm{B}\left(V^{\mathrm{CS}}\right)$, which is already expanded to $V, D^{\mathrm{PT}} \in \mathcal{T}_{U, V}$. Second, if the substrate decomposition is well behaved, $D \in \mathcal{D}_{\mathrm{w}, U}$, the crown transform, transformCrown $(U)(D)$, constructed from the transforms fud, $\operatorname{transforms}(D)$ and the slices fud, $\operatorname{slices}(U)(D)$, can be expanded, $\left\{(X \%(V \cup\{w\}),\{w\})^{\mathrm{PVT}}: w \in W\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V}$ where $(X, W)=$ transformCrown $(U)(D)$. Third, if the substrate decomposition is well behaved, $D \in \mathcal{D}_{\mathrm{w}, U}$, the nullable transform, $D^{\mathrm{T}}$, constructed from the transforms fud, transforms $(D)$ and the nullable fud, nullable $(U)(D)$, can also be expanded, $\left\{(X \%(V \cup\{w\}),\{w\})^{\mathrm{PVT}}: w \in W\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V}$ where $(X, W)=D^{\mathrm{T}}$.

The substrate functional definition set decompositions $\mathcal{D}_{\mathrm{F}, U, V} \subset \operatorname{trees}(\mathcal{S} \times \mathcal{F})$ is a subset of the distinct fud decompositions, $\mathcal{D}_{\mathrm{F}, \mathrm{d}}$, and can be defined similarly to substrate transform decompositions, $\mathcal{D}_{U, V} \subset \operatorname{trees}(\mathcal{S} \times \mathcal{T})$. That is, all of the fuds are substrate fuds and none can appear more than once in a path

$$
\begin{aligned}
& \mathcal{D}_{\mathrm{F}, U, V}=\left\{D: D \in \mathcal{D}_{\mathrm{F}, \mathrm{~d}}, \quad \operatorname{fuds}(D) \subseteq \mathcal{F}_{U, V},\right. \\
& \quad \forall L \in \operatorname{paths}(D)(\operatorname{maxr}(\operatorname{count}(\{(F, i):(i,(\cdot, F)) \in L\}))=1)\}
\end{aligned}
$$

The set of substrate fud decompositions, $\mathcal{D}_{\mathrm{F}, U, V}$, is also finite. The substrate fuds are a subset of the partition fuds, $\mathcal{F}_{U, V} \subset \mathcal{F}_{U, \mathrm{P}}$, so the substrate fud decompositions are a subset of the partition fud decompositions, $\mathcal{D}_{\mathrm{F}, U, V} \subset \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}$. The depth of the tree of a substrate fud decomposition $D \in \mathcal{D}_{\mathrm{F}, U, V}$ is less than or equal to the cardinality of the substrate fuds set, $\operatorname{depth}(D) \leq\left|\mathcal{F}_{U, V}\right|$. The accumulated fud along any path $L \in \operatorname{paths}(D)$ is a subset of the power fud, $\bigcup \operatorname{ran}(\operatorname{set}(L)) \subseteq \operatorname{power}(U)(V) \in \mathcal{F}_{U, \mathrm{P}}$. Note that the map of a substrate fud decomposition $D \in \mathcal{D}_{\mathrm{F}, U, V}$ to a transform decomposition, $D^{\mathrm{D}} \in \mathcal{D}_{U}$, is not generally a substrate transform decomposition, $D^{\mathrm{D}} \notin \mathcal{D}_{U, V}$, unless it so happens that the fuds are singletons of substrate transforms, fuds $(D) \subset\left\{\{T\}: T \in \mathcal{T}_{U, V}\right\}$.

The substrate fud decompositions set, $\mathcal{D}_{\mathrm{F}, U, V}$, maps to the substrate transforms set $\mathcal{T}_{U, V}$. First, a substrate fud decomposition $D \in \mathcal{D}_{\mathrm{F}, U, V}$ has a partition, $D^{\mathrm{DP}}$, which requires expanding to $V, D^{\mathrm{DPVT}} \in \mathcal{T}_{U, V}$. Second, the nullable transform, $D^{\mathrm{T}}$, constructed from the union of the fuds, $\bigcup$ fuds $(D)$, and the nullable fud, nullable $(U)\left(D^{\mathrm{D}}\right)$, can be expanded, $\left\{(X \%(V \cup\{w\}),\{w\})^{\mathrm{PVT}}\right.$ : $w \in W\}^{\mathrm{T}} \in \mathcal{T}_{U, V}$ where $(X, W)=D^{\mathrm{T}}$.

Given substrate variables $V$, the non-overlapping subset of the substrate transforms set $\mathcal{T}_{U, V, \mathrm{n}} \subset \mathcal{T}_{U, V}$ is defined

$$
\mathcal{T}_{U, V, \mathrm{n}}=\left\{T: T \in \mathcal{T}_{U, V}, \neg \operatorname{overlap}(T)\right\}
$$

The non-overlapping substrate transforms set, $\mathcal{T}_{U, V, \mathrm{n}}$, can also be defined in terms of substrate partition-sets. Let the non-overlapping substrate partitionsets set $\mathcal{N}_{U, V, \mathrm{n}} \subset \mathcal{N}_{U, V}$ be defined in terms of the strong partition of the substrate variables

$$
\begin{aligned}
& \mathcal{N}_{U, V, \mathrm{n}}= \\
& \quad\left\{N: N \in \mathcal{N}_{U, V}, M=\{\operatorname{vars}(P): P \in N\},|M|=|N|, M \in \mathrm{~B}(V)\right\}
\end{aligned}
$$

The non-overlapping substrate partition-sets set is empty if the substrate variables is empty, $\mathcal{N}_{U, \emptyset, \mathrm{n}}=\emptyset$. The non-overlapping substrate partition-sets set excludes the empty partition-set, $\emptyset \notin \mathcal{N}_{U, V, \mathrm{n}}$.

Let the weak non-overlapping substrate partition-sets set $\mathcal{N}^{\prime}{ }_{U, V, \mathrm{n}} \subset \mathcal{N}_{U, V}$ be defined in terms of the weak partition of the substrate variables including the empty partition-set

$$
\begin{aligned}
& \mathcal{N}^{\prime}{ }_{U, V, \mathrm{n}}= \\
& \quad\left\{N: N \in \mathcal{N}_{U, V}, M=\{\operatorname{vars}(P): P \in N\},|M|=|N|, M \in \mathrm{~B}^{\prime}(V)\right\} \cup\{\emptyset\}
\end{aligned}
$$

where the weak partition function is $\mathrm{B}^{\prime}(V):=\mathrm{B}(V) \cup\{Y \cup\{\emptyset\}: Y \in \mathrm{~B}(V)\}$ and $B^{\prime}(\emptyset):=\{\{\emptyset\}\}$. The weak non-overlapping substrate partition-sets set includes the empty partition-set, $\emptyset \in \mathcal{N}^{\prime}{ }_{U, V, \mathrm{n}}$. If the substrate variables set is empty, the weak non-overlapping substrate partition-sets set is a set of the empty partition-set and a singleton of the contracted unary partition, $\mathcal{N}_{U, \emptyset, \mathrm{n}}^{\prime}=\left\{\emptyset,\left\{\left\{\emptyset^{\mathrm{CS}}\right\}\right\}\right\}$, where the unary partition is $\left\{\emptyset^{\mathrm{CS}}\right\}^{V}=\left\{V^{\mathrm{CS}}\right\}$. The non-overlapping substrate partition-sets set is a subset of the weak nonoverlapping substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{n}} \subset \mathcal{N}^{\prime}{ }_{U, V, \mathrm{n}}$,

$$
V \neq \emptyset \Longrightarrow \mathcal{N}_{U, V, \mathrm{n}}^{\prime}=\mathcal{N}_{U, V, \mathrm{n}} \cup\left\{N \cup\left\{\left\{\emptyset^{\mathrm{CS}}\right\}\right\}: N \in \mathcal{N}_{U, V, \mathrm{n}}\right\} \cup\{\emptyset\}
$$

The non-overlapping substrate transforms set is defined in terms of the weak non-overlapping substrate partition-sets set

$$
\mathcal{T}_{U, V, \mathrm{n}}=\left\{\left\{P^{V \mathrm{~T}}: P \in N\right\}^{\mathrm{T}}: N \in \mathcal{N}_{U, V, \mathrm{n}}^{\prime}\right\}=\left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, \mathrm{n}}^{\prime}\right\}
$$

where $P^{V}:=\operatorname{expand}(U)(V, P)$. The non-overlapping substrate transforms set is therefore such that

$$
\forall T \in \mathcal{T}_{U, V, \mathrm{n}} \forall P_{1}, P_{2} \in \operatorname{der}\left(T^{\%}\right)\left(P_{1} \neq P_{2} \Longrightarrow \operatorname{vars}\left(P_{1}\right) \cap \operatorname{vars}\left(P_{2}\right)=\emptyset\right)
$$

The non-overlapping substrate partition-sets set can be defined explicitly

$$
\mathcal{N}_{U, V, \mathrm{n}}=\left\{N: Y \in \mathrm{~B}(V), N \in \prod_{K \in Y} \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}
$$

and, similarly, the weak non-overlapping substrate partition-sets set can be defined explicitly

$$
\mathcal{N}_{U, V, \mathrm{n}}^{\prime}=\left\{N: Y \in \mathrm{~B}^{\prime}(V), N \in \prod_{K \in Y} \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\} \cup\{\emptyset\}
$$

and so the non-overlapping substrate transforms set can be defined explicitly

$$
\mathcal{T}_{U, V, \mathrm{n}}=\left\{N^{\mathrm{T} V}: Y \in \mathrm{~B}^{\prime}(V), N \in \prod_{K \in Y} \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\} \cup\{(\emptyset, \emptyset)\}
$$

The non-overlapping substrate transforms set includes the empty transform, $(\emptyset, \emptyset) \in \mathcal{T}_{U, V, \mathrm{n}}$, the unary partition transform, $\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V, \mathrm{n}}$, the self partition transform, $V^{\mathrm{CS}\{ \} \mathrm{T}} \in \mathcal{T}_{U, V, \mathrm{n}}$, and the value full functional transform, $\left\{\{v\}^{\operatorname{CS}\{ \} V \mathrm{~T}}: v \in V\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V, \mathrm{n}}$. The base functional definition set is a subset, $F_{U, V} \subseteq \mathcal{T}_{U, V, \mathrm{n}}$.

The strong non-overlapping substrate transforms set is the set of transforms
of the non-overlapping substrate partition-sets set, $\left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, \mathrm{n}}\right\}$. The non-overlapping substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{n}}$, is constructed from strong partitions of the substrate variables, $\mathrm{B}(V)$. The strong non-overlapping substrate transforms set is a subset of the non-overlapping substrate transforms set,

$$
\left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, \mathrm{n}}\right\} \subseteq \mathcal{T}_{U, V, \mathrm{n}}
$$

In the case of non-empty substrate variables, $V \neq \emptyset$, the cardinality of the non-overlapping substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{n}}$, is

$$
\left|\mathcal{N}_{U, V, \mathrm{n}}\right|=\sum_{Y \in \mathrm{~B}(V)} \prod_{K \in Y}\left|\mathrm{~B}\left(K^{\mathrm{CS}}\right)\right|
$$

The cardinality of the strong non-overlapping substrate transforms set is therefore bounded

$$
\left|\mathrm{B}\left(V^{\mathrm{CS}}\right)\right| \leq\left|\left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, \mathrm{n}}\right\}\right| \leq \sum_{Y \in \mathrm{~B}(V)} \prod_{K \in Y}\left|\mathrm{~B}\left(K^{\mathrm{CS}}\right)\right|
$$

If the underlying variables are regular, having dimension $n=|V|$ and common valency $d$, $\{d\}=\left\{\left|U_{x}\right|: x \in V\right\}$, then the cardinality of the nonoverlapping substrate partition-sets set is

$$
\left|\mathcal{N}_{U, V, \mathrm{n}}\right|=\sum_{Y \in \mathrm{~B}(V)} \prod_{K \in Y} \operatorname{bell}\left(d^{|K|}\right)=\sum_{(L, c) \in \operatorname{bcd}(n)}\left(c \prod_{(k, m) \in L} \operatorname{bell}\left(d^{k}\right)^{m}\right)
$$

where $\mathrm{bcd}=$ bellcd and the partition function cardinality function bellcd $\in$ $\mathbf{N}_{>0} \rightarrow(\mathcal{L}(\mathbf{N}) \rightarrow \mathbf{N})$, defined in appendix 'Partitions', below, computes the histogram of the histograms of the component cardinalities.

The cardinality of the strong non-overlapping substrate transforms set is bounded

$$
\operatorname{bell}\left(d^{n}\right) \leq\left|\left\{N^{\mathrm{T} V}: N \in \mathcal{N}_{U, V, \mathrm{n}}\right\}\right| \leq \operatorname{bell}(n) \times \operatorname{bell}\left(d^{n}\right)
$$

Generalising to irregular,

$$
\operatorname{bell}(y) \leq\left|\left\{N^{\mathrm{T} V}: N \in \mathcal{N}_{U, V, \mathrm{n}}\right\}\right| \leq \operatorname{bell}(n) \times \operatorname{bell}(y)
$$

where $y=\operatorname{volume}(U)(V)$.
The cardinality of the weak non-overlapping substrate partition-sets set is
twice that of the non-overlapping substrate partition-sets set plus one, $\left|\mathcal{N}^{\prime}{ }_{U, V, \mathrm{n}}\right|=$ $2 \times\left|\mathcal{N}_{U, V, \mathrm{n}}\right|+1$. The cardinality of the non-overlapping substrate transforms set is therefore bounded

$$
2 \times\left|\mathrm{B}\left(V^{\mathrm{CS}}\right)\right| \leq\left|\mathcal{T}_{U, V, \mathrm{n}}\right| \leq 2 \times \sum_{Y \in \mathrm{~B}(V)} \prod_{K \in Y}\left|\mathrm{~B}\left(K^{\mathrm{CS}}\right)\right|+1
$$

If the underlying variables are regular, the cardinality of the non-overlapping substrate transforms set is bounded $2 \times \operatorname{bell}\left(d^{n}\right) \leq\left|\mathcal{T}_{U, V, \mathrm{n}}\right| \leq 2 \times \operatorname{bell}(n) \times$ $\operatorname{bell}\left(d^{n}\right)+1$. Generalising to irregular,

$$
2 \times \operatorname{bell}(y) \leq\left|\mathcal{T}_{U, V, \mathrm{n}}\right| \leq 2 \times \operatorname{bell}(n) \times \operatorname{bell}(y)+1
$$

where $y=$ volume $(U)(V)$. Compare the cardinality of the substrate transforms set itself,

$$
\left|\mathcal{T}_{U, V}\right|=2^{\operatorname{bell}(y)}
$$

The cardinality of the non-overlapping subset, $\left|\mathcal{T}_{U, V, \mathrm{n}}\right|$, may be compared to the cardinality of the subset of the substrate transforms set which limits the cardinality of the derived variables to the dimension, the fixed dimension substrate transforms set,

$$
\left|\left\{T: T \in \mathcal{T}_{U, V},|\operatorname{der}(T)| \leq n\right\}\right|=\sum_{k \in\{0 \ldots n\}} \frac{\operatorname{bell}(y)!}{k!(\operatorname{bell}(y)-k)!}>\frac{1}{n!}(\operatorname{bell}(y))^{\underline{n}}
$$

where $x^{\underline{n}}$ is the falling factorial.
A practicable volume of regular variables $V$ of the non-overlapping substrate transforms set, $\mathcal{T}_{U, V, \mathrm{n}}$, is $y=8$, for example, the bi-valent tri-variate case $y=2^{3}$.

Consider the binary non-overlapping substrate transforms set $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{b}}$ which is a subset of the non-overlapping substrate transforms set, $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{b}} \subseteq \mathcal{T}_{U, V, \mathrm{n}}$. The binary non-overlapping substrate partition-sets set $\mathcal{N}_{U, V, \mathrm{n}, \mathrm{b}} \subset \mathcal{N}_{U, V, \mathrm{n}}$ constrains the partition of the substrate variables to have a cardinality of two

$$
\mathcal{N}_{U, V, \mathrm{n}, \mathrm{~b}}=\left\{N: N \in \mathcal{N}_{U, V, \mathrm{n}},|N|=2\right\}
$$

The binary non-overlapping substrate transforms set is defined in terms of the binary non-overlapping substrate partition-sets set

$$
\mathcal{T}_{U, V, \mathrm{n}, \mathrm{~b}}=\left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, \mathrm{n}, \mathrm{~b}}\right\}
$$

The binary non-overlapping substrate transforms set is such that

$$
\forall T \in \mathcal{T}_{U, V, \mathrm{n}, \mathrm{~b}}\left(T \neq\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \Longrightarrow|\operatorname{der}(T)|=2\right)
$$

In the case of empty or singleton substrate variables the binary non-overlapping substrate transforms set is empty, $|V|<2 \Longrightarrow \mathcal{T}_{U, V, \mathrm{n}, \mathrm{b}}=\emptyset$. In the case of pluri-variate substrate the binary non-overlapping substrate transforms set includes the unary partition transform, $|V| \geq 2 \Longrightarrow\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V, \mathrm{n}, \mathrm{b}}$.

The binary non-overlapping substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{n}, \mathrm{b}}$, can be defined explicitly

$$
\begin{aligned}
\mathcal{N}_{U, V, \mathrm{n}, \mathrm{~b}}=\{\{P, Q\}: K \subset V, & K \neq \emptyset, K \neq V, \\
& \left.P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right), Q \in \mathrm{~B}\left((V \backslash K)^{\mathrm{CS}}\right)\right\}
\end{aligned}
$$

The cardinality is

$$
\left|\mathcal{N}_{U, V, \mathrm{n}, \mathrm{~b}}\right|=1 / 2 \times \sum_{K \in \mathrm{P}(V) \backslash\{\emptyset, V\}}\left|\mathrm{B}\left(K^{\mathrm{CS}}\right)\right| \times\left|\mathrm{B}\left((V \backslash K)^{\mathrm{CS}}\right)\right|
$$

In the case of regular variables of valency $d$ and dimension $n$, the cardinality is

$$
\left|\mathcal{N}_{U, V, \mathrm{n}, \mathrm{~b}}\right|=1 / 2 \times \sum_{k \in\{1 \ldots n-1\}}\binom{n}{k} \operatorname{bell}\left(d^{k}\right) \times \operatorname{bell}\left(d^{n-k}\right)
$$

The binary non-overlapping substrate transforms set, $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{b}}$, can be defined explicitly

$$
\begin{aligned}
\mathcal{T}_{U, V, \mathrm{n}, \mathrm{~b}}=\left\{\left\{P^{V \mathrm{~T}}, Q^{V \mathrm{~T}}\right\}^{\mathrm{T}}:\right. & K \subset V, K \neq \emptyset, K \neq V, \\
& \left.P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right), Q \in \mathrm{~B}\left((V \backslash K)^{\mathrm{CS}}\right)\right\}
\end{aligned}
$$

The cardinality of $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{b}}$ is less than $2^{n-2} \times \operatorname{bell}(y)$ where volume $y=\left|V^{\mathrm{C}}\right|$.
Consider the self non-overlapping substrate transforms set $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$ which is a subset of the non-overlapping substrate transforms set, $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}} \subseteq \mathcal{T}_{U, V, \mathrm{n}}$. The self non-overlapping substrate partition-sets set $\mathcal{N}_{U, V, \mathrm{n}, \mathrm{s}} \subset \mathcal{N}_{U, V, \mathrm{n}}$ constrains the partition of the substrate variables to have a cardinality equal to that of the substrate variables

$$
\mathcal{N}_{U, V, \mathrm{n}, \mathrm{~s}}=\left\{N: N \in \mathcal{N}_{U, V, \mathrm{n}},|N|=|V|\right\}
$$

The self non-overlapping substrate transforms set is defined in terms of the self non-overlapping substrate partition-sets set

$$
\mathcal{T}_{U, V, \mathrm{n}, \mathrm{~s}}=\left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, \mathrm{n}, \mathrm{~s}}\right\}
$$

The self non-overlapping substrate transforms set is such that

$$
\forall T \in \mathcal{T}_{U, V, \mathrm{n}, \mathrm{~s}} \forall P \in \operatorname{der}\left(T^{\%}\right)(|\operatorname{vars}(P)| \leq 1)
$$

In the case of empty substrate variables the self non-overlapping substrate transforms set is empty, $\mathcal{T}_{U, \emptyset, \mathrm{n}, \mathrm{s}}=\emptyset$. In the case of multi-variate substrate the self non-overlapping substrate transforms set includes the unary partition transform, $V \neq \emptyset \Longrightarrow\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$, and the value full functional transform, $V \neq \emptyset \Longrightarrow\left\{\{v\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: v \in V\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$.

The self non-overlapping substrate partition-sets set, $\mathcal{N}_{U, V, n, s}$, can be defined explicitly

$$
\mathcal{N}_{U, V, \mathrm{n}, \mathrm{~s}}=\prod_{w \in V} \mathrm{~B}\left(\{w\}^{\mathrm{CS}}\right)
$$

The cardinality is

$$
\left|\mathcal{N}_{U, V, \mathrm{n}, \mathrm{~s}}\right|=\prod_{w \in V}\left|\mathrm{~B}\left(\{w\}^{\mathrm{CS}}\right)\right|
$$

If $V$ is regular having dimension $n=|V|$ and valency $\{d\}=\left\{\left|U_{w}\right|: w \in V\right\}$, the cardinality is

$$
\left|\mathcal{N}_{U, V, \mathrm{n}, \mathrm{~S}}\right|=\operatorname{bell}(d)^{n}
$$

The self non-overlapping substrate transforms set, $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$, can be defined explicitly

$$
\mathcal{T}_{U, V, \mathrm{n}, \mathrm{~s}}=\left\{N^{\mathrm{TV}}: N \in \prod_{w \in V} \mathrm{~B}\left(\{w\}^{\mathrm{CS}}\right)\right\}
$$

If $V$ is regular the cardinality of $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$ is less than $\operatorname{bell}(d)^{n}$.
In the case of pluri-variate substrate the intersection of the binary nonoverlapping substrate transforms set and the self non-overlapping substrate transforms set is non-empty, including at least the unary partition transform, $|V| \geq 2 \Longrightarrow\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V, \mathrm{n}, \mathrm{b}} \cap \mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$. The binary non-overlapping substrate transforms set equals the self non-overlapping substrate transforms set if the substrate is bi-variate, $|V|=2 \Longrightarrow \mathcal{T}_{U, V, \mathrm{n}, \mathrm{b}}=\mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$.

Having considered the self non-overlapping substrate transforms set, $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$, now consider the less constrained self overlapping substrate transforms set $\mathcal{T}_{U, V, \mathrm{os} \mathrm{s}} \subseteq \mathcal{T}_{U, V}$. Here the substrate is still self-partitioned, $V^{\{ \}}$, but more than one derived partition variable for each substrate variable is allowed. The self overlapping substrate partition-sets set $\mathcal{N}_{U, V, \mathrm{os} \mathrm{s}} \subset \mathcal{N}_{U, V}$ is explicitly defined

$$
\mathcal{N}_{U, V, \mathrm{o}, \mathrm{~s}}=\left\{\bigcup H: H \in \prod_{w \in V} \mathrm{P}\left(\mathrm{~B}\left(\{w\}^{\mathrm{CS}}\right)\right)\right\}
$$

The self overlapping substrate transforms set is defined in terms of the self overlapping substrate partition-sets set

$$
\mathcal{T}_{U, V, \mathrm{o}, \mathrm{~s}}=\left\{N^{\mathrm{T} V}: N \in \mathcal{N}_{U, V, \mathrm{o}, \mathrm{~s}}\right\}
$$

The self overlapping substrate transforms set is such that

$$
\forall T \in \mathcal{T}_{U, V, \mathrm{o}, \mathrm{~s}} \forall P \in \operatorname{der}\left(T^{\%}\right)(|\operatorname{vars}(P)| \leq 1)
$$

The self non-overlapping substrate transforms set is a subset of the self overlapping substrate transforms set, $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}} \subseteq \mathcal{T}_{U, V, \mathrm{os},}$. In the case of empty substrate variables the self overlapping substrate transforms set is empty, $\mathcal{T}_{U, \emptyset, \mathrm{o}, \mathrm{s}}=\emptyset$. In the case of multi-variate substrate the self overlapping substrate transforms set includes the empty transform, $V \neq \emptyset \Longrightarrow(\emptyset, \emptyset) \in$ $\mathcal{T}_{U, V, \mathrm{os},}$, the unary partition transform, $V \neq \emptyset \Longrightarrow\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V, \mathrm{os,s}}$, and the value full functional transform, $V \neq \emptyset \Longrightarrow\left\{\{v\}^{\mathrm{CS}\{ \}^{\mathrm{CT}}}: v \in V\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V, \mathrm{o}, \mathrm{s}}$.

The self overlapping substrate partition-sets set, $\mathcal{N}_{U, V, 0, s}$, has cardinality

$$
\left|\mathcal{N}_{U, V, \mathrm{o}, \mathrm{~S}}\right|=\prod\left(2^{m}: w \in V, m=\left|\mathrm{B}\left(\{w\}^{\mathrm{CS}}\right)\right|\right)
$$

If $V$ is regular, having dimension $n=|V|$ and valency $\{d\}=\left\{\left|U_{w}\right|: w \in V\right\}$, the cardinality of $\mathcal{T}_{U, V, \mathrm{o}, \mathrm{s}}$ equals $2^{n \times \operatorname{bell}(d)}$.

In the case of non-empty substrate variables, $V \neq \emptyset$, the subset of the non-overlapping substrate transforms set, $\mathcal{T}_{U, V, \mathrm{n}}$, which are unary partitions of the substrate, unary $(V)=\{V\}$, is simply the base fud, $|V| \geq 1 \Longrightarrow$ $\left\{T: T \in \mathcal{T}_{U, V, \mathrm{n}},|\operatorname{der}(T)|=1\right\}=F_{U, V}$, which has cardinality bell $(y)$ where $y=\left|V^{\mathrm{CS}}\right|$. In the case of pluri-variate substrate the intersection of the unary substrate transforms set, the binary non-overlapping substrate transforms set and the self non-overlapping substrate transforms set is non-empty, including at least the unary partition transform, $|V| \geq 2 \Longrightarrow\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in$ $\bigcap\left\{F_{U, V}, \mathcal{T}_{U, V, \mathrm{n}, \mathrm{b}}, \mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}\right\}$.

In contrast to subsets of the substrate transforms set, $\mathcal{T}_{U, V}$, that partition the substrate variables in various ways, consider subsets that impose constraints on the partitions of the cartesian states of subsets of the substrate. Consider the substrate self-cartesian transforms set $\mathcal{T}_{U, V, \mathrm{c}}$ which is a subset of the substrate transforms set, $\mathcal{T}_{U, V, \mathrm{c}} \subseteq \mathcal{T}_{U, V}$. Let the substrate self-cartesian partition-sets set $\mathcal{N}_{U, V, \mathrm{c}} \subset \mathcal{N}_{U, V}$ be defined such that the partition sets consist only of self partitions of the cartesian states of subsets of the substrate, $\operatorname{self}\left(K^{\mathrm{CS}}\right)^{V}$ where $K \subseteq V$

$$
\begin{aligned}
\mathcal{N}_{U, V, \mathrm{c}} & =\left\{N: N \in \mathcal{N}_{U, V}, \forall P \in N\left(P=(\bigcup P)^{\{ \}}\right)\right\} \\
& =\left\{N: N \in \mathcal{N}_{U, V}, \forall P \in N(|P|=|\bigcup P|)\right\}
\end{aligned}
$$

using the shorthand $X^{\{ \}}=\operatorname{self}(X)$. The substrate self-cartesian partitionsets set includes the empty partition-set, $\emptyset \in \mathcal{N}_{U, V, \mathrm{c}}$. If the substrate variables is empty, the substrate self-cartesian partition-sets set is a set of the empty partition-set and a singleton of the contracted unary partition, $\mathcal{N}_{U, \emptyset, \mathrm{c}}=$ $\mathcal{N}^{\prime}{ }_{U, \emptyset, \mathrm{n}}=\left\{\emptyset,\left\{\left\{\emptyset^{\mathrm{CS}}\right\}\right\}\right\}$.

The substrate self-cartesian transforms set is defined in terms of substrate self-cartesian partition-sets set

$$
\mathcal{T}_{U, V, \mathrm{c}}=\left\{N^{\mathrm{T} V}: N \in \mathcal{N}_{U, V, \mathrm{c}}\right\}
$$

The substrate self-cartesian transforms set is such that

$$
\left.\forall T \in \mathcal{T}_{U, V, \mathrm{c}} \forall P \in \operatorname{der}\left(T^{\%}\right) \diamond K=\operatorname{vars}(P)\left(P=K^{\mathrm{CS}\{ \}}\right)\right)
$$

The substrate self-cartesian partition-sets set, $\mathcal{N}_{U, V, \mathrm{c}}$, can be defined explicitly

$$
\mathcal{N}_{U, V, \mathrm{c}}=\left\{\left\{K^{\mathrm{CS}\{ \}}: K \in X\right\}: X \subseteq \mathrm{P}(V)\right\}
$$

The substrate self-cartesian transforms set, $\mathcal{T}_{U, V, \mathrm{c}}$, can be defined explicitly

$$
\mathcal{T}_{U, V, \mathrm{c}}=\left\{\left\{P^{V \mathrm{~T}}: K \in X, P=K^{\mathrm{CS}\{ \}}\right\}^{\mathrm{T}}: X \subseteq \mathrm{P}(V)\right\}
$$

The substrate self-cartesian transforms set includes the empty transform, $(\emptyset, \emptyset) \in \mathcal{T}_{U, V, \mathrm{c}}$, the unary partition transform, $\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V, \mathrm{c}}$, the self partition transform, $V^{\mathrm{CS}\{ \} \mathrm{T}} \in \mathcal{T}_{U, V, \mathrm{c}}$, and the value full functional transform, $\left\{\{v\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: v \in V\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V, c}$.

The cardinality of the substrate self-cartesian partition-sets set is $\left|\mathcal{N}_{U, V, \mathrm{c}}\right|=$ $2^{2^{n}}$ where dimension $n=|V|$. Therefore the cardinality of the substrate selfcartesian transforms set is bounded $\left|\mathcal{T}_{U, V, \mathrm{c}}\right| \leq 2^{2^{n}}$.

The intersection between the substrate self-cartesian partition-sets set, $\mathcal{N}_{U, V, \mathrm{c}}$, and the non-overlapping substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{n}}$, is

$$
\mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}}=\left\{\left\{K^{\mathrm{CS}\{ \}}: K \in Y\right\}: Y \in \mathrm{~B}(V)\right\}
$$

In the case of non-empty substrate variables, the cardinality of the intersection is $V \neq \emptyset \Longrightarrow\left|\mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}}\right|=\operatorname{bell}(n)$ where dimension $n=|V|$.

The intersection between the substrate self-cartesian partition-sets set, $\mathcal{N}_{U, V, \mathrm{c}}$, and the weak non-overlapping substrate partition-sets set, $\mathcal{N}^{\prime}{ }_{U, V, \mathrm{n}}$, is

$$
\mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}}^{\prime}=\left\{\left\{K^{\mathrm{CS}\{ \}}: K \in Y\right\}: Y \in \mathrm{~B}^{\prime}(V)\right\} \cup\{\emptyset\}
$$

In the case of non-empty substrate variables, the cardinality of the intersection is $V \neq \emptyset \Longrightarrow\left|\mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}^{\prime}{ }_{U, V, \mathrm{n}}\right|=2 \times \operatorname{bell}(n)+1$ where dimension $n=|V|$. The cardinality of the substrate transforms of the intersection between the substrate self-cartesian partition-sets set, $\mathcal{N}_{U, V, \mathrm{c}}$, and the weak non-overlapping substrate partition-sets set, $\mathcal{N}^{\prime}{ }_{U, V, \mathrm{n}}$, is bounded

$$
\left|\left\{N^{\mathrm{T} V}: N \in \mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}}^{\prime}\right\}\right| \leq 2 \times \operatorname{bell}(n)+1
$$

The transforms of the intersection are bijective between the underlying states and derived states, $\operatorname{split}\left(V, X^{\mathrm{S}}\right) \in V^{\mathrm{CS}} \leftrightarrow W^{\mathrm{CS}}$, where $T \in\left\{N^{\mathrm{TV}}: N \in\right.$ $\left.\mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}}^{\prime}\right\}$ and $(X, W)=T$. The substrate transforms of the intersection form a subset of the intersection between the substrate self-cartesian transforms set, $\mathcal{T}_{U, V, \mathrm{c}}$, and the non-overlapping substrate transforms set, $\mathcal{T}_{U, V, \mathrm{n}}$,

$$
\left\{N^{\mathrm{T} V}: N \in \mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}}^{\prime}\right\} \subseteq \mathcal{T}_{U, V, \mathrm{c}} \cap \mathcal{T}_{U, V, \mathrm{n}}
$$

The unary transform is a member of the intersection between the substrate self-cartesian transforms set and the non-overlapping substrate transforms set, $\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V, \mathrm{c}} \cap \mathcal{T}_{U, V, \mathrm{n}}$, but it is only a member of the substrate transforms of the intersection between the substrate self-cartesian partition-sets set and the weak non-overlapping substrate partition-sets set if the substrate consists only of mono-valent variables, $\left.\exists v \in V\left(\left|U_{v}\right|>1\right)\right) \Longrightarrow\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \notin$ $\left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}^{\prime}{ }_{U, V, \mathrm{n}}\right\}$.

The intersection between the substrate self-cartesian partition-sets set, $\mathcal{N}_{U, V, \mathrm{c}}$, and the binary non-overlapping substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{n}, \mathrm{b}}$, is

$$
\mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{~b}}=\left\{\left\{K^{\mathrm{CS}\{ \}},(V \backslash K)^{\mathrm{CS}\{ \}}\right\}: K \subset V, K \neq \emptyset, K \neq V\right\}
$$

In the case of pluri-variate substrate variables, the cardinality of the intersection is $\left|\mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{b}}\right|=2^{n-1}-1$ where dimension $n=|V|$. The cardinality of the substrate transforms of the intersection between the substrate self-cartesian partition-sets set, $\mathcal{N}_{U, V, c}$, and the binary substrate partition-sets set, $\mathcal{N}^{\prime}{ }_{U, V, \mathrm{n}, \mathrm{b}}$, is bounded

$$
\left|\left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{~b}}\right\}\right| \leq 2^{n-1}-1
$$

The substrate transforms of the intersection form a subset of the intersection between the substrate self-cartesian transforms set, $\mathcal{T}_{U, V, \mathrm{c}}$, and the binary non-overlapping substrate transforms set, $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{b}}$,

$$
\left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{~b}}\right\} \subseteq \mathcal{T}_{U, V, \mathrm{c}} \cap \mathcal{T}_{U, V, \mathrm{n}, \mathrm{~b}}
$$

The intersection between the substrate self-cartesian transforms set, $\mathcal{N}_{U, V, \mathrm{c}}$, and the self non-overlapping substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{n}, \mathrm{s}}$, is a singleton

$$
\mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{~s}}=\left\{\left\{\{v\}^{\mathrm{CS}\{ \}}: v \in V\right\}\right\}
$$

The corresponding substrate transform is the value full functional transform, $\left\{\{v\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: v \in V\right\}^{\mathrm{T}}$. The value full functional transform is a member of the intersection between the substrate self-cartesian transforms set, $\mathcal{T}_{U, V, \mathrm{c}}$, and the self non-overlapping substrate transforms set, $\mathcal{T}_{U, V, n, s}$,

$$
\left\{\{v\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: v \in V\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V, \mathrm{c}} \cap \mathcal{T}_{U, V, \mathrm{n}, \mathrm{~s}}
$$

Consider the substrate binary-cartesian partition transforms set $\mathcal{T}_{U, V, 2}$ which is a subset of the substrate transforms set, $\mathcal{T}_{U, V, 2} \subseteq \mathcal{T}_{U, V}$. Let the substrate binary-cartesian partition-sets set $\mathcal{N}_{U, V, 2} \subset \mathcal{N}_{U, V}$ be defined such that the partition sets consist only of binary partitions of the cartesian states of subsets of the substrate, $\left|P^{V}\right|=|P|=2$ where $P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)$ and $K \subseteq V$,

$$
\mathcal{N}_{U, V, 2}=\left\{N: N \in \mathcal{N}_{U, V}, \forall P \in N(|P|=2)\right\}
$$

The substrate binary-cartesian partition-sets set includes the empty partitionset, $\emptyset \in \mathcal{N}_{U, V, 2}$.

The substrate binary-cartesian transforms set is defined in terms of substrate binary-cartesian partition-sets set

$$
\mathcal{T}_{U, V, 2}=\left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, 2}\right\}
$$

The substrate binary-cartesian transforms set is such that

$$
\forall T \in \mathcal{T}_{U, V, 2} \forall P \in \operatorname{der}(T)(|P|=2)
$$

The substrate binary-cartesian partition-sets set, $\mathcal{N}_{U, V, 2}$, can be defined explicitly

$$
\begin{aligned}
\mathcal{N}_{U, V, 2} & =\mathrm{P}\left(\left\{P: K \subseteq V, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right),|P|=2\right\}\right) \\
& =\mathrm{P}\left(\left\{\left\{C, K^{\mathrm{CS}} \backslash C\right\}: K \subseteq V, C \in \mathrm{P}\left(K^{\mathrm{CS}}\right) \backslash\left\{\emptyset, K^{\mathrm{CS}}\right\}\right\}\right)
\end{aligned}
$$

The cardinality of the substrate binary-cartesian partition partition-sets set is $\left|\mathcal{N}_{U, V, 2}\right|=2^{m}$ where

$$
\begin{aligned}
m & =\sum\left|\mathrm{P}\left(K^{\mathrm{CS}}\right)\right| / 2-1: K \subseteq V,\left|K^{\mathrm{CS}}\right| \geq 2 \\
& =\sum 2^{x-1}-1: K \subseteq V, x=\left|K^{\mathrm{CS}}\right|, x \geq 2
\end{aligned}
$$

In the case where the substrate volume is at least two, $y \geq 2$, where $y=\left|V^{\mathrm{CS}}\right|$, the cardinality of the substrate binary-cartesian partition partition-sets set is bounded, $2^{2^{y-1}-1} \leq\left|\mathcal{N}_{U, V, 2}\right| \leq 2^{2^{n+y-1}}$, where $n=|V|$.

In the case of regular variables of valency $d \geq 2$ and dimension $n$, the cardinality of the substrate binary-cartesian partition partition-sets set is

$$
\left|\mathcal{N}_{U, V, 2}\right|=2^{m}: m=\sum_{k \in\{1 \ldots n\}}\binom{n}{k}\left(2^{2^{k}-1}-1\right)
$$

The substrate binary-cartesian partition transforms set includes the empty transform, $(\emptyset, \emptyset) \in \mathcal{T}_{U, V, 2}$, but excludes the self partition transform, $V^{\mathrm{CS}\{ \} \mathrm{T}} \notin$ $\mathcal{T}_{U, V, 2}$, unless the volume is two, $y=2$. The substrate binary-cartesian partition transforms set excludes the unary partition transform, $\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \notin \mathcal{T}_{U, V, 2}$.

The crown transform, transformCrown $(D)$, of a substrate decomposition $D \in$ $\mathcal{D}_{U, V}$ maps to a substrate transform in the substrate binary-cartesian partition transforms set, $\left\{(X \%(V \cup\{w\}),\{w\})^{\mathrm{PVT}}: w \in W\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V, 2}$ where $(X, W)=$ transformCrown $(D)$. This is because contingent slice binary partitions form the derived variables of the crown transform, $\forall P \in W(|P|=2)$.

The intersection between the substrate binary-cartesian partition partitionsets set and the non-overlapping substrate partition-sets set is

$$
\begin{aligned}
& \mathcal{N}_{U, V, 2} \cap \mathcal{N}_{U, V, \mathrm{n}} \\
& \quad=\left\{N: Y \in \mathrm{~B}(V), N \in \prod_{K \in Y}\left\{P: P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right),|P|=2\right\}\right\} \\
& \quad=\left\{N: Y \in \mathrm{~B}(V), N \in \prod_{K \in Y}\left\{\left\{C, K^{\mathrm{CS}} \backslash C\right\}: C \in \mathrm{P}\left(K^{\mathrm{CS}}\right) \backslash\left\{\emptyset, K^{\mathrm{CS}}\right\}\right\}\right\}
\end{aligned}
$$

In the case of non-empty substrate variables, $V \neq \emptyset$, the intersection has cardinality

$$
\left|\mathcal{N}_{U, V, 2} \cap \mathcal{N}_{U, V, \mathrm{n}}\right|=\sum\left(\prod_{K \in Y} 2^{\left|K^{\mathrm{CS}}\right|-1}-1\right): Y \in \mathrm{~B}(V), \forall K \in Y\left(\left|K^{\mathrm{CS}}\right| \geq 2\right)
$$

The cardinality is bounded $\left|\mathcal{N}_{U, V, 2} \cap \mathcal{N}_{U, V, \mathrm{n}}\right| \leq \operatorname{bell}(n) \times\left(2^{y}-1\right)$, where volume $y=\left|V^{\mathrm{CS}}\right|$ and dimension $n=|V|$.

In the case of regular variables of valency $d \geq 2$ and dimension $n$, the cardinality of the intersection is

$$
\left|\mathcal{N}_{U, V, 2} \cap \mathcal{N}_{U, V, \mathrm{n}}\right|=\sum_{(L, c) \in \operatorname{bcd}(n)}\left(c \prod_{(k, m) \in L}\left(2^{d^{k}-1}-1\right)^{m}\right)
$$

The subset of the substrate transforms set, $\mathcal{T}_{U, V}$, which consists of transforms having unary partitions of the cartesian states is simply the empty transform and the unary partition transform. Let the substrate unary-cartesian partition-sets set $\mathcal{N}_{U, V, 1} \subset \mathcal{N}_{U, V}$ be defined such that the partition sets consist only of unary partitions of the cartesian states of subsets of the substrate, $\left|P^{V}\right|=|P|=1$ where $P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)$ and $K \subseteq V$,

$$
\begin{aligned}
\mathcal{N}_{U, V, 1} & =\left\{N: N \in \mathcal{N}_{U, V}, \forall P \in N(|P|=1)\right\} \\
& =\mathrm{P}\left(\left\{\left\{K^{\mathrm{CS}}\right\}: K \subseteq V\right\}\right)
\end{aligned}
$$

The cardinality of the substrate unary-cartesian partition-sets set is $\left|\mathcal{N}_{U, V, 1}\right|=$ $2^{2^{n}}$. The set of substrate transforms is

$$
\left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, 1}\right\}=\left\{(\emptyset, \emptyset),\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}\right\} \subset \mathcal{T}_{U, V}
$$

Consider the substrate decremented transforms set $\mathcal{T}_{U, V,-}$ which is a subset of the substrate transforms set, $\mathcal{T}_{U, V,-} \subseteq \mathcal{T}_{U, V}$. Let the substrate decremented partition-sets set $\mathcal{N}_{U, V,-} \subset \mathcal{N}_{U, V}$ be defined such that the partition sets contain exactly one decremented self partition, $\operatorname{decs}\left(\operatorname{self}\left(J^{\mathrm{CS}}\right)\right)$ where $J \subseteq V$ and decs $=$ decrements $\in \mathcal{R}_{U} \rightarrow \mathrm{P}\left(\mathcal{R}_{U}\right)$, with the remainder being self partitions of the cartesian states, $\operatorname{self}\left(K^{\mathrm{CS}}\right)$ where $K \subseteq V$

$$
\begin{array}{r}
\mathcal{N}_{U, V,-}=\left\{N: N \in \mathcal{N}_{U, V}, \exists Q \in N((|Q|=|\bigcup Q|-1) \wedge\right. \\
(\forall P \in N(P \neq Q \Longrightarrow|P|=|\bigcup P|)))\}
\end{array}
$$

The substrate decremented partition-sets set excludes the empty partitionset, $\emptyset \notin \mathcal{N}_{U, V,-}$. Note that this definition does not prevent the partition-set from containing both the decremented partition, $Q \in \operatorname{decs}\left(\operatorname{self}\left(J^{\mathrm{CS}}\right)\right)$ and the self-partition, $P=\operatorname{self}\left(J^{\mathrm{CS}}\right)$, on the same subset, $J \subseteq V$, of the substrate variables.

The substrate decremented transforms set is defined in terms of substrate decremented partition-sets set

$$
\mathcal{T}_{U, V,-}=\left\{N^{\mathrm{T} V}: N \in \mathcal{N}_{U, V,-}\right\}
$$

The substrate decremented transforms set is such that

$$
\begin{aligned}
& \forall T \in \mathcal{T}_{U, V,-} \exists Q \in \operatorname{der}\left(T^{\%}\right) \diamond J=\operatorname{vars}(Q)\left(\left(Q \in \operatorname{decs}\left(J^{\mathrm{CS}\{ \}}\right)\right) \wedge\right. \\
& \left.\quad\left(\forall P \in \operatorname{der}\left(T^{\%}\right) \diamond K=\operatorname{vars}(P)\left(P \neq Q \Longrightarrow P=K^{\mathrm{CS}\{ \}}\right)\right)\right)
\end{aligned}
$$

The substrate decremented partition-sets set, $\mathcal{N}_{U, V,-}$, can be defined explicitly

$$
\begin{aligned}
\mathcal{N}_{U, V,-}= & \left\{\{Q\} \cup N: J \subseteq V, Q \in \operatorname{decs}\left(J^{\mathrm{CS}\{ \}}\right), N \in \mathcal{N}_{U, V,, c}\right\} \\
= & \left\{\{Q\} \cup\left\{K^{\mathrm{CS}\{ \}}: K \in X\right\}: J \subseteq V, Q \in \operatorname{decs}\left(J^{\mathrm{CS}\{ \}}\right), X \subseteq \mathrm{P}(V)\right\} \\
= & \left\{\left\{J^{\mathrm{CS}\{ \}} \backslash\left\{\left\{S_{1}\right\},\left\{S_{2}\right\}\right\} \cup\left\{\left\{S_{1}, S_{2}\right\}\right\}\right\} \cup\left\{K^{\mathrm{CS}\{ \}}: K \in X\right\}:\right. \\
& \left.\quad J \subseteq V, S_{1}, S_{2} \in J^{\mathrm{CS}}, S_{1} \neq S_{2}, X \subseteq \mathrm{P}(V)\right\}
\end{aligned}
$$

The substrate decremented transforms set excludes the empty transform, $(\emptyset, \emptyset) \notin \mathcal{T}_{U, V,-}$. If the substrate variables is a singleton of a bi-valent variable, the substrate decremented transforms set includes the self partition transform, $(|V|=1) \wedge\left(\left|V^{\mathrm{CS}}\right|=2\right) \Longrightarrow V^{\mathrm{CS}\{ \} \mathrm{T}} \in \mathcal{T}_{U, V,-}$. The substrate decremented transforms set includes the decremented self partition transforms, $\left\{Q^{\mathrm{T}}: Q \in \operatorname{decs}\left(V^{\mathrm{CS}\{ \}}\right)\right\} \subset \mathcal{T}_{U, V,-}$. The substrate decremented transforms set excludes the unary partition transform, $\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \notin \mathcal{T}_{U, V,-}$, if none of the substrate variables are bi-valent, $\forall w \in V\left(\left|U_{w}\right| \neq 2\right)$.

The cardinality of the substrate decremented partition-sets set is

$$
\left|\mathcal{N}_{U, V,-}\right|=2^{2^{n}} \sum_{J \in \mathrm{P}(V) \backslash\{\theta\}}\left|J^{\mathrm{CS}}\right|\left(\left|J^{\mathrm{CS}}\right|-1\right) / 2
$$

where dimension $n=|V|$. Thus $\left|\mathcal{N}_{U, V,-}\right|<2^{2^{n}+n-1} y^{2}$ where substrate volume $y=\left|V^{\mathrm{CS}}\right|$. If the substrate $V$ is regular having valency $d$, the cardinality is

$$
\left|\mathcal{N}_{U, V,-}\right|=2^{2^{n}} \sum_{k \in\{1 \ldots n\}}\binom{n}{k} d^{k}\left(d^{k}-1\right) / 2
$$

which is bounded $\left|\mathcal{N}_{U, V,-}\right|<2^{2^{n}+n-1} d^{2 n}$.
The intersection of the substrate decremented partition-sets set and the weak non-overlapping substrate partition-sets set can be defined explicitly

$$
\begin{aligned}
& \mathcal{N}_{U, V,-} \cap \mathcal{N}^{\prime}{ }_{U, V, \mathrm{n}}= \\
& \quad\left\{\{Q\} \cup\left\{K^{\mathrm{CS}\{ \}}: K \in Y, K \neq J\right\}: Y \in \mathrm{~B}^{\prime}(V), J \in Y, Q \in \operatorname{decs}\left(J^{\mathrm{CS}\{ \}}\right)\right\}
\end{aligned}
$$

The cardinality of the intersection is

$$
\left|\mathcal{N}_{U, V,-} \cap \mathcal{N}_{U, V, \mathrm{n}}^{\prime}\right|=\sum_{Y \in \mathrm{~B}^{\prime}(V)} \sum_{J \in Y \backslash\{\emptyset\}}\left|J^{\mathrm{CS}}\right|\left(\left|J^{\mathrm{CS}}\right|-1\right) / 2
$$

So $\left|\mathcal{N}_{U, V,-} \cap \mathcal{N}^{\prime}{ }_{U, V, \mathrm{n}}\right| \leq \operatorname{bell}(n) \times n y^{2}$, where dimension $n=|V|$ and volume $y=\left|V^{\mathrm{CS}}\right|$.

Similarly, the intersection of the substrate decremented partition-sets set and the non-overlapping substrate partition-sets set can be defined explicitly

$$
\begin{aligned}
& \mathcal{N}_{U, V,-} \cap \mathcal{N}_{U, V, \mathrm{n}}= \\
& \quad\left\{\{Q\} \cup\left\{K^{\mathrm{CS}\{ \}}: K \in Y, K \neq J\right\}: Y \in \mathrm{~B}(V), J \in Y, Q \in \operatorname{decs}\left(J^{\operatorname{cs}\{ \}}\right)\right\}
\end{aligned}
$$

The cardinality of the intersection is

$$
\left|\mathcal{N}_{U, V,-} \cap \mathcal{N}_{U, V, \mathrm{n}}\right|=\sum_{Y \in \mathrm{~B}(V)} \sum_{J \in Y \backslash\{\theta\}}\left|J^{\mathrm{CS}}\right|\left(\left|J^{\mathrm{CS}}\right|-1\right) / 2
$$

So $\left|\mathcal{N}_{U, V,-} \cap \mathcal{N}_{U, V, \mathrm{n}}\right| \leq \operatorname{bell}(n) \times n y^{2} / 2$, where dimension $n=|V|$ and volume $y=\left|V^{\mathrm{CS}}\right|$. In the case of regular variables of valency $d$ and dimension $n$, the cardinality is

$$
\left|\mathcal{N}_{U, V,-} \cap \mathcal{N}_{U, V, \mathrm{n}}\right|=\sum_{(L, c) \in \operatorname{bcd}(n)}\left(c \sum_{(k, m) \in L} m d^{k}\left(d^{k}-1\right) / 2\right)
$$

The intersection of the substrate decremented partition-sets set and the self non-overlapping substrate partition-sets set can be defined explicitly

$$
\begin{aligned}
& \mathcal{N}_{U, V,-} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{~s}} \\
& =\left\{\{Q\} \cup\left\{\{u\}^{\mathrm{CS}\{ \}}: u \in V \backslash\{w\}\right\}: w \in V, Q \in \operatorname{decs}\left(\{w\}^{\mathrm{CS}\{ \}}\right)\right\} \\
& =\left\{\left\{\{w\}^{\mathrm{CS}\{ \}} \backslash\left\{\left\{S_{1}\right\},\left\{S_{2}\right\}\right\} \cup\left\{\left\{S_{1}, S_{2}\right\}\right\}\right\} \cup\left\{\{u\}^{\mathrm{CS}\{ \}}: u \in V \backslash\{w\}\right\}:\right. \\
& \left.\quad w \in V, s, t \in U_{w}, s \neq t, S_{1}=\{(w, s)\}, S_{2}=\{(w, t)\}\right\}
\end{aligned}
$$

The cardinality of the intersection is

$$
\left|\mathcal{N}_{U, V,-} \cap \mathcal{N}_{U, V, \mathbf{n}, \mathrm{~s}}\right|=\sum_{w \in V}\left|\{w\}^{\mathrm{CS}}\right|\left(\left|\{w\}^{\mathrm{CS}}\right|-1\right) / 2
$$

So $\left|\mathcal{N}_{U, V,-} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{s}}\right| \leq 1 / 2 \times n y^{2}$, where dimension $n=|V|$ and volume $y=\left|V^{\mathrm{CS}}\right|$. If the substrate $V$ is regular having valency $d$, then

$$
\left|\mathcal{N}_{U, V,-} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{~S}}\right|=n d(d-1) / 2
$$

By contrast, consider the substrate incremented transforms set $\mathcal{T}_{U, V,+}$ which is a subset of the substrate transforms set, $\mathcal{T}_{U, V,+} \subseteq \mathcal{T}_{U, V}$. The substrate incremented transforms set consists of the transforms of the increments of a pointed partition, increments $\in \mathcal{R}_{*} \rightarrow \mathrm{P}\left(\mathcal{R}_{*}\right)$. The only pointed partition that can be constructed from a substrate transform, without specifically defining a point component, is that of the unary partition transform, $\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$, which has only one component. Let the substrate incremented partition-sets set $\mathcal{N}_{U, V,+} \subset \mathcal{N}_{U, V}$ be defined such that the partition sets are singletons of the incremented self partitions which are singleton pointed binary partitions incremented from the unary partition, incs $\left(\left(\left\{J^{\mathrm{CS}}\right\}, J^{\mathrm{CS}}\right)\right)$ where $J \subseteq V$ and incs $=$ increments $\in \mathcal{R}_{*, U} \rightarrow \mathrm{P}\left(\mathcal{R}_{*, U}\right)$,

$$
\mathcal{N}_{U, V,+}=\left\{N: N \in \mathcal{N}_{U, V}, N=\{Q\},|Q|=2,(\exists C \in Q(|C|=1))\right\}
$$

The substrate incremented partition-sets set excludes the empty partition-set, $\emptyset \notin \mathcal{N}_{U, V,+}$.

The substrate incremented transforms set is defined in terms of substrate incremented partition-sets set

$$
\mathcal{T}_{U, V,+}=\left\{N^{\mathrm{T} V}: N \in \mathcal{N}_{U, V,+}\right\}
$$

The substrate incremented transforms set is such that

$$
\begin{aligned}
\forall T \in \mathcal{T}_{U, V,+}\left(\left|\operatorname{der}\left(T^{\%}\right)\right|\right. & =1 \wedge \\
\left(\forall Q \in \operatorname{der}\left(T^{\%}\right) \diamond J\right. & \left.\left.=\operatorname{vars}(Q)\left(Q \in \operatorname{incs}\left(\left(\left\{J^{\mathrm{CS}}\right\}, J^{\mathrm{CS}}\right)\right)\right)\right)\right)
\end{aligned}
$$

The substrate incremented partition-sets set, $\mathcal{N}_{U, V,+}$, can be defined explicitly

$$
\mathcal{N}_{U, V,+}=\left\{\left\{\left\{\{S\}, J^{\mathrm{CS}} \backslash\{S\}\right\}\right\}: J \subseteq V,\left|J^{\mathrm{CS}}\right|>1, S \in J^{\mathrm{CS}}\right\}
$$

The substrate incremented transforms set is a subset of the substrate binarycartesian partition transforms set, $\mathcal{T}_{U, V,+} \subset \mathcal{T}_{U, V, 2}$. The substrate incremented
transforms set excludes the empty transform, $(\emptyset, \emptyset) \notin \mathcal{T}_{U, V,+}$, and the unary partition transform, $\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \notin \mathcal{T}_{U, V,+}$. The substrate incremented transforms set excludes the self partition transform, $V^{\mathrm{CS}\{ \} \mathrm{T}} \notin \mathcal{T}_{U, V,+}$, unless the volume is two, $\left|V^{\mathrm{CS}}\right|=2$.

The cardinality of the substrate incremented partition-sets set is

$$
\left|\mathcal{N}_{U, V,+}\right|=\sum\left(\left|J^{\mathrm{CS}}\right| / 2: J \subseteq V,\left|J^{\mathrm{CS}}\right|=2\right)+\sum\left(\left|J^{\mathrm{CS}}\right|: J \subseteq V,\left|J^{\mathrm{CS}}\right|>2\right)
$$

The cardinality of the substrate incremented partition-sets set is bounded $\left|\mathcal{N}_{U, V,+}\right| \leq 2^{n} y$ where dimension $n=|V|$ and $y=\left|V^{\mathrm{CS}}\right|$ if $y>2$.

Now consider subsets of the substrate partition-sets set which are defined by parameter. The definition of the substrate partition-sets set is

$$
\mathcal{N}_{U, V}=\mathrm{P}\left(\left\{P: K \subseteq V, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}\right)
$$

The corresponding substrate transforms set is $\mathcal{T}_{U, V}=\left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V}\right\}$.
The cardinality of the substrate partition-sets set is

$$
\left|\mathcal{N}_{U, V}\right|=2^{c}: c=\sum_{K \subseteq V} \operatorname{bell}\left(\left|K^{\mathrm{CS}}\right|\right)
$$

This is bounded

$$
2^{\operatorname{bell}(y)} \leq\left|\mathcal{N}_{U, V}\right| \leq 2^{2^{n} \operatorname{bell}(y)}
$$

where $y=\left|V^{\mathrm{CS}}\right|$. In the case of regular variables $V$, having valency $\{d\}=$ $\left\{\left|U_{w}\right|: w \in V\right\}$ and dimension $n=|V|$, the cardinality is

$$
\left|\mathcal{N}_{U, V}\right|=2^{c}: c=\sum_{k \in\{0 \ldots n\}}\binom{n}{k} \operatorname{bell}\left(d^{k}\right)
$$

First consider the limited-underlying-dimension substrate partition-sets set $\mathcal{N}_{U, V, \mathrm{kmax}}$ which is parameterised by kmax $\in \mathbf{N}$ such that the cardinality of the variables of each of the partitions is limited,

$$
\mathcal{N}_{U, V, \mathrm{kmax}}=\mathrm{P}\left(\left\{P: K \subseteq V,|K| \leq \operatorname{kmax}, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}\right)
$$

The cardinality of the limited-underlying-dimension substrate partition-sets set is

$$
\left|\mathcal{N}_{U, V, \mathrm{kmax}}\right|=2^{c}: c=\sum\left(\operatorname{bell}\left(\left|K^{\mathrm{CS}}\right|\right): K \subseteq V,|K| \leq \operatorname{kmax}\right)
$$

In the case of regular variables $V$, having valency $d$ and dimension $n$, such that kmax $\leq n$, the cardinality is

$$
\left|\mathcal{N}_{U, V, \mathrm{kmax}}\right|=2^{c}: c=\sum_{k \in\{0 \ldots \mathrm{kmax}\}}\binom{n}{k} \operatorname{bell}\left(d^{k}\right)
$$

This is bounded

$$
2^{\operatorname{bell}\left(d^{k \max }\right)} \leq\left|\mathcal{N}_{U, V, \mathrm{kmax}}\right| \leq 2^{2^{n} \operatorname{bell}\left(d^{k \max }\right)}
$$

where $d^{\mathrm{kmax}} \leq\left|V^{\mathrm{CS}}\right|$.
Similarly, consider the limited-underlying-volume substrate partition-sets set $\mathcal{N}_{U, V, \mathrm{xmax}}$ which is parameterised by xmax $\in \mathbf{N}_{>0}$ such that the underlying volume of each of the partitions is limited,

$$
\mathcal{N}_{U, V, \mathrm{xmax}}=\mathrm{P}\left(\left\{P: K \subseteq V,\left|K^{\mathrm{CS}}\right| \leq \operatorname{xmax}, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}\right)
$$

The cardinality of the limited-underlying-volume substrate partition-sets set is

$$
\left|\mathcal{N}_{U, V, \mathrm{xmax}}\right|=2^{c}: c=\sum\left(\operatorname{bell}\left(\left|K^{\mathrm{CS}}\right|\right): K \subseteq V,\left|K^{\mathrm{CS}}\right| \leq \operatorname{xmax}\right)
$$

This is bounded

$$
\left|\mathcal{N}_{U, V, \mathrm{xmax}}\right| \leq 2^{2^{n} \operatorname{bell}(\mathrm{xmax})}
$$

where xmax $\leq\left|V^{\mathrm{CS}}\right|$.
In the case of pluri-valent regular variables $V$, having valency $d>1$ and dimension $n$, the cardinality is defined in terms of the implied underlyingdimension limit $\mathrm{kmax}=\ln \mathrm{xmax} / \ln d$, where $\ln \mathrm{xmax} / \ln d \in \mathbf{N}$,

$$
\left|\mathcal{N}_{U, V, \mathrm{xmax}}\right|=2^{c}: c=\sum_{k \in\{0 \ldots \mathrm{kmax}\}}\binom{n}{k} \operatorname{bell}\left(d^{k}\right)
$$

The limited-valency substrate partition-sets set $\mathcal{N}_{U, V, \text { umax }}$ is parameterised by umax $\in \mathbf{N}_{>0}$ such that the valency of the partition variables is limited,

$$
\mathcal{N}_{U, V, \operatorname{umax}}=\mathrm{P}\left(\left\{P: K \subseteq V, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right),|P| \leq \mathrm{umax}\right\}\right)
$$

The cardinality of the limited-valency substrate partition-sets set is

$$
\begin{aligned}
& \left|\mathcal{N}_{U, V, u m a x}\right|=2^{c}: \\
& \quad c=\sum\left(\operatorname{stir}\left(\left|K^{\mathrm{CS}}\right|, u\right): K \subseteq V, u \in\{1 \ldots \mathrm{umax}\}, u \leq\left|K^{\mathrm{CS}}\right|\right)
\end{aligned}
$$

where stir $\in \mathbf{N}_{>0} \times \mathbf{N} \rightarrow \mathbf{N}_{>0}$ is the Stirling number of the second kind.
In the case of regular variables $V$, having valency $d$ and dimension $n$, the cardinality is

$$
\begin{aligned}
& \left|\mathcal{N}_{U, V, \mathrm{umax}}\right|=2^{c}: \\
& \quad c=\sum\left(\binom{n}{k} \operatorname{stir}\left(d^{k}, u\right): k \in\{0 \ldots n\}, u \in\{1 \ldots \operatorname{umax}\}, u \leq d^{k}\right)
\end{aligned}
$$

Similarly, the lower-limited-valency substrate partition-sets set $\mathcal{N}_{U, V, \text { umin }}$ is parameterised by umin $\in \mathbf{N}_{>0}$ such that the valency of the partition variables is lower-limited,

$$
\mathcal{N}_{U, V, \text { umin }}=\mathrm{P}\left(\left\{P: K \subseteq V, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right),|P| \geq \text { umin }\right\}\right)
$$

The cardinality of the lower-limited-valency substrate partition-sets set is
$\left|\mathcal{N}_{U, V, \text { umin }}\right|=2^{c}: c=\sum\left(\operatorname{stir}\left(\left|K^{\mathrm{CS}}\right|, u\right): K \subseteq V, u \in\left\{\operatorname{umin} \ldots\left|K^{\mathrm{CS}}\right|\right\}\right)$
In the case of regular variables $V$, having valency $d$ and dimension $n$, the cardinality is
$\left|\mathcal{N}_{U, V, \mathrm{umin}}\right|=2^{c}: c=\sum\left(\binom{n}{k} \operatorname{stir}\left(d^{k}, u\right): k \in\{0 \ldots n\}, u \in\left\{u \min \ldots d^{k}\right\}\right)$
In the special case where umin $=2$ the cardinality is

$$
\left|\mathcal{N}_{U, V, \mathrm{umin}}\right|=2^{c}: c=\sum\left(\binom{n}{k}\left(\operatorname{bell}\left(d^{k}\right)-1\right): k \in\{0 \ldots n\}\right)
$$

The limited-component substrate partition-sets set $\mathcal{N}_{U, V, \mathrm{cmin}}$ is parameterised by cmin $\in \mathbf{N}_{>0}$ such that the cardinality of the components of the partition variables is limited,

$$
\mathcal{N}_{U, V, \mathrm{cmin}}=\mathrm{P}\left(\left\{P: K \subseteq V, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right), \forall C \in P(|C| \geq \mathrm{cmin})\right\}\right)
$$

In the case of regular variables $V$, having valency $d$ and dimension $n$, the cardinality is

$$
\begin{aligned}
& \left|\mathcal{N}_{U, V, \mathrm{cmin}}\right|=2^{c}: \\
& \qquad c=\sum\left(\binom{n}{k} b: k \in\{0 \ldots n\},(L, b) \in \operatorname{bcd}\left(d^{k}\right),\right. \\
& \forall \quad \forall(j, m) \in L(m \neq 0 \Longrightarrow j \geq \mathrm{cmin}))
\end{aligned}
$$

The intersecting substrate partition-sets set $\mathcal{N}_{U, V, X}$ is parameterised by a set of variables $X \subseteq \operatorname{vars}(U)$ such that the variables of the partitions intersect with the given set,

$$
\mathcal{N}_{U, V, X}=\mathrm{P}\left(\left\{P: K \subseteq V, K \cap X \neq \emptyset, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}\right)
$$

The cardinality of the intersecting substrate partition-sets set is

$$
\left|\mathcal{N}_{U, V, X}\right|=2^{c}: c=\sum\left(\operatorname{bell}\left(\left|K^{\mathrm{CS}}\right|\right): K \subseteq V, K \cap X \neq \emptyset\right)
$$

In the case where the intersection with the substrate variables is not empty, $V \cap X \neq \emptyset$, the cardinality is bounded

$$
2^{\operatorname{bell}(y)} \leq\left|\mathcal{N}_{U, V, X}\right| \leq 2^{x 2^{n-1} \operatorname{bell}(y)}
$$

where $x=|V \cap X|$ and $y=\left|V^{\mathrm{CS}}\right|$. In the case of regular variables $V$, having valency $d$ and dimension $n$, the cardinality is

$$
\begin{aligned}
\left|\mathcal{N}_{U, V, X}\right|=2^{c}: c= & \left(\sum_{k \in\{1 \ldots n-x\}}\left(\binom{n}{k}-\binom{n-x}{k}\right) \operatorname{bell}\left(d^{k}\right)\right)+ \\
& \left(\sum_{k \in\{n-x+1 \ldots n\}}\binom{n}{k} \operatorname{bell}\left(d^{k}\right)\right)
\end{aligned}
$$

This may be written more succinctly if the binomial coefficient is defined $\forall a, b \in \mathbf{N}\left(b>a \Longrightarrow\binom{a}{b}=0\right)$,

$$
\left|\mathcal{N}_{U, V, X}\right|=2^{c}: c=\sum_{k \in\{1 \ldots n\}}\left(\binom{n}{k}-\binom{n-x}{k}\right) \operatorname{bell}\left(d^{k}\right)
$$

The limited-breadth substrate partition-sets set $\mathcal{N}_{U, V, b m a x}$ is parameterised by bmax $\in \mathbf{N}$ such that the cardinalities of the partition-sets are limited,

$$
\mathcal{N}_{U, V, \operatorname{bmax}}=\left\{N: N \in \mathcal{N}_{U, V},|N| \leq \operatorname{bmax}\right\}
$$

The cardinality of the limited-breadth substrate partition-sets set is

$$
\left|\mathcal{N}_{U, V, \mathrm{bmax}}\right|=\left(\sum_{b \in\{0 \ldots \operatorname{bmax}\}}\binom{c}{b}\right): c=\sum_{K \subseteq V} \operatorname{bell}\left(\left|K^{\mathrm{CS}}\right|\right)
$$

This is bounded

$$
\left|\mathcal{N}_{U, V, \text { bmax }}\right| \leq \sum_{b \in\{0 \ldots \mathrm{bmax}\}}\binom{2^{n} \operatorname{bell}(y)}{b}
$$

where $y=\left|V^{\mathrm{CS}}\right|$. In the case of regular variables $V$, having valency $d$ and dimension $n$, the cardinality is

$$
\left|\mathcal{N}_{U, V, \mathrm{bmax}}\right|=\left(\sum_{b \in\{0 \ldots \mathrm{bmax}\}}\binom{c}{b}\right): c=\sum_{k \in\{0 \ldots n\}}\binom{n}{k} \operatorname{bell}\left(d^{k}\right)
$$

The intersection of the limited-underlying-dimension substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{kmax}}$, and the limited-breadth substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{bmax}}$, is

$$
\begin{aligned}
& \mathcal{N}_{U, V, \mathrm{kmax}} \cap \mathcal{N}_{U, V, \mathrm{bmax}}= \\
& \quad\left\{N: N \subseteq\left\{P: K \subseteq V,|K| \leq \operatorname{kmax}, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\},|N| \leq \mathrm{b} \max \right\}
\end{aligned}
$$

The cardinality of the intersection is

$$
\begin{aligned}
& \left|\mathcal{N}_{U, V, \mathrm{kmax}} \cap \mathcal{N}_{U, V, \mathrm{bmax}}\right|= \\
& \quad\left(\sum_{b \in\{0 \ldots \mathrm{bmax}\}}\binom{c}{b}\right): c=\sum\left(\operatorname{bell}\left(\left|K^{\mathrm{CS}}\right|\right): K \subseteq V,|K| \leq \mathrm{kmax}\right)
\end{aligned}
$$

In the case of regular variables $V$, having valency $d$ and dimension $n$, the cardinality of the intersection is

$$
\begin{aligned}
\mid \mathcal{N}_{U, V, \mathrm{kmax}} \cap & \mathcal{N}_{U, V, \mathrm{bmax}} \mid= \\
& \left(\sum_{b \in\{0 \ldots \mathrm{bmax}\}}\binom{c}{b}\right): c=\sum_{k \in\{0 \ldots \mathrm{kmax}\}}\binom{n}{k} \operatorname{bell}\left(d^{k}\right) .
\end{aligned}
$$

The intersection of the intersecting substrate partition-sets set $\mathcal{N}_{U, V, X}$, the limited-underlying-dimension substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{kmax}}$, and the limited-breadth substrate partition-sets set, $\mathcal{N}_{U, V, b \max }$, is

$$
\begin{aligned}
& \mathcal{N}_{U, V, X} \cap \mathcal{N}_{U, V, \mathrm{kmax}} \cap \mathcal{N}_{U, V, \mathrm{bmax}}= \\
& \qquad N: N \subseteq\left\{P: K \subseteq V, K \cap X \neq \emptyset,|K| \leq \operatorname{kmax}, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\} \\
& \\
& \quad|N| \leq \operatorname{bmax}\}
\end{aligned}
$$

The cardinality of the intersection is

$$
\begin{aligned}
& \left|\mathcal{N}_{U, V, X} \cap \mathcal{N}_{U, V, \mathrm{kmax}} \cap \mathcal{N}_{U, V, \mathrm{bmax}}\right|= \\
& \left(\sum_{b \in\{0 \ldots b \max \}}\binom{c}{b}\right): \\
& c=\sum\left(\operatorname{bell}\left(\left|K^{\mathrm{CS}}\right|\right): K \subseteq V, K \cap X \neq \emptyset,|K| \leq \operatorname{kmax}\right)
\end{aligned}
$$

In the case of regular variables $V$, having valency $d$, dimension $n$ and intersecting dimension $x=|X|$, the cardinality of the intersection is

$$
\begin{aligned}
& \left|\mathcal{N}_{U, V, X} \cap \mathcal{N}_{U, V, \mathrm{kmax}} \cap \mathcal{N}_{U, V, \mathrm{bmax}}\right|= \\
& \quad\left(\sum_{b \in\{0 \ldots \mathrm{bmax}\}}\binom{c}{b}\right): c=\sum_{k \in\{0 \ldots \mathrm{kmax}\}}\left(\binom{n}{k}-\binom{n-x}{k}\right) \operatorname{bell}\left(d^{k}\right)
\end{aligned}
$$

The range-limited-breadth substrate partition-sets set $\mathcal{N}_{U, V, \text { bran }}$ is parameterised by bran $=($ bmin, $\operatorname{bmax}) \in \mathbf{N}^{2}$ such that the cardinalities of the partition-sets are limited,

$$
\mathcal{N}_{U, V, \text { bran }}=\left\{N: N \in \mathcal{N}_{U, V}, \quad \text { bmin } \leq|N| \leq \operatorname{bmax}\right\}
$$

The cardinality of the range-limited-breadth substrate partition-sets set is

$$
\left|\mathcal{N}_{U, V, \text { bran }}\right|=\left(\sum_{b \in\{\text { bmin...bmax }\}}\binom{c}{b}\right): c=\sum_{K \subseteq V} \operatorname{bell}\left(\left|K^{\mathrm{CS}}\right|\right)
$$

In the case of regular variables $V$, having valency $d$ and dimension $n$, the cardinality is

$$
\left|\mathcal{N}_{U, V, \text { bran }}\right|=\left(\sum_{b \in\{\operatorname{bmin} . . . \operatorname{bmax}\}}\binom{c}{b}\right): c=\sum_{k \in\{0 \ldots n\}}\binom{n}{k} \operatorname{bell}\left(d^{k}\right)
$$

The intersection of the non-overlapping substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{n}}$, and the range-limited-breadth substrate partition-sets set, $\mathcal{N}_{U, V, b r a n}$, is

$$
\begin{aligned}
& \mathcal{N}_{U, V, \mathrm{n}, \text { bran }} \\
& \quad=\left\{N: Y \in \mathrm{~B}(V), N \in \prod_{K \in Y} \mathrm{~B}\left(K^{\mathrm{CS}}\right), \text { bmin } \leq|N| \leq \operatorname{bmax}\right\} \\
& =\left\{N: Y \in \mathrm{~B}(V), \operatorname{bmin} \leq|Y| \leq \operatorname{bmax}, N \in \prod_{K \in Y} \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}
\end{aligned}
$$

In the case where $\operatorname{bmax} \leq n$,
$\mathcal{N}_{U, V, \mathrm{n}, \mathrm{bran}}=\left\{N: b \in\{\operatorname{bmin} \ldots \mathrm{bmax}\}, Y \in \mathrm{~S}(V, b), N \in \prod_{K \in Y} \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}$
where the fixed cardinality partition function is $\mathrm{S} \in \mathrm{P}(\mathcal{X}) \times \mathbf{N}_{>0} \rightarrow \mathrm{P}(\mathrm{P}(\mathrm{P}(\mathcal{X}) \backslash$ $\{\emptyset\})$ ).

In the case of regular variables $V$, having valency $d$ and dimension $n$, the cardinality of the range-limited-breadth non-overlapping substrate partition-sets set is

$$
\begin{aligned}
& \left|\mathcal{N}_{U, V, \mathrm{n}, \mathrm{bran}}\right| \\
& \quad=\sum\left(\prod_{K \in Y} \operatorname{bell}\left(d^{|K|}\right)\right): b \in\{\operatorname{bmin} \ldots \operatorname{bmax}\}, Y \in \mathrm{~S}(V, b) \\
& =\sum\left(c \prod_{(k, m) \in L} \operatorname{bell}\left(d^{k}\right)^{m}\right): b \in\{\operatorname{bmin} \ldots \operatorname{bmax}\}, \quad(L, c) \in \operatorname{sscd}(n, b)
\end{aligned}
$$

where sscd $=$ stircd and the fixed cardinality partition function cardinality function is stircd $\in \mathbf{N}_{>0} \times \mathbf{N}_{>0} \rightarrow(\mathcal{L}(\mathbf{N}) \rightarrow \mathbf{N})$, defined in appendix 'Partitions', below.

The special case of the fixed-breadth non-overlapping substrate partition-sets set given cardinality $b \in \mathbf{N}_{>0}$ is defined

$$
\mathcal{N}_{U, V, \mathbf{n}, b}=\left\{N: Y \in \mathrm{~B}(V), N \in \prod_{K \in Y} \mathrm{~B}\left(K^{\mathrm{CS}}\right),|N|=b\right\}
$$

In the case of regular variables $V$, having valency $d$ and dimension $n$, the cardinality is

$$
\left|\mathcal{N}_{U, V, \mathrm{n}, b}\right|=\sum_{(L, c) \in \operatorname{sscd}(n, b)}\left(c \prod_{(k, m) \in L} \operatorname{bell}\left(d^{k}\right)^{m}\right)
$$

In the case where the fixed-breadth is two, $b=2$, the fixed-breadth nonoverlapping substrate partition-sets set equals the binary non-overlapping substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{n}, 2}=\mathcal{N}_{U, V, \mathrm{n}, \mathrm{b}}$. In the case where the fixedbreadth equals the dimension, $b=n$, the fixed-breadth non-overlapping substrate partition-sets set equals the self non-overlapping substrate partitionsets set, $\mathcal{N}_{U, V, \mathrm{n}, n}=\mathcal{N}_{U, V, \mathrm{n}, \mathrm{s}}$.

The intersection of the substrate self-cartesian partition-sets set and the limited-breadth non-overlapping substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{bmax}}$, is

$$
\mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{bmax}}=\left\{\left\{K^{\mathrm{CS}\{ \}}: K \in Y\right\}: Y \in \mathrm{~B}(V),|Y| \leq \operatorname{bmax}\right\}
$$

In the case where $\operatorname{bmax} \leq n$, the cardinality of the intersection is

$$
\left|\mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{bmax}}\right|=\sum_{b \in\{1 \ldots \mathrm{bmax}\}} \operatorname{stir}(n, b)
$$

where stir $\in \mathbf{N}_{>0} \times \mathbf{N} \rightarrow \mathbf{N}_{>0}$ is the Stirling number of the second kind.

Similarly to the limited-breadth substrate partition-sets set, $\mathcal{N}_{U, V, b m a x}$, the limited-derived-volume substrate partition-sets set $\mathcal{N}_{U, V, \mathrm{wmax}}$ is parameterised by wmax $\in \mathbf{N}_{>0}$ such that the volumes of the partition-sets are limited,

$$
\mathcal{N}_{U, V, \mathrm{wmax}}=\left\{N: N \in \mathcal{N}_{U, V},\left|N^{\mathrm{C}}\right| \leq \operatorname{wmax}\right\}
$$

Having considered the analysis of the substrate transforms set, $\mathcal{T}_{U, V}$, into various subsets, now consider its synthesis and the synthesis of its subsets. That is, consider possible sequences of construction from smaller subsets.

Substrate structures may be constructed by means of linear fuds. A linear fud $F \in \mathcal{F}_{U, 1}$ is a non-circular fud such that the underlying variables of the transforms in each layer fud are the derived variables of the layer fud immediately below, $\forall i \in\{2 \ldots|L|\}\left(\operatorname{und}\left(L_{i}\right) \subseteq \operatorname{der}\left(L_{i-1}\right)\right)$ where $L \in \mathcal{L}(\mathrm{P}(F))$ and $\operatorname{set}(L) \in \mathrm{B}(F)$. Thus a linear fud may be represented as a list of transforms, $\left\{\left(i, G^{\mathrm{T}}\right):(i, G) \in L\right\} \in \mathcal{L}\left(\mathcal{T}_{\mathrm{f}, \mathrm{U}}\right)$.

Let system $U$ contain all of the partition variables of the substrate fuds set, $\mathcal{F}_{U, V}$, on variables $V, \bigcup\left\{\operatorname{vars}(T): T \in \mathcal{F}_{U, V}\right\} \subseteq \operatorname{vars}(U)$. The substrate transforms set, $\mathcal{T}_{U, V}$, can be constructed from partition-sets of linear fuds of pairs of multi-partition transforms, $T_{1}, T_{2} \in \mathcal{T}_{U, \mathrm{P}^{*}}$. The first transform is a substrate self-cartesian transform, $T_{1} \in \mathcal{T}_{U, V, \mathrm{c}}$. The second transform is a non-empty self overlapping substrate transform, $T_{2} \in \mathcal{T}_{U, W, o, s}, T_{2} \neq(\emptyset, \emptyset)$, in the derived variables of the first, $W=\operatorname{der}\left(T_{1}\right)$,

$$
\begin{aligned}
& \mathcal{T}_{U, V}= \\
& \quad\left\{\left\{T_{1}, T_{2}\right\}^{\mathrm{TPT}}: T_{1} \in \mathcal{T}_{U, V, \mathrm{c},}, W=\operatorname{der}\left(T_{1}\right), T_{2} \in \mathcal{T}_{U, W, \mathrm{o}, \mathrm{~s}} \backslash\{(\emptyset, \emptyset)\}\right\} \cup\{(\emptyset, \emptyset)\}
\end{aligned}
$$

where shorthand $T^{\mathbb{N}}:=\operatorname{partitionset}(T)$. Note that the second $\operatorname{transform}, T_{2}$, is non-empty so that the fud is one functional, $\left\{T_{1}, T_{2}\right\} \in \mathcal{F}_{U, 1}$.

The substrate self-cartesian transform set, $\mathcal{T}_{U, V, \mathrm{c}}$, is constructed explicitly as

$$
\mathcal{T}_{U, V, \mathrm{c}}=\left\{\left\{K^{\mathrm{CS}\{ \} V \mathrm{~T}}: K \in X\right\}^{\mathrm{T}}: X \subseteq \mathrm{P}(V)\right\}
$$

The self overlapping substrate transforms set, $\mathcal{T}_{U, W, \mathrm{n}, \mathrm{s}}$, is constructed explicitly as

$$
\mathcal{T}_{U, W, \mathrm{o}, \mathrm{~s}}=\left\{(\bigcup H)^{\mathrm{T} W}: H \in \prod_{w \in W} \mathrm{P}\left(\mathrm{~B}\left(\{w\}^{\mathrm{CS}}\right)\right)\right\}
$$

So the substrate transforms set, $\mathcal{T}_{U, V}$, can be constructed explicitly as

$$
\begin{aligned}
& \mathcal{T}_{U, V}=\left\{(W \cup \bigcup H)^{\mathrm{TPTV}}: X \subseteq \mathrm{P}(V),\right. \\
&\left.W=\left\{K^{\mathrm{CS}\{ \}}: K \in X\right\}, H \in \prod_{w \in W} \mathrm{P}\left(\mathrm{~B}\left(\{w\}^{\mathrm{CS}}\right)\right)\right\} \cup\{(\emptyset, \emptyset)\}
\end{aligned}
$$

which has cardinality of construction

$$
\begin{aligned}
\left|\left\{(X, H): X \subseteq \mathrm{P}(V), H \in \prod_{K \in X} \mathrm{P}\left(\mathrm{~B}\left(\left\{K^{\mathrm{CS}\{ \}}\right\}^{\mathrm{CS}}\right)\right)\right\}\right| & =\sum_{X \subseteq \mathrm{P}(V)} \prod_{K \in X} 2^{\left|\mathrm{B}\left(K^{\mathrm{CS}}\right)\right|} \\
& \leq 2^{2^{n}(1+\operatorname{bell}(y))}
\end{aligned}
$$

where volume $y=\left|V^{\mathrm{CS}}\right|$, and dimension $n=|V|$. This may be compared to the explicit constructions from (i) subsets of the base substrate partitions, $\mathrm{B}\left(V^{\mathrm{CS}}\right)$,

$$
\mathcal{T}_{U, V}=\left\{N^{\mathrm{T}}: N \subseteq \mathrm{~B}\left(V^{\mathrm{CS}}\right)\right\}
$$

which has cardinality of construction

$$
\left|\mathrm{P}\left(\mathrm{~B}\left(V^{\mathrm{CS}}\right)\right)\right|=2^{\operatorname{bell}(y)}
$$

and (ii) the substrate partition-sets set, $\mathcal{N}_{U, V}$,

$$
\mathcal{T}_{U, V}=\left\{N^{\mathrm{TV}}: N \subseteq\left\{P: K \subseteq V, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}\right\}
$$

which has cardinality of construction

$$
\left|\mathcal{N}_{U, V}\right|=\left|\mathrm{P}\left(\left\{P: K \subseteq V, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}\right)\right|=\prod_{K \subseteq V} 2^{\left|\mathrm{B}\left(K^{\mathrm{CS}}\right)\right|}
$$

and which is bounded $2^{\operatorname{bell}(y)} \leq\left|\mathcal{N}_{U, V}\right| \leq 2^{2^{n} \times \operatorname{bell}(y)}$.
The non-overlapping substrate transforms set, $\mathcal{T}_{U, V, \mathrm{n}} \subset \mathcal{T}_{U, V}$, can also be constructed from partition-sets of linear fuds of pairs of multi-partition transforms, $T_{1}, T_{2} \in \mathcal{T}_{U, \mathrm{P}^{*}}$. In this case the first transform is in the non-overlapping subset of the substrate self-cartesian transform set, $T_{1} \in \mathcal{T}_{U, V, \mathrm{c}} \cap \mathcal{T}_{U, V, \mathrm{n}}$. The second transform is a self non-overlapping substrate transform, $T_{2} \in \mathcal{T}_{U, W, \mathrm{n}, \mathrm{s}}$, in the derived variables of the first, $W=\operatorname{der}\left(T_{1}\right)$,

$$
\begin{aligned}
& \mathcal{T}_{U, V, \mathrm{n}}= \\
& \quad\left\{\left\{T_{1}, T_{2}\right\}^{\mathrm{TPT}}: T_{1} \in \mathcal{T}_{U, V, \mathrm{c}} \cap \mathcal{T}_{U, V, \mathrm{n}}, W=\operatorname{der}\left(T_{1}\right), T_{2} \in \mathcal{T}_{U, W, \mathrm{n}, \mathrm{~s}}\right\} \cup\{(\emptyset, \emptyset)\}
\end{aligned}
$$

The strong non-overlapping substrate transforms set, $\left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, \mathrm{n}}\right\} \subseteq$ $\mathcal{T}_{U, V, \mathrm{n}}$ can be constructed from the transforms of the non-overlapping subset of the substrate self-cartesian partition-sets set, $T_{1} \in\left\{M^{\mathrm{T}}: M \in \mathcal{N}_{U, V, \mathrm{c}} \cap\right.$ $\left.\mathcal{N}_{U, V, \mathrm{n}}\right\}$, followed by the transforms of the self non-overlapping substrate partition-sets set, $T_{2} \in\left\{N^{\mathrm{T}}: N \in \mathcal{N}_{U, W, \mathrm{n}, \mathrm{s}}\right\}$, where $W=\operatorname{der}\left(T_{1}\right)$,

$$
\left\{N^{\mathrm{T} V}: N \in \mathcal{N}_{U, V, \mathrm{n}}\right\}=\left\{(M \cup N)^{\mathrm{TPT}}: M \in \mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}}, N \in \mathcal{N}_{U, M, \mathrm{n}, \mathrm{~s}}\right\}
$$

The intersection between the substrate self-cartesian partition-sets set, $\mathcal{N}_{U, V, \mathrm{c}}$, and the non-overlapping substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{n}}$, is constructed explicitly as

$$
\mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}}=\left\{\left\{K^{\mathrm{CS}\{ \}}: K \in Y\right\}: Y \in \mathrm{~B}(V)\right\}
$$

The self non-overlapping substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{n}, \mathrm{S}}$, is constructed explicitly as

$$
\mathcal{N}_{U, M, \mathrm{n}, \mathrm{~s}}=\prod_{w \in M} \mathrm{~B}\left(\{w\}^{\mathrm{CS}}\right)
$$

So the strong non-overlapping substrate transforms set, $\left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, \mathrm{n}}\right\}$, can be constructed explicitly as

$$
\begin{aligned}
&\left\{N^{\mathrm{T} V}: N \in \mathcal{N}_{U, V, \mathrm{n}}\right\}=\left\{(M \cup N)^{\mathrm{TPT}}: Y \in \mathrm{~B}(V),\right. \\
&\left.M=\left\{K^{\mathrm{CS}\{ \}}: K \in Y\right\}, N \in \prod_{w \in M} \mathrm{~B}\left(\{w\}^{\mathrm{CS}}\right)\right\}
\end{aligned}
$$

which has cardinality of construction equal to the cardinality of construction of the non-overlapping substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{n}}$,

$$
\begin{aligned}
\left|\left\{(Y, N): Y \in \mathrm{~B}(V), N \in \prod_{K \in Y} \mathrm{~B}\left(\left\{K^{\mathrm{CS}\{ \}}\right\}^{\mathrm{CS}}\right)\right\}\right| & =\sum_{Y \in \mathrm{~B}(V)} \prod_{K \in Y}\left|\mathrm{~B}\left(K^{\mathrm{CS}}\right)\right| \\
& \leq \operatorname{bell}(n) \times \operatorname{bell}(y)
\end{aligned}
$$

where volume $y=\left|V^{\mathrm{CS}}\right|$, and dimension $n=|V|$.
The self non-overlapping substrate transforms set, $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$, can be constructed from linear fuds of multi-partition transforms, $L \in \mathcal{L}\left(\mathcal{T}_{U, \mathrm{P}^{*}}\right)$. The starting transform in the sequence is the singleton strong self non-overlapping substrate self-cartesian transforms set, $L_{1} \in\left\{N^{\mathrm{T}}: N \in \mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{s}}\right\}$. That is, the first transform is the value full functional transform, $L_{1}=$
$\left\{\{v\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: v \in V\right\}^{\mathrm{T}}$. The subsequent transforms are strong self nonoverlapping substrate decremented transforms, $L_{2} \in\left\{N^{\mathrm{T}}: N \in \mathcal{N}_{U, W_{1},-} \cap\right.$ $\left.\mathcal{N}_{U, W_{1}, \mathrm{n}, \mathrm{s}}\right\}, L_{3} \in\left\{N^{\mathrm{T}}: N \in \mathcal{N}_{U, W_{2},-} \cap \mathcal{N}_{U, W_{2}, \mathrm{n}, \mathrm{s}}\right\}$, and so on,
$\mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}=$

$$
\begin{aligned}
& \left\{\operatorname{set}(L)^{\mathrm{TPT}}: L \in \mathcal{L}\left(\mathcal{T}_{U, \mathrm{f}, 1}\right),\left\{L_{1}\right\}=\left\{N^{\mathrm{T}}: N \in \mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{~s}}\right\}\right. \\
& \left.\left.\quad \forall i \in\{2 \ldots|L|\} \diamond W=\operatorname{der}\left(L_{i-1}\right)\left(L_{i} \in\left\{N^{\mathrm{T}}: N \in \mathcal{N}_{U, W,-} \cap \mathcal{N}_{U, W, \mathrm{n}, \mathrm{~s}}\right\}\right)\right)\right\}
\end{aligned}
$$

The intersection of the substrate decremented partition-sets set and the self non-overlapping substrate partition-sets set is constructed explicitly

$$
\begin{aligned}
& \mathcal{N}_{U, W,-} \cap \mathcal{N}_{U, W, \mathrm{n,s}}= \\
& \quad\left\{\{Q\} \cup\left\{\{u\}^{\mathrm{CS}\{ \}}: u \in W \backslash\{w\}\right\}: w \in W, Q \in \operatorname{decs}\left(\{w\}^{\mathrm{CS}\{ \}}\right)\right\}
\end{aligned}
$$

where decs $=$ decrements $\in \mathcal{R}_{U} \rightarrow \mathrm{P}\left(\mathcal{R}_{U}\right)$.
So the self non-overlapping substrate transforms set, $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$, can be constructed explicitly as

$$
\begin{aligned}
& \mathcal{T}_{U, V, \mathrm{n}, \mathrm{~s}}= \\
& \left\{(\bigcup \operatorname{set}(L))^{\mathrm{TPT}}: M \in \mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{~s}},\right. \\
& L \in \operatorname{subpaths}(\{(M, \operatorname{tdec}(U)(M))\})\}
\end{aligned}
$$

and, in the case of non-empty substrate, $V \neq \emptyset$,

$$
\begin{aligned}
& V \neq \emptyset \Longrightarrow \mathcal{T}_{U, V, \mathrm{n,s}}= \\
& \qquad(\bigcup \operatorname{set}(L))^{\mathrm{TPT}}: M=\left\{\{v\}^{\operatorname{CS}\{ \}}: v \in V\right\}, \\
& \\
& \quad L \in \operatorname{subpaths}(\{(M, \operatorname{tdec}(U)(M))\})\}
\end{aligned}
$$

where the tree of self non-overlapping substrate decremented partition-sets is defined $\operatorname{tdec}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathrm{P}\left(\mathcal{R}_{U}\right)\right)$ as

$$
\operatorname{tdec}(U)(M):=\left\{(N, \operatorname{tdec}(U)(N)): N \in \mathcal{N}_{U, M,-} \cap \mathcal{N}_{U, M, \mathrm{n}, \mathrm{~s}}\right\}
$$

and $\operatorname{tdec}(U)(\emptyset):=\emptyset$. Explicitly this is

$$
\begin{aligned}
& \operatorname{tdec}(U)(M):=\{(N, \operatorname{tdec}(U)(N)): \\
& \left.\quad w \in M, Q \in \operatorname{decs}\left(\{w\}^{\operatorname{CS}\{ \}}\right), N=\{Q\} \cup\left\{\{u\}^{\operatorname{CS}\{ \}}: u \in M, u \neq w\right\}\right\}
\end{aligned}
$$

The cardinality of the self non-overlapping substrate decremented partitionsets tree may be computed by defining $\operatorname{tdeccd}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}(\mathbf{N} \times$ $\mathcal{L}(\mathbf{N}))$ as
$\operatorname{tdeccd}(U)(V):=\left\{((1, L), \operatorname{tdeccd}(1, L)): L=\left\{\left(i,\left|U_{v}\right|\right):(v, i) \in \operatorname{order}\left(D_{\mathrm{V}}, V\right)\right\}\right\}$
where order $D_{\mathrm{V}}$ is such that $\operatorname{order}\left(D_{\mathrm{V}}, V\right) \in \operatorname{enums}(V)$, and $\operatorname{tdeccd} \in \mathbf{N} \times$ $\mathcal{L}(\mathbf{N}) \rightarrow \operatorname{trees}(\mathbf{N} \times \mathcal{L}(\mathbf{N}))$ as
$\operatorname{tdeccd}(k, L):=\{((m, M), \operatorname{tdeccd}(m, M)):$

$$
\left.i \in\{1 \ldots|L|\}, L_{i}>1, m=k L_{i}\left(L_{i}-1\right) / 2, M=L \backslash\left\{\left(i, L_{i}\right)\right\} \cup\left\{\left(i, L_{i}-1\right)\right\}\right\}
$$

In the case of regular substrate variables of valency $d$ and dimension $n$, the self non-overlapping substrate decremented partition-sets tree is defined tdeccd $\in$ $\mathbf{N} \times \mathbf{N} \rightarrow \operatorname{trees}(\mathbf{N} \times \mathcal{L}(\mathbf{N}))$ as

$$
\operatorname{tdeccd}(d, n):=\{((1, L), \operatorname{tdeccd}(1, L)): L=\{1 \ldots n\} \times\{d\}\}
$$

In the case of non-empty substrate variables, $V \neq \emptyset$, the depth is

$$
\operatorname{depth}(\operatorname{tdec}(U)(V))=\operatorname{depth}(\operatorname{tdeccd}(U)(V))-1=\sum_{v \in V}\left(\left|U_{v}\right|-1\right)
$$

and the cardinalities are

$$
|\operatorname{paths}(\operatorname{tdec}(U)(V))|=\sum\left(m: L \in \operatorname{paths}(\operatorname{tdeccd}(U)(V)),(m, \cdot)=L_{|L|}\right)
$$

and
$|\operatorname{nodes}(\operatorname{tdec}(U)(V))|=\sum\left(m: L \in \operatorname{subpaths}(\operatorname{tdeccd}(U)(V)),(m, \cdot)=L_{|L|}\right)-1$
If the substrate, $V$, is non-empty, $n>0$, and regular having valency $d>1$, then the depth is

$$
\operatorname{depth}(\operatorname{tdec}(U)(V))=n(d-1)
$$

the initial cardinality of the decrements is

$$
\left|\mathcal{N}_{U, V,-} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{~S}}\right|=n d(d-1) / 2
$$

and the cardinalities are bounded

$$
|\operatorname{paths}(\operatorname{tdec}(U)(V))| \leq(n d(d-1) / 2)^{n(d-1)}
$$

and

$$
|\operatorname{nodes}(\operatorname{tdec}(U)(V))| \leq n(d-1)(n d(d-1) / 2)^{n(d-1)} \leq\left(n d^{2}\right)^{n d}
$$

This may be compared to the explicit construction of the self non-overlapping substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{n}, \mathrm{s}}$,

$$
\mathcal{N}_{U, V, \mathrm{n}, \mathrm{~s}}=\prod_{w \in V} \mathrm{~B}\left(\{w\}^{\mathrm{CS}}\right)
$$

which has cardinality of construction

$$
\left|\mathcal{N}_{U, V, \mathrm{n}, \mathrm{~s}}\right|=\prod_{w \in V}\left|\mathrm{~B}\left(\{w\}^{\mathrm{CS}}\right)\right|
$$

that is bounded $\left|\mathcal{N}_{U, V, \mathrm{n}, \mathrm{s}}\right| \leq \operatorname{bell}(d)^{n} \leq d^{n d}$.
In the special case of mono-variate substrate, $n=1$, the cardinality of construction is

$$
|\operatorname{paths}(\operatorname{tdec}(U)(V))|=\frac{d!(d-1)!}{2^{d-1}} \leq d^{2 d}
$$

and

$$
|\operatorname{nodes}(\operatorname{tdec}(U)(V))|=\frac{d!(d-1)!}{2^{d-1}} \sum_{j \in\{1 \ldots d-1\}} \frac{2^{j}}{j!(j-1)!} \leq d^{2 d+1}
$$

Similarly the strong non-overlapping substrate transforms set, $\left\{N^{\mathrm{TV}}: N \in\right.$ $\left.\mathcal{N}_{U, V, \mathrm{n}}\right\} \subseteq \mathcal{T}_{U, V, \mathrm{n}}$, can be constructed explicitly in terms of strong self substrate decremented transforms as

$$
\begin{aligned}
& \left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, \mathrm{n}}\right\} \\
& =\left\{(\bigcup \operatorname{set}(L))^{\mathrm{TPT}}: M \in \mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}},\right. \\
& L \in \operatorname{subpaths}(\{(M, \operatorname{tdec}(U)(M))\})\} \\
& =\left\{(\bigcup \operatorname{set}(L))^{\mathrm{TPT}}: Y \in \mathrm{~B}(V), M=\left\{K^{\mathrm{CS}\{ \}}: K \in Y\right\},\right. \\
& L \in \operatorname{subpaths}(\{(M, \operatorname{tdec}(U)(M))\})\}
\end{aligned}
$$

which has cardinality of construction

$$
\begin{aligned}
& \left|\left\{(Y, L): Y \in \mathrm{~B}(V), L \in \operatorname{subpaths}\left(\operatorname{tdec}(U)\left(\left\{K^{\mathrm{CS}\{ \}}: K \in Y\right\}\right)\right) \cup\{\emptyset\}\right\}\right| \\
& \quad=\sum_{Y \in \mathrm{~B}(V)}\left(\left|\operatorname{nodes}\left(\operatorname{tdec}(U)\left(\left\{K^{\mathrm{CS}\{ \}}: K \in Y\right\}\right)\right)\right|+1\right) \\
& \quad=\sum_{Y \in \mathrm{~B}(V)} \sum\left(m: L \in \operatorname{subpaths}\left(\operatorname{tdeccd}(U)\left(\left\{K^{\mathrm{CS}\{ \}}: K \in Y\right\}\right)\right),(m, \cdot)=L_{|L|}\right) \\
& \quad \leq \operatorname{bell}(n) \times y^{2 y}
\end{aligned}
$$

where volume $y=\left|V^{\mathrm{CS}}\right|$, and dimension $n=|V|$. This may be compared to the cardinality of construction by transform pair linear fud which equals the cardinality of construction of the non-overlapping substrate partition-sets
set, $\mathcal{N}_{U, V, \mathrm{n}}$,

$$
\begin{aligned}
\mid\{(Y, N): Y \in \mathrm{~B}(V), N & \left.\in \prod_{K \in Y} \mathrm{~B}\left(\left\{K^{\mathrm{CS}\{ \}}\right\}^{\mathrm{CS}}\right)\right\} \mid \\
& =\left|\left\{N: Y \in \mathrm{~B}(V), N \in \prod_{K \in Y} \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}\right| \\
& =\sum_{Y \in \mathrm{~B}(V)} \prod_{K \in Y}\left|\mathrm{~B}\left(K^{\mathrm{CS}}\right)\right| \\
& \leq \operatorname{bell}(n) \times \operatorname{bell}(y)
\end{aligned}
$$

where volume $y=\left|V^{\mathrm{CS}}\right|$, and dimension $n=|V|$.

The self non-overlapping substrate transforms set, $\mathcal{T}_{U, V, n, s}$, can also be constructed more directly by means of a tree of decremented partitions as

$$
\begin{aligned}
& \mathcal{T}_{U, V, \mathrm{n}, \mathrm{~s}}= \\
& \quad\left\{N^{\mathrm{TPT}}: M \in \mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{~s}}, N \in \operatorname{elements}(\{(M, \operatorname{tpdec}(M))\})\right\}
\end{aligned}
$$

and, in the case of non-empty substrate, $V \neq \emptyset$,

$$
\begin{aligned}
& V \neq \emptyset \Longrightarrow \mathcal{T}_{U, V, \mathrm{n}, \mathrm{~s}}= \\
& \\
& \quad\left\{N^{\mathrm{TPT}}: M=\left\{\{v\}^{\mathrm{CS}\{ \}}: v \in V\right\}, N \in \operatorname{elements}(\{(M, \operatorname{tpdec}(M))\})\right\}
\end{aligned}
$$

where the partition tree of self non-overlapping substrate decremented partitionsets is defined tpdec $\in \mathrm{P}(\mathcal{R}) \rightarrow \operatorname{trees}(\mathrm{P}(\mathcal{R}))$ as
$\operatorname{tpdec}(M):=\{(N, \operatorname{tpdec}(N)): P \in M, Q \in \operatorname{decs}(P), N=M \backslash\{P\} \cup\{Q\}\}$
Here the subpaths of the tree of decremented partitions do not form multilayer linear fuds. Instead the node partition-sets form the second transform of a transform pair linear fud. The self non-overlapping substrate decremented partition-sets partition tree maps bijectively to the self nonoverlapping substrate decremented partition-sets tree, places $(\operatorname{tpdec}(M)): \leftrightarrow$ : places $(\operatorname{tdec}(U)(M))$ where the value full functional partition-set is $M=$ $\left\{\{v\}^{\operatorname{CS}\{ \}}: v \in V\right\}$, so the cardinalities of construction are equal.

The strong non-overlapping substrate transforms set, $\left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, \mathrm{n}}\right\} \subseteq$ $\mathcal{T}_{U, V, \mathrm{n}}$, can be constructed using the self non-overlapping substrate decre-
mented partition-sets partition tree

$$
\begin{aligned}
& \left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, \mathrm{n}}\right\} \\
& =\left\{N^{\mathrm{TPT}}: M \in \mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}},\right. \\
& \quad N \in \operatorname{elements}(\{(M, \operatorname{tpdec}(M))\})\} \\
& =\left\{N^{\mathrm{TPT}}: Y \in \mathrm{~B}(V), M=\left\{K^{\mathrm{CS}\{ \}}: K \in Y\right\},\right. \\
& \\
& \quad N \in \operatorname{elements}(\{(M, \operatorname{tpdec}(M))\})\}
\end{aligned}
$$

which has cardinality of construction

$$
\begin{aligned}
& \left|\left\{(Y, L): Y \in \mathrm{~B}(V), L \in \operatorname{subpaths}\left(\operatorname{tpdec}\left(\left\{K^{\mathrm{CS}\{ \}}: K \in Y\right\}\right)\right) \cup\{\emptyset\}\right\}\right| \\
& \quad=\sum_{Y \in \mathrm{~B}(V)} \sum\left(m: L \in \operatorname{subpaths}\left(\operatorname{tdeccd}(U)\left(\left\{K^{\mathrm{CS}\{ \}}: K \in Y\right\}\right)\right),(m, \cdot)=L_{|L|}\right) \\
& \leq \operatorname{bell}(n) \times y^{2 y}
\end{aligned}
$$

where volume $y=\left|V^{\mathrm{CS}}\right|$, and dimension $n=|V|$.
The self non-overlapping substrate transforms set, $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$, can be constructed by means of a tree of incremented pointed partitions as

$$
\begin{aligned}
& \mathcal{T}_{U, V, \mathrm{n}, \mathrm{~s}}= \\
& \left\{N_{*}^{\mathrm{TPT}}: M \in \mathcal{N}_{U, V, 1} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{~s}}, M_{*}=\left\{\left(\left\{C_{*}\right\}, C_{*}\right):\left\{C_{*}\right\} \in M\right\},\right. \\
& \left.N_{*} \in \operatorname{elements}\left(\left\{\left(M_{*}, \operatorname{tinc}\left(M_{*}\right)\right)\right\}\right)\right\}
\end{aligned}
$$

and, in the case of non-empty substrate, $V \neq \emptyset$,

$$
\begin{aligned}
& V \neq \emptyset \Longrightarrow \mathcal{T}_{U, V, \mathrm{n}, \mathrm{~s}}= \\
& \qquad N_{*}^{\mathrm{TPT}}: M_{*}=\left\{\left(\left\{\{v\}^{\mathrm{CS}}\right\},\{v\}^{\mathrm{CS}}\right): v \in V\right\}, \\
& \\
& \left.\quad N_{*} \in \operatorname{elements}\left(\left\{\left(M_{*}, \operatorname{tinc}\left(M_{*}\right)\right)\right\}\right)\right\}
\end{aligned}
$$

where the tree of self non-overlapping substrate incremented pointed partitionsets is defined tinc $\in \mathrm{P}\left(\mathcal{R}_{*}\right) \rightarrow \operatorname{trees}\left(\mathrm{P}\left(\mathcal{R}_{*}\right)\right)$ as
$\operatorname{tinc}\left(M_{*}\right):=\left\{\left(N_{*}, \operatorname{tinc}\left(N_{*}\right)\right): P_{*} \in M_{*}, Q_{*} \in \operatorname{incs}\left(P_{*}\right), N_{*}=M_{*} \backslash\left\{P_{*}\right\} \cup\left\{Q_{*}\right\}\right\}$
where incs $=$ increments $\in \mathcal{R}_{*} \rightarrow \mathrm{P}\left(\mathcal{R}_{*}\right)$. Again, the subpaths of the tree of incremented pointed partitions do not form multi-layer linear fuds because the transforms would forget the point component. Instead the node pointed partition-sets form the second transform of a transform pair linear fud.

The cardinality of the self non-overlapping substrate incremented pointed
partition-sets tree may be computed by defining tinccd $(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow$ $\operatorname{trees}\left(\mathbf{N} \times \mathcal{L}\left(\mathbf{N}^{2}\right)\right)$ as

```
tinccd}(U)(V):
{((1,L),\operatorname{tinccd}(1,L)):L={(i,(|\mp@subsup{U}{v}{}|,0)):(v,i)\in\operatorname{order}(\mp@subsup{D}{\textrm{V}}{},V)}}
```

where order $D_{\mathrm{V}}$ is such that $\operatorname{order}\left(D_{\mathrm{V}}, V\right) \in \operatorname{enums}(V)$, and tinccd $\in \mathbf{N} \times$ $\mathcal{L}\left(\mathbf{N}^{2}\right) \rightarrow \operatorname{trees}\left(\mathbf{N} \times \mathcal{L}\left(\mathbf{N}^{2}\right)\right)$ is

$$
\begin{aligned}
& \operatorname{tinccd}(k, L):= \\
& \qquad \begin{array}{l}
\left\{((m, M), \operatorname{tinccd}(m, M)): i \in\{1 \ldots|L|\},(d, c)=L_{i}, d>1, m=k d,\right. \\
\quad M=L \backslash\{(i,(d, c))\} \cup\{(i,(d-1, c+1))\}\} \cup \\
\left\{((m, M), \operatorname{tinccd}(m, M)): i \in\{1 \ldots|L|\},(d, c)=L_{i}, d>1, m=k d c,\right. \\
\quad M=L \backslash\{(i,(d, c))\} \cup\{(i,(d-1, c))\}\}
\end{array}
\end{aligned}
$$

Then in the case of non-empty substrate variables, $V \neq \emptyset$, the depth is

$$
\operatorname{depth}\left(\operatorname{tinc}\left(M_{*}\right)\right)=\operatorname{depth}(\operatorname{tinccd}(U)(V))-1=\sum_{v \in V}\left(\left|U_{v}\right|-1\right)
$$

where $M_{*}=\left\{\left(\left\{\{v\}^{\mathrm{CS}}\right\},\{v\}^{\mathrm{CS}}\right): v \in V\right\}$. The cardinalities are

$$
\left|\operatorname{paths}\left(\operatorname{tinc}\left(M_{*}\right)\right)\right|=\sum\left(m: L \in \operatorname{paths}(\operatorname{tinccd}(U)(V)),(m, \cdot)=L_{|L|}\right)
$$

and
$\left|\operatorname{places}\left(\operatorname{tinc}\left(M_{*}\right)\right)\right|=\sum\left(m: L \in \operatorname{subpaths}(\operatorname{tinccd}(U)(V)),(m, \cdot)=L_{|L|}\right)-1$
If the substrate, $V$, is non-empty, $n>0$, and regular having valency $d>1$, then the depth is

$$
\operatorname{depth}\left(\operatorname{tinc}\left(M_{*}\right)\right)=n(d-1)
$$

the initial cardinality of the increments is $n d$. The cardinalities are bounded

$$
|\operatorname{paths}(\operatorname{tinc}(U)(V))| \leq\left(2 n d^{2}\right)^{n(d-1)}
$$

and

$$
|\operatorname{nodes}(\operatorname{tinc}(U)(V))| \leq n(d-1)\left(2 n d^{2}\right)^{n(d-1)} \leq\left(2 n d^{2}\right)^{n d}
$$

The strong non-overlapping substrate transforms set, $\left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, \mathrm{n}}\right\} \subseteq$ $\mathcal{T}_{U, V, \mathrm{n}}$, can be constructed using the self non-overlapping substrate incremented pointed partition-sets tree

$$
\begin{aligned}
& \left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, \mathrm{n}}\right\} \\
& =\left\{N_{*}^{\mathrm{TPT}}: M \in \mathcal{N}_{U, V, 1} \cap \mathcal{N}_{U, V, \mathrm{n}}, M_{*}=\left\{\left(\left\{C_{*}\right\}, C_{*}\right):\left\{C_{*}\right\} \in M\right\},\right. \\
& \left.N_{*} \in \operatorname{elements}\left(\left\{\left(M_{*}, \operatorname{tinc}\left(M_{*}\right)\right)\right\}\right)\right\} \\
& =\left\{N_{*}^{\mathrm{TPT}}: Y \in \mathrm{~B}(V), M_{*}=\left\{\left(\left\{K^{\mathrm{CS}}\right\}, K^{\mathrm{CS}}\right): K \in Y\right\},\right. \\
& \left.N_{*} \in \operatorname{elements}\left(\left\{\left(M_{*}, \operatorname{tinc}\left(M_{*}\right)\right)\right\}\right)\right\}
\end{aligned}
$$

which has cardinality of construction

$$
\begin{aligned}
& \left|\left\{(Y, L): Y \in \mathrm{~B}(V), L \in \operatorname{subpaths}\left(\operatorname{tinc}(U)\left(\left\{\left(\left\{K^{\mathrm{CS}}\right\}, K^{\mathrm{CS}}\right): K \in Y\right\}\right)\right) \cup\{\emptyset\}\right\}\right| \\
& \quad=\sum_{Y \in \mathrm{~B}(V)} \sum\left(m: L \in \operatorname{subpaths}\left(\operatorname{tinccd}(U)\left(\left\{K^{\mathrm{CS}\{ \}}: K \in Y\right\}\right)\right),(m, \cdot)=L_{|L|}\right) \\
& \quad \leq \operatorname{bell}(n) \times(2 y)^{2 y}
\end{aligned}
$$

where volume $y=\left|V^{\mathrm{CS}}\right|$, and dimension $n=|V|$.
The substrate models set $\mathcal{M}_{U, V}$ of system $U$ and variables $V$ is the set of substrate structures that correspond to a transform in the substrate transforms set, $\mathcal{T}_{U, V}$. Define transform $(U, V) \in \mathcal{M}_{U, V} \rightarrow \mathcal{T}_{U, V}$. Thus

$$
F_{U, V}, \mathcal{T}_{U, V}, \mathcal{N}_{U, V}, \mathcal{N}_{*, U, V}, \mathcal{F}_{U, V}, \mathcal{D}_{U, V}, \mathcal{D}_{F, U, V} \subset \mathcal{M}_{U, V}
$$

Define transform $(U, V)(F):=F^{\mathrm{TV}}$ where $F \in \mathcal{F}_{U, V}$. Define transform $(U, V)(D):=$ $D^{\mathrm{T} V}$ where $D \in \mathcal{D}_{U, V}$.

### 3.12 Independent histograms

A histogram $A$ of variables $V=\operatorname{vars}(A)$ is said to be partially independent in a subset $K$ of its variables $K \subseteq V$ if

$$
A=\frac{1}{Z_{A}} *(A \% K) *(A \%(V \backslash K))
$$

where $Z_{A}=\operatorname{scalar}(\operatorname{size}(A))$. The scaling factor ensures that the histogram expression has the same size as $A$, because the size of the product of two histograms of disjoint variables is the product of their sizes. In the trivial cases of $K=\emptyset$ and $K=V$ the histogram expression always evaluates to $A$.

Having considered the partitioning of states in the discussion of derived variables, consider the special case of the partitioning of variables which is the partially independent set. Given an argument histogram $A$ of variables $V=\operatorname{vars}(A)$, construct a set of histogram expressions in a single free variable, each element of which evaluates to a partially independent histogram. The partially independent set $R_{A}$ is

$$
R_{A}=\left\{Z_{A} * \prod\left\{\frac{A}{Z_{A}} \% C: C \in P\right\}: P \in \mathrm{~B}(V)\right\}
$$

where $B$ is the partition function.

A histogram $A$ of variables $V$ that is partially independent in a subset $K$ is the special case of a partially independent histogram where the partition is binary, $P=\{K, V \backslash K\}$,

$$
\frac{1}{Z_{A}} *(A \% K) *(A \%(V \backslash K)) \in R_{A}
$$

The special case of a partially independent histogram where the cardinality of each of the partition components is one, i.e. the self partition, $P=V^{\{ \}}$, is the independent histogram. Define function independent $\in \mathcal{A} \rightarrow \mathcal{A}$

$$
\operatorname{independent}(A):=Z_{A} * \prod\left\{\frac{A}{Z_{A}} \%\{w\}: w \in V\right\}
$$

where $V=\operatorname{vars}(A)$ and $Z_{A}=\operatorname{scalar}(\operatorname{size}(A))$. Define independent $(\emptyset):=\emptyset$. If $A$ is a zero histogram, $\operatorname{size}(A)=0$, define independent $(A):=\prod\{A \%\{w\}$ : $w \in V\}$. Define notation $A^{\mathrm{X}}=\operatorname{independent}(A)$.

The independent function can also be equivalently defined

$$
\operatorname{independent}(A):=\operatorname{scalar}\left(z^{-(n-1)}\right) * \prod_{w \in V} A \%\{w\}
$$

where $V=\operatorname{vars}(A), n=|V|$ and $z=\operatorname{size}(A)>0$.
The independent histogram is in the partially independent set, $A^{\mathrm{X}} \in R_{A}$. The independent histogram has the greatest degree of independence of any of the partially independent set. See later for the definition of degree of dependence with respect to the partially independent set in the discussion of 'Minimum alignment'. The independent histogram is contained recursively in all the partially independent sets of elements of partially independent sets, $\forall B \in R_{A}\left(A^{\mathrm{X}} \in R_{B}\right)$.

Independent histograms are such that $\operatorname{states}\left(A^{\mathrm{X}}\right) \supseteq \operatorname{states}(A), \operatorname{size}\left(A^{\mathrm{X}}\right)=$ $\operatorname{size}(A), \operatorname{vars}\left(A^{\mathrm{X}}\right)=\operatorname{vars}(A)$ and so $A$ and $A^{\mathrm{X}}$ are congruent, congruent $\left(A, A^{\mathrm{X}}\right)$. Also volume $(U)\left(A^{\mathrm{X}}\right)=\operatorname{volume}(U)(A)$ where $A$ is in system $U$. Note, however, that independent $(A)$ can be calculated without reference to a system.

A histogram is said to be independent if it is equivalent to its own independent, $A \equiv A^{\mathrm{X}}$. An independent histogram is its own independent histogram, independent $\left(A^{\mathrm{X}}\right)=A^{\mathrm{X}}$. Empty histograms and scalars, $V=\emptyset$, are defined as independent. If the histogram is mono-variate $|V|=1$ then it is independent $A=A \%\{w\}=A^{\mathrm{X}}$ where $\{w\}=V$. Uniform-cartesian histograms, which are
scalar multiples of the cartesian, $A=\operatorname{scalar}(z / v) * A^{\mathrm{C}}$ where $z=\operatorname{size}(A)$ and $v=\left|A^{\mathrm{C}}\right|$, including zero histograms, are independent. Singleton histograms $\left|A^{\mathrm{F}}\right|=1$ are independent. The effective states of an independent histogram form a cartesian sub-volume, that is, $A^{\mathrm{XF}}=\prod\left\{(A \%\{w\})^{\mathrm{F}}: w \in V\right\}$. Putting it the other way around, a histogram $A$ is a cartesian sub-volume if $A^{\mathrm{F}}=A^{\mathrm{XF}}$.

The perimeter of a histogram is the set of its reductions indexed by variable. Histogram $A$ in variables $V$ has perimeter $Q_{A}=\{(w, A \%\{w\}): w \in V\}$. The histograms of the perimeter have the same size as the given histogram, $\forall B \in$ $\operatorname{ran}\left(Q_{A}\right)(\operatorname{size}(B)=\operatorname{size}(A))$. The histograms of the perimeter are integral if the given histogram is integral, $A \in \mathcal{A}_{\mathbf{i}} \Longrightarrow \forall B \in \operatorname{ran}\left(Q_{A}\right)\left(B \in \mathcal{A}_{\mathbf{i}}\right)$. The independent is constructed from the perimeter $A^{\mathrm{X}}=Z_{A} * \prod_{w \in V}\left(Q_{A}(w) / Z_{A}\right)$ where $Z_{A}=\operatorname{scalar}(\operatorname{size}(A))$.

A completely effective pluri-variate independent histogram, $A^{\mathrm{XF}}=A^{\mathrm{C}}$, for which all of the variables are pluri-valent, $\forall w \in V\left(\left|A^{\mathrm{XF}} \%\{w\}\right|>1\right)$, must be non-causal, $\neg$ causal $\left(A^{\mathrm{X}}\right)$. Thus it cannot be the histogram of a functional transform, $\forall T \in \mathcal{T}_{\mathrm{f}}(A \neq \operatorname{his}(T))$.

Given a partially independent histogram $A \in R_{A}$ of variables $V$ having a partition of the variables $P$, where $A=Z_{A} * \prod_{K \in P}\left(A / Z_{A}\right) \% K$, subsets of the variables can be chosen such that the reduction is independent. Let $M \in P \leftrightarrow V$ be such that $\forall(K, w) \in M(w \in K)$, then $A \% J=(A \% J)^{\mathrm{X}}$ where $J=\operatorname{ran}(M)$.

Consider the regular integral histogram $A \in \mathcal{A}_{\mathrm{i}}$ of variables $V=\operatorname{vars}(A)$, dimension $n=|V|$, valency $\{d\}=\left\{\left|U_{w}\right|: w \in V\right\}$, size $z=\operatorname{size}(A)$, and such that the independent is completely effective, $A^{\mathrm{XF}}=V^{\mathrm{C}}$. The fraction of integral histograms congruent to $A$ that are independent may be estimated. In the case where the histogram is binary, $\left\{w_{1}, w_{2}\right\}=V$, consider perimeter states $\{(\cdot, x)\} \in A \%\left\{w_{1}\right\}$ and $\{(\cdot, y)\} \in A \%\left\{w_{2}\right\}$, which are such that $x, y \in\{1 \ldots z\}$. If the histogram is independent, $A=A^{\mathrm{X}}$, then $x y=k z$, where $k \in \mathbf{N}_{>0}$. If $z$ is prime, the fraction of the $z^{2}$ pairs $(x, y) \in\{1 \ldots z\}^{2}$ for which $x y=k z$ is $2 z / z^{2}=2 / z$. If $z$ is the product of two primes, then the fraction is $\left(2 z+2 p_{2}\right) / z^{2}$, where $p_{1} p_{2}=z$ and $p_{1} \leq p_{2}$. For arbitrary size, $z$, numerical analysis suggests that the fraction is of the order of $(\ln z) / z$. Generalising to arbitrary dimension, $n$, gives $(\ln z)^{n-1} / z$. The fraction of congruent integral histograms that are independent for a given set of perimeters is therefore estimated as $\left((\ln z)^{n-1} / z\right)^{d^{n}}$. The cardinality of perimeters is $((z+d-1)!/(z!(d-1)!))^{n}$, so the cardinality of congruent integral independent
histograms is estimated as

$$
\left(\frac{(z+d-1)!}{z!(d-1)!}\right)^{n} \times\left(\frac{(\ln z)^{n-1}}{z}\right)^{d^{n}}
$$

The logarithm of this cardinality approximates to

$$
n d \ln \frac{z}{d}-d^{n} \ln \frac{z}{(\ln z)^{n-1}}
$$

So, in the case where the logarithm of the size is of the order of the valency, $\ln z \approx d$, the logarithm of the cardinality of congruent integral independent histograms varies against the volume $v=d^{n}$,

$$
\ln \left|\left\{A: A \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{XF}}=V^{\mathrm{C}}, \operatorname{size}(A)=z, A=A^{\mathrm{X}}\right\}\right| \sim-v
$$

That is, for a given size, the smaller the volume, the more probable an integral histogram is independent.

### 3.12.1 Transforms and Independent

The application $A * T$ of a functional transform $T \in \mathcal{T}_{f}$ to a histogram $A \in \mathcal{A}$, such that the underlying variables are a subset of the histogram variables, $\operatorname{und}(T) \subseteq \operatorname{vars}(A)$, is called the derived histogram, $A * T \in \mathcal{A}$. In this context, $A$ is called the underlying histogram.

A functional transform $T$ is said to be abstract with respect to a histogram $A$ if the derived histogram, $A * T$, is independent, $A * T \equiv(A * T)^{\mathrm{x}}$. Define abstract $\in \mathcal{A} \times \mathcal{T}_{\mathrm{f}} \rightarrow \mathbf{B}$

$$
\operatorname{abstract}(A, T):=A * T \equiv(A * T)^{\mathrm{X}}
$$

where $\operatorname{size}(A)>0$ and $\operatorname{und}(T) \subseteq \operatorname{vars}(A)$. The independent of the derived histogram, $(A * T)^{\mathrm{X}} \in \mathcal{A}$, is called the abstract histogram.

A functional transform $T$ is said to be formal with respect to a histogram $A$ if the derived histogram, $A * T$, is equivalent to the transformed independent, $A^{\mathrm{X}} * T$. Define formal $\in \mathcal{A} \times \mathcal{T}_{\mathrm{f}} \rightarrow \mathbf{B}$

$$
\text { formal }(A, T):=A * T \equiv A^{\mathrm{X}} * T
$$

where $\operatorname{size}(A)>0$ and $\operatorname{vars}(A) \subseteq \operatorname{und}(T)$. The derived of the independent histogram, $A^{\mathrm{X}} * T \in \mathcal{A}$, is called the formal histogram. The formal independent histogram, $\left(A^{\mathrm{x}} * T\right)^{\mathrm{X}} \in \mathcal{A}$, is sometimes called the independent abstract
histogram.
If the derived histogram is equivalent to the formal independent histogram then the transform is abstract. That is, the derived histogram is equivalent to the abstract histogram, because the derived histogram is independent

$$
A * T \equiv\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}} \Longrightarrow A * T \equiv(A * T)^{\mathrm{X}}
$$

If the formal histogram is equivalent to the abstract histogram then the formal histogram is independent

$$
A^{\mathrm{X}} * T \equiv(A * T)^{\mathrm{x}} \Longrightarrow A^{\mathrm{X}} * T \equiv\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}
$$

and the abstract histogram is equivalent to the formal independent histogram

$$
A^{\mathrm{X}} * T \equiv(A * T)^{\mathrm{X}} \Longrightarrow(A * T)^{\mathrm{X}} \equiv\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}}
$$

Therefore the formal histogram is equivalent to the abstract histogram only if the abstract histogram is equivalent to the formal independent histogram and the formal histogram is independent

$$
\left((A * T)^{\mathrm{x}} \equiv\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}\right) \wedge\left(A^{\mathrm{x}} * T \equiv\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}\right) \Longleftrightarrow A^{\mathrm{x}} * T \equiv(A * T)^{\mathrm{x}}
$$

The formal histogram is equivalent to the abstract histogram in another stricter case if the formal histogram is equivalent to the derived histogram and the derived histogram is independent.

$$
\left(A^{\mathrm{x}} * T \equiv A * T\right) \wedge\left(A * T \equiv(A * T)^{\mathrm{x}}\right) \Longrightarrow A^{\mathrm{x}} * T \equiv(A * T)^{\mathrm{x}}
$$

In this case the transform is formal, formal $(A, T)$, and abstract, abstract $(A, T)$.
At first sight, it would appear that the derived histogram of a functional transform $T \in \mathcal{T}_{\text {f }}$, which has more than one derived variable $|\operatorname{der}(T)| \geq 2$, cannot be non-trivially independent if $A$ is not independent, $A \neq A^{\mathrm{x}} \wedge(\forall w \in$ $\left.\operatorname{der}(T)\left(\left|(A * T \%\{w\})^{\mathrm{F}}\right|>1\right)\right) \Longrightarrow A * T \neq(A * T)^{\mathrm{X}}$. This is because the transform can only do one reduction to derived variables that are functionally synchronised, whereas the independent operator requires a reduction for each of the derived variables. However, there are cases where a single reduction is sufficient to reduce all of the derived variables so that the derived histogram is independent. A one functional transform $T \in \mathcal{T}_{U, f, 1}$ in system $U$ that is non-overlapping, $\neg \operatorname{overlap}(T)$, and such that the derived variables partition the underlying variables of a partially independent underlying histogram, $A$, must be abstract, $A * T=(A * T)^{\mathrm{X}}$. Let $Q \in \mathrm{~B}(\operatorname{und}(T))$ be the partition of
the underlying variables such that resize $\left(z, \prod\{A \% K: K \in Q\}\right) \equiv A$. Let $F \in \mathcal{F}_{U, 1}$ be the non-overlapping fud having equivalent transform, $F^{\mathrm{T}}=T$, such that $\{\operatorname{und}(R): R \in F\}=Q$. Then

$$
\begin{aligned}
A * T & =A * F^{\mathrm{T}} \\
& =Z_{n} * \prod_{K \in Q} A \% K * \prod_{R \in F} \operatorname{his}(R) \% \bigcup_{R \in F} \operatorname{der}(R) \\
& =Z_{n} * \prod\{A \% K * \operatorname{his}(R) \% \operatorname{der}(R): K \in Q, R \in F, \operatorname{und}(R)=K\} \\
& =\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}} \\
& =(A * T)^{\mathrm{X}}
\end{aligned}
$$

where $Z_{n}=\operatorname{scalar}\left(z / z^{n}\right)$ and $n=|\operatorname{und}(T)|$.
The independent underlying histogram $A^{\mathrm{X}}$ is a partially independent histogram by definition and so it follows that for non-overlapping transforms the formal histogram, $A^{\mathrm{X}} * T$, is independent, $\neg \operatorname{overlap}(T) \Longrightarrow A^{\mathrm{X}} * T \equiv$ $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$.

However, note that it not always the case that the converse, $A^{\mathrm{X}} * T \equiv$ $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}} \Longrightarrow \neg \operatorname{overlap}(T)$, is true. That is, the formal histogram is independent for some overlapping transforms, $\exists A \in \mathcal{A}_{U} \exists T \in \mathcal{T}_{U, f, 1}$ (overlap $(T) \wedge$ $\left.\left(A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right)\right)$. For example, a tautology having singleton derived, $\operatorname{tautology}(T) \wedge\left|W^{\mathrm{C}}\right|=1$. Or for example, let $\left\{P_{1}, P_{2}\right\}=W \subset \mathrm{~B}\left(V^{\mathrm{CS}}\right)$ where $V=\operatorname{und}(T)$ and $W=\operatorname{der}(T)$. Then the formal is independent, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, if
$\forall C_{1} \in P_{1} \forall C_{2} \in P_{2}\left(\operatorname{size}\left(A^{\mathrm{X}} * C_{1}^{\mathrm{U}} * C_{2}^{\mathrm{U}}\right)=\frac{1}{z} * \operatorname{size}\left(A^{\mathrm{X}} * C_{1}^{\mathrm{U}}\right) * \operatorname{size}\left(A^{\mathrm{X}} * C_{2}^{\mathrm{U}}\right)\right)$
where $z=\operatorname{size}(A)$. This condition may be satisfied by some overlapping transforms. In these cases the components intersect, $\forall C_{1} \in P_{1} \forall C_{2} \in$ $P_{2}\left(C_{1} \cap C_{2} \neq \emptyset\right)$, and the transform is right total, $(X \% W)^{\mathrm{F}}=W^{\mathrm{C}}$ where $X=\operatorname{his}(T)$.

The formal histogram is equivalent to the abstract histogram if the transform is non-overlapping, $\neg \operatorname{overlap}(T) \Longrightarrow A^{\mathrm{X}} * T \equiv\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, and the abstract histogram is equivalent to the formal independent histogram

$$
\neg \operatorname{overlap}(T) \wedge\left((A * T)^{\mathrm{X}} \equiv\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \Longrightarrow A^{\mathrm{X}} * T \equiv(A * T)^{\mathrm{X}}
$$

Given congruent histograms $A, B \in \mathcal{A}$, in variables $V=\operatorname{vars}(A)=\operatorname{vars}(B)$, and substrate transform $T \in \mathcal{T}_{U, V}$, having derived variables $W=\operatorname{der}(T)$, the abstracts are equal if all of the derived reductions to partition variable are equal,

$$
(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}} \Longleftrightarrow \forall P \in W(B * T \%\{P\}=A * T \%\{P\})
$$

or

$$
(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}} \Longleftrightarrow \forall P \in W\left(B * P^{\mathrm{T}}=A * P^{\mathrm{T}}\right)
$$

In the special case where $B=A^{\mathrm{X}}$, the formal independent, or independent abstract, equals the abstract if and only if each partition derived equals its partition independent derived,

$$
\begin{aligned}
&\left(A^{\mathrm{x}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{x}} \Longleftrightarrow \\
& \quad \forall P \in W\left(A * P^{\mathrm{T}}=A^{\mathrm{x}} * P^{\mathrm{T}}\right) \\
&= \forall P \in W \forall(R, \cdot) \in\left(P^{\mathrm{T}}\right)^{-1}\left(\left(A * P^{\mathrm{T}}\right)_{R}=\left(A^{\mathrm{x}} * P^{\mathrm{T}}\right)_{R}\right) \\
&= \forall P \in W \forall C \in P\left(\operatorname{size}\left(A * C^{\mathrm{U}}\right)=\operatorname{size}\left(A^{\mathrm{X}} * C^{\mathrm{U}}\right)\right)
\end{aligned}
$$

In the case where the formal is independent, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, the formals are equal if and only if all of the independent derived reductions to partition variable are equal,

$$
\begin{aligned}
& A^{\mathrm{x}} * T=\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}} \Longrightarrow \\
& \quad B^{\mathrm{x}} * T=A^{\mathrm{X}} * T \Longleftrightarrow \forall P \in W\left(B^{\mathrm{X}} * P^{\mathrm{T}}=A^{\mathrm{x}} * P^{\mathrm{T}}\right)
\end{aligned}
$$

This is the case where the transform is non-overlapping, $\neg \operatorname{overlap}(T) \Longrightarrow$ $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$. In this case the equality can be reduced to the underlying variables of the partition,

$$
\begin{aligned}
& \neg \operatorname{overlap}(T) \Longrightarrow \\
& \qquad B^{\mathrm{x}} * T=A^{\mathrm{x}} * T \Longleftrightarrow \forall P \in W\left(B^{\mathrm{X}} \% V_{P} * P^{\% \mathrm{~T}}=A^{\mathrm{x}} \% V_{P} * P^{\% \mathrm{~T}}\right)
\end{aligned}
$$

where $V_{P}=\operatorname{vars}\left(P^{\%}\right) \subseteq V$.
If the transform is both non-overlapping and the formal independent equals the abstract, then the constraint on the partition transforms can be expressed in terms of the contraction of the partition variable,

$$
\begin{aligned}
\neg \operatorname{overlap}(T) \wedge\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}} & =(A * T)^{\mathrm{X}} \Longleftrightarrow \\
& \forall P \in W\left(A \% V_{P} * P^{\% \mathrm{~T}}=A^{\mathrm{x}} \% V_{P} * P^{\% \mathrm{~T}}\right)
\end{aligned}
$$

The application of an action, action $(C, A)$ where $C \in$ actions $\subset \mathcal{T} \times \mathcal{T}$ and $A \in \mathcal{A}$, may be independent even if $A$ is not. This is because the second transform $R$ of the pair $(L, R)=C$ need not be functional. A trivial example is where $L$ is a null transform and thus $A$ is reduced to a scalar.

### 3.12.2 Independent converse

The simple converse converseSimple $\in \mathcal{T} \rightarrow \mathcal{T}$ and natural converse converseNatural $\in \mathcal{T} \rightarrow \mathcal{T}$ for a transform $T \in \mathcal{T}$ have already been defined. The independent converse is defined converseIndependent $\in \mathcal{A} \times \mathcal{T}_{\mathrm{f}} \rightarrow \mathcal{T}$

$$
\begin{aligned}
& \text { converseIndependent }(B, T):= \\
& \qquad\left(\sum \frac{(B * C)^{\mathrm{x}}}{(B * C) \% \emptyset} *\{R\}^{\mathrm{U}}:(R, C) \in \operatorname{inverse}(T), V\right)
\end{aligned}
$$

where $\operatorname{size}(B)>0$ and $\operatorname{vars}(B)=V=\operatorname{underlying}(T)$. Define notation

$$
T^{\dagger B}=\text { converseIndependent }(B, T)
$$

Unlike the other converses, the argument transform must be functional $T \in$ $\mathcal{T}_{\mathfrak{f}}$. This is the case if $T$ is the transform of a partition $P \in \mathcal{R}_{U}, T=$ transform $(U)(P)$, because then $T \in \mathcal{T}_{U, \mathrm{f}, 1}$.

Also the independent converse requires an extra argument $B \in \mathcal{A}$ to provide the independent histogram for each component of the functional transform. The histogram $B$ must be non-zero, $\operatorname{size}(B)>0$, and have the same variables as the underlying variables of the transform, $\operatorname{vars}(B)=$ underlying $(T)$.

The action of a one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ and its independent converse, $\left(T, T^{\dagger B}\right)$, is size conserving if all of the components of $T$ are nonzero when applied to $B$. Thus

$$
\operatorname{size}\left(A * T * T^{\dagger B}\right)=\operatorname{size}(A)
$$

if $\forall C \in \operatorname{ran}(\operatorname{inverse}(T))(\operatorname{size}(B * C)>0)$ or $(A * T)^{\mathrm{F}} \leq(B * T)^{\mathrm{F}}$. Thus $\operatorname{size}\left(\left(A * B^{\mathrm{F}}\right) * T * T^{\dagger B}\right)=\operatorname{size}\left(A * B^{\mathrm{F}}\right)$. When $B=A$, then the action $\left(T, T^{\dagger A}\right)$ is always size conserving $\operatorname{size}\left(A * T * T^{\dagger A}\right)=\operatorname{size}(A)$ irrespective of whether zero components exist.

If any of the components of the one functional transform $T \in \mathcal{T}_{U, f, 1}$ are not cartesian sub-volumes $\exists C \in \operatorname{ran}($ inverse $(T))\left((B * C)^{\mathrm{F}}<(B * C)^{\mathrm{XF}}\right)$ then the independent converse may be more effective

$$
\left(A * T * T^{\dagger B}\right)^{\mathrm{F}} \geq A^{\mathrm{F}}
$$

If the given histogram is unit cartesian $B=V^{\mathrm{C}}$ and all of the components of one funtional transform $T \in \mathcal{T}_{U, f, 1}$ are cartesian sub-volumes $\forall C \in \operatorname{ran}(\operatorname{inverse}(T))\left(C^{\mathrm{F}}=C^{\mathrm{XF}}\right)$ then

$$
\operatorname{converseIndependent}\left(V^{\mathrm{C}}, T\right)=\operatorname{converseNatural}(T)
$$

or $T^{\dagger^{\mathrm{C}}}=T^{\dagger}$. Let $(X, W)=T$

$$
\begin{aligned}
\frac{X^{\mathrm{F}}}{X \% W} & =\sum\left\{\frac{C^{\mathrm{F}}}{C^{2} \emptyset} *\{R\}^{\mathrm{U}}:(R, C) \in \operatorname{inverse}(T)\right\} \\
& =\sum\left\{\frac{\left(V^{\mathrm{C}} * C\right)^{\mathrm{F}}}{\left(V^{\mathrm{C}} * C\right) \% \emptyset} *\{R\}^{\mathrm{U}}:(R, C) \in \operatorname{inverse}(T)\right\} \\
& =\sum\left\{\frac{\left(V^{\mathrm{C}} * C\right)^{\mathrm{X}}}{\left(V^{\mathrm{C}} * C\right) \% \emptyset} *\{R\}^{\mathrm{U}}:(R, C) \in \operatorname{inverse}(T)\right\}
\end{aligned}
$$

where the last step holds only if all components of $T$, the partition of $V^{\mathrm{C}}$, are cartesian sub-volumes.

The application to $A$ of the independent converse action $\left(T, T^{\dagger A}\right)$ of a unit functional transform $T \in \mathcal{T}_{\mathrm{f}, \mathrm{U}}$ with respect to $A$ is called the idealisation, $A * T * T^{\dagger A}$. If the idealisation of $A$ is equivalent to $A$ then the transform is ideal. Define ideal $\in \mathcal{A} \times \mathcal{T}_{\mathrm{f}, \mathrm{U}} \rightarrow \mathbf{B}$

$$
\operatorname{ideal}(A, T):=A * T * T^{\dagger A} \equiv A
$$

where $\operatorname{size}(A)>0$ and $\operatorname{vars}(A)=\operatorname{und}(T)$. An idealisation is size-conserving, $\operatorname{size}\left(A * T * T^{\dagger A}\right)=\operatorname{size}(A)$. An idealisation is effective if the transform is effective with respect to the histogram, $(X \% V)^{\mathrm{F}} \geq A^{\mathrm{F}}$ where $X=\operatorname{his}(T)$ and $V=\operatorname{und}(T)$. An ideal transform must be effective. A one functional transform, $T \in \mathcal{T}_{U, \mathrm{f}, 1}$, is always effective.

An idealisation can be defined as the summation of its independent components

$$
A * T * T^{\dagger A} \equiv \sum_{C \in T^{\mathrm{P}}}\left(A * C^{\mathrm{U}}\right)^{\mathrm{X}}
$$

or,

$$
A * T * T^{\dagger A} \equiv \sum_{(R, C) \in T^{-1}}(A * C)^{\mathrm{X}}
$$

In some cases, but not all, the components of an effective ideal transform $T$ with respect to histogram $A$, ideal $(A, T)$, are cartesian sub-volumes, $\exists A \in$ $\mathcal{A} \exists T \in \mathcal{T}_{\mathrm{f}, \mathrm{U}}\left(\operatorname{ideal}(A, T) \wedge \forall C \in T^{\mathrm{P}}\left(\left(A * C^{\mathrm{U}}\right)^{\mathrm{F}}=\left(A * C^{\mathrm{U}}\right)^{\mathrm{XF}}\right)\right)$.

The independent of an effective idealisation equals the independent of the given histogram

$$
\left(A * T * T^{\dagger A}\right)^{\mathrm{x}} \equiv A^{\mathrm{X}}
$$

This is true because the sum of the perimeters of the components are equal, $\forall w \in V$

$$
\begin{aligned}
A * T * T^{\dagger A} \%\{w\} & \equiv \sum_{C \in T^{\mathrm{P}}} A * T * T^{\dagger A} * C^{\mathrm{U}} \%\{w\} \\
& \equiv \sum_{C \in T^{\mathrm{P}}}\left(A * C^{\mathrm{U}}\right)^{\mathrm{X}} \%\{w\} \\
& \equiv \sum_{C \in T^{\mathrm{P}}} A * C^{\mathrm{U}} \%\{w\} \\
& \equiv A \%\{w\} \\
& \equiv A^{\mathrm{X}} \%\{w\}
\end{aligned}
$$

where $V=\operatorname{und}(T)=\operatorname{vars}(A)$. Thus

$$
\left(A * T * T^{\dagger A}\right)^{\mathrm{X}} \equiv\left(\sum_{C \in T^{\mathrm{P}}}\left(A * C^{\mathrm{U}}\right)^{\mathrm{X}}\right)^{\mathrm{X}} \equiv A^{\mathrm{X}}
$$

A special case of an ideal transform is where the transform is a self-partition. In this case, the transform is ideal with respect to any histogram $A$ in its underlying variables $\operatorname{vars}(A)=V=\operatorname{und}(T)$, so long as the transform $T$ is as effective as $A$

$$
\left((X \% V)^{\mathrm{F}} \geq A^{\mathrm{F}}\right) \wedge(\forall C \in \operatorname{ran}(\operatorname{inverse}(T))(|C|=1)) \Longrightarrow \operatorname{ideal}(A, T)
$$

where $X=\operatorname{histogram}(T)$. In this case, each component is a singleton and hence is independent. An example is the self partition transform $V^{\mathrm{CS}\{ \} \mathrm{T}} \in$ $\mathcal{T}_{U, V} \subset \mathcal{T}_{U, f, 1}$ which is always ideal, ideal $\left(A, V^{\mathrm{CS}\{ \} \mathrm{T}}\right)$. Another example is the value full functional transform $\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in V\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V} \subset \mathcal{T}_{U, \mathrm{f}, 1}$ which is always ideal, ideal $\left(A,\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in V\right\}^{\mathrm{T}}\right)$.

If a transform $T$ is a unary-partition, $|X \% W|=1$ where $(X, W)=T$, then $T$ is an ideal transform of $A^{\mathrm{X}}$ if $T$ is as effective as $A^{\mathrm{X}},(X \% V)^{\mathrm{F}} \geq A^{\mathrm{XF}}$ where $\operatorname{vars}(A)=V=\operatorname{und}(T)$ and $A^{\mathrm{X}}$ is non-zero, $\operatorname{size}\left(A^{\mathrm{X}}\right)>0$,

$$
\left((X \% V)^{\mathrm{F}} \geq A^{\mathrm{XF}}\right) \wedge(|\operatorname{inverse}(T)|=1) \Longrightarrow \operatorname{ideal}\left(A^{\mathrm{X}}, T\right)
$$

It is also the case that the idealisation, $A * T * T^{\dagger A}$, equals the independent, $A^{\mathrm{X}}, A * T * T^{\dagger A}=A^{\mathrm{X}}$. An example is the unary partition transform
$\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V} \subset \mathcal{T}_{U, \mathrm{f}, 1}$ which is always an ideal transform of the independent histogram $A^{\mathrm{X}}$, $\operatorname{ideal}\left(A^{\mathrm{X}},\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}\right)$ or $A *\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} *\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T} \dagger A}=A^{\mathrm{X}}$.

A one functional transform $T \in \mathcal{T}_{U, f, 1}$ must be ideal with respect to histogram $A$ if each of the effective states of $A$ is in a separate component, $A^{\mathrm{F}} \leftrightarrow T^{\mathrm{P}}$, because each component is a singleton and therefore independent, $\forall C \in T^{\mathrm{P}}\left(\left|\left(A * C^{\mathrm{U}}\right)^{\mathrm{F}}\right| \leq 1\right)$. Thus, in the case where the cardinality of effective states is less than the volume, $b<v$, there must exist at least $\operatorname{stir}(v-b, b)$ ideal partition transforms, where $v=\left|V^{\mathrm{C}}\right|, b=\left|A^{\mathrm{F}}\right|$ and stir $\in \mathbf{N}_{>0} \times \mathbf{N} \rightarrow \mathbf{N}_{>0}$ is the Stirling number of the second kind. This is the case if the size is less than the volume, $z<v$, where $z=\operatorname{size}(A)$. Thus the cardinality of the set of ideal substrate transforms is bounded $\left|\left\{T: T \in \mathcal{T}_{U, V}, A * T * T^{\dagger A} \equiv A\right\}\right| \geq \operatorname{stir}(v-b, b)$. This lower bound may be compared to the cardinality of the substrate partition transforms $\left|F_{U, V}\right|=\left|\left\{P^{\mathrm{T}}: P \in \mathrm{~B}\left(V^{\mathrm{CS}}\right)\right\}\right|=\left|\mathrm{B}\left(V^{\mathrm{CS}}\right)\right|=\operatorname{bell}(v)=\sum_{k \in 0 \ldots v} \operatorname{stir}(v, k)$. Note that the Stirling number of the second $\operatorname{kind}, \operatorname{stir}(n, k)$ is maximised where $k \approx n / \ln n$ for large $n$. So conjecture that the maximisation of the fraction of the cardinality of the idealisations per cardinality of the substrate transforms, $\left|\left\{T: T \in \mathcal{T}_{U, V}, A * T * T^{\dagger} \equiv A\right\}\right| /\left|\mathcal{T}_{U, V}\right|$, occurs approximately where $b \approx v / \ln v$.

The nullable transform $D^{\mathrm{T}}$ of a well behaved distinct decomposition $D \in \mathcal{D}_{\mathrm{w}, U}$ is ideal with respect to histogram $A$ if each of the effective states of $A$ is in a separate component or slice, $A^{\mathrm{F}} \leftrightarrow D^{\mathrm{TP}}$. That is, $\forall C \in D^{\mathrm{TP}}\left(\left|\left(A * C^{\mathrm{U}}\right)^{\mathrm{F}}\right| \leq\right.$ $1) \Longrightarrow \operatorname{ideal}\left(A, D^{\mathrm{T}}\right)$. This is also true of the partition transform, $D^{\mathrm{PT}}$, because both have the same partition, $D^{\mathrm{TP}}=D^{\mathrm{PTP}}=D^{\mathrm{P}}$. The decomposition is said to be effectively sliced with respect to the histogram, $A$. Note that a decomposition may be ideal even when not effectively sliced. If a sub-decomposition $E \in \operatorname{subtrees}(D)$ is effectively sliced with respect to $A$, $\forall C \in E^{\mathrm{P}}\left(\left|\left(A * C^{\mathrm{U}}\right)^{\mathrm{F}}\right| \leq 1\right)$, then $D$ must also be effectively sliced, because the expanded partition of $E$ is a parent partition, parent $\left(E^{\mathrm{PV}}, D^{\mathrm{P}}\right)$.

A special case of an ideal transform is a naturally ideal transform

$$
A * T * T^{\dagger}=A
$$

If it is the case that all of the components of $T \in \mathcal{T}_{U, f, 1}$ are cartesian subvolumes, $\forall C \in \operatorname{ran}(\operatorname{inverse}(T))\left(C^{\mathrm{F}}=C^{\mathrm{XF}}\right)$, then $T^{\dagger V^{\mathrm{C}}}=T^{\dagger}$ and so $T$ is a naturally ideal transform with respect to $V^{\mathrm{C}}, V^{\mathrm{C}} * T * T^{\dagger}=V^{\mathrm{C}}$, where $V=\operatorname{und}(T)$.

If $T$ is a naturally ideal transform of histogram $A$ then each of the components must be uniform

$$
\forall C \in \operatorname{ran}(\operatorname{inverse}(T))(|\operatorname{ran}(A * C)|=1)
$$

Given the naturally ideal transform $T$ and the sizes of each of the components $Q=\{(R, \operatorname{size}(A * C)):(R, C) \in$ inverse $(T)\}$, then $A$ can be reconstructed

$$
A=\sum\left\{\operatorname{scalar}\left(Q_{R}\right) * \frac{C}{C \% \emptyset}:(R, C) \in \operatorname{inverse}(T)\right\}
$$

Similarly, a histogram $A$ can be reconstructed from an ideal transform $T$, where the components of the effective transform are cartesian sub-volumes, given the perimeters of each of these components
$Q=\left\{\left(R,\{B \% \emptyset\} \cup\left\{\frac{B \%\{w\}}{B \% \emptyset}: w \in V\right\}\right):(R, C) \in \operatorname{inv}(\operatorname{eff}(A, T)), B=A * C\right\}$
where inv $=$ inverse and eff $=$ effective. So

$$
A=\sum\left\{\prod Q_{R}: R \in \operatorname{dom}(Q)\right\}
$$

Let non-zero sample histogram $A \in \mathcal{A}_{U}$ have non-empty variables $V=$ $\operatorname{vars}(A) \neq \emptyset$. The normalisation is a probability histogram, $\hat{A} \in \mathcal{A} \cap \mathcal{P}$. Let non-zero query histogram $Q \in \mathcal{A}_{U}$ have variables $K=\operatorname{vars}(Q)$ that are a subset of the sample variables, $K \subseteq V$. The normalisation of the query histogram is a probability histogram, $\hat{Q} \in \mathcal{A} \cap \mathcal{P}$. The difference between the sample variables and the query variables, $V \backslash K$, is called the set of label variables. As discussed above in section 'Transforms', given a one functional transform $T=(M, W) \in \mathcal{T}_{U, \mathrm{f}, 1}$, having underlying variables $J=\operatorname{und}(T)$, the model analog of the transformed conditional product, $\hat{Q} * T_{A}^{\prime}=\hat{Q} *$ $(A /(A \% K),(V \backslash K)) \in \mathcal{A} \cap \mathcal{P}^{\prime}$, is the renormalisation of the application of the normalised sample action, $(T,(\hat{A} * M, V))$, to the expanded query probability histogram, $\hat{Q}_{J}=\hat{Q} *(J \backslash K)^{\mathrm{C} \wedge} \in \mathcal{A} \cap \mathcal{P}$,

$$
\left(\hat{Q}_{J} * T *(\hat{A} * M, V)\right)^{\wedge} \%(V \backslash K) \in \mathcal{A} \cap \mathcal{P}
$$

if the intersection of derived effective states is not empty, $(Q * T)^{\mathrm{F}} \cap(A * T)^{\mathrm{F}} \neq$ $\emptyset$. The modelled transformed conditional product may be expressed in terms of the actual converse transform,

$$
\hat{Q}_{J} * T * T^{\odot A} \%(V \backslash K) \in \mathcal{A} \cap \mathcal{P}
$$

In the case where the transform is ideal with respect to the sample histogram, ideal $(A, T)$, the actual converse equals the ideal converse, $T^{\odot A}=T^{\dagger A}$, and so

$$
\begin{aligned}
& \hat{Q}_{J} * T * T^{\odot A} \%(V \backslash K) \\
= & \hat{Q}_{J} * T * T^{\dagger A} \%(V \backslash K) \\
= & \hat{Q}_{J} * T * \sum_{(R, C) \in T^{-1}}\{R\}^{\mathrm{U}} *(A * C)^{\mathrm{X} \wedge} \%(V \backslash K)
\end{aligned}
$$

### 3.12.3 Actual converse and Independent

The actual converse is very similar to the independent converse except that the literal application of the component to the argument histogram is used, rather than the independent of the applied component. The actual converse is defined above as converseActual $\in \mathcal{A} \times \mathcal{T}_{\mathrm{f}} \rightarrow \mathcal{T}$

$$
\begin{aligned}
& \text { converseActual }(B, T):= \\
& \qquad\left(\sum \frac{B * C}{(B * C) \% \emptyset} *\{R\}^{\mathrm{U}}:(R, C) \in \operatorname{inverse}(T), V\right)
\end{aligned}
$$

where $\operatorname{size}(B)>0$ and $\operatorname{vars}(B)=V=\operatorname{underlying}(T)$. Define notation

$$
T^{\odot B}=\operatorname{converseActual}(B, T)
$$

Like the independent converse, the argument transform must be functional $T \in \mathcal{T}_{\mathrm{f}}$. The actual converse may be expressed more concisely,

$$
\begin{equation*}
T^{\odot B}:=\left(\sum_{(R, C) \in T^{-1}}\{R\}^{\mathrm{U}} *(B * C)^{\wedge}, V\right) \tag{4}
\end{equation*}
$$

where the normalisation is defined $\hat{A}=A /(A \% \emptyset)$ so that normalised zero histograms are empty, $\left(V^{\mathrm{CZ}}\right)^{\wedge}=\emptyset$.

The actual converse of unit functional transform $T \in \mathcal{T}_{\mathfrak{f}, \mathrm{U}}$ of a histogram $A$ applied to the abstract histogram $(A * T)^{\mathrm{X}}$ is called the surrealisation, $(A * T)^{\mathrm{X}} * T^{\odot A}$. The surrealisation is equivalent to the histogram only if the transform is abstract, $\operatorname{abstract}(A, T)$,

$$
A * T \equiv(A * T)^{\mathrm{x}} \Longleftrightarrow(A * T)^{\mathrm{X}} * T^{\odot A} \equiv A
$$

An example of an abstract transform is the unary partition transform $\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in$ $\mathcal{T}_{U, \mathrm{f}, 1}$ which is always abstract, abstract $\left(A,\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}\right)$. Another example is the
self partition transform $V^{\mathrm{CS}\{ \} \mathrm{T}} \in \mathcal{T}_{U, f, 1}$. In this case there is only one derived variable and so the derived histogram is independent, abstract $\left(A, V^{\mathrm{CS}\{ \} \mathrm{T}}\right)$. A value full functional transform is abstract if the histogram is independent, $\operatorname{abstract}\left(A^{\mathrm{X}},\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in V\right\}^{\mathrm{T}}\right)$.

A surrealisation is size-conserving if the derived histogram is as effective as the abstract histogram, $(A * T)^{\mathrm{F}}=(A * T)^{\mathrm{XF}} \Longrightarrow \operatorname{size}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)=$ $\operatorname{size}(A)$. Otherwise the size of the surrealisation is less than the size of the histogram, $(A * T)^{\mathrm{F}}<(A * T)^{\mathrm{XF}} \Longrightarrow \operatorname{size}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)<\operatorname{size}(A)$. An abstract transform is necessarily size-conserving.

The independent of an effective surrealisation equals the independent of the given histogram if the transform is abstract, abstract $(A, T)$

$$
A * T \equiv(A * T)^{\mathrm{X}} \Longrightarrow\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)^{\mathrm{X}} \equiv A^{\mathrm{X}}
$$

because the surrealisation is equivalent to the histogam, $(A * T)^{\mathrm{X}} * T^{\odot A} \equiv A$.
In the case where the formal histogram is independent, $A^{\mathrm{X}} * T \equiv\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, then the surrealisation of the independent, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}} * T^{\odot} A^{\mathrm{X}}$, equals the independent, $A^{\mathrm{X}}$

$$
A^{\mathrm{x}} * T \equiv\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}} \Longrightarrow\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}} * T^{\odot A^{\mathrm{x}}} \equiv A^{\mathrm{X}}
$$

This is the case where the transform is non-overlapping because the formal histogram is independent, $\neg \operatorname{overlap}(T) \Longrightarrow A^{\mathrm{X}} * T \equiv\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$.

A histogram $A$ can be reconstructed from an abstract transform $T$ if the components of the transform are diagonalised, $\forall C \in T^{\mathrm{P}}$ (diagonal $\left.\left(\left(A * C^{\mathrm{U}}\right)^{\mathrm{F}}\right)\right)$, given the choice of diagonal and the counts along it. In the case where the applied component is a fully diagonalised regular cartesian volume the cardinality of diagonals is $(d!)^{n-1}$ where $n=|\operatorname{vars}(A)|$ and $d=\left|(B * C)^{\mathrm{F}}\right|$. Then the choice of diagonal is in $\left\{1 \ldots(d!)^{n-1}\right\}$.

In the case where the transform is a substrate transform $T \in \mathcal{T}_{U, V}$, having derived variables $W=\operatorname{der}(T)$, the derived of the partition transform is independent, $\forall P \in W\left(A * P^{\mathrm{T}}=\left(A * P^{\mathrm{T}}\right)^{\mathrm{X}}\right)$, because the partition transforms are mono-derived-variate, $\left|\operatorname{der}\left(P^{\mathrm{T}}\right)\right|=1$. So the surrealisations of the partition transforms equal the histogram,

$$
\forall P \in W\left(\left(A * P^{\mathrm{T}}\right)^{\mathrm{X}} * P^{\mathrm{T} \odot A}=A\right)
$$

The actual converse of unit functional transform $T \in \mathcal{T}_{\mathrm{f}, \mathrm{U}}$ of a histogram $A$ applied to the formal histogram $A^{\mathrm{X}} * T$ is called the contentisation, $A^{\mathrm{X}}{ }^{*}$ $T * T^{\odot A}$. A transform $T$ formal with respect to a histogram $A$ if the derived histogram, $A * T$, equals the formal histogram, $A^{\mathrm{X}} * T$. This is the case if the contentisation of $A$ is equivalent to $A$. The contentisation is equivalent to the histogram only if the transform is formal, formal $(A, T)$

$$
A * T \equiv A^{\mathrm{x}} * T \Longleftrightarrow A^{\mathrm{x}} * T * T^{\odot A} \equiv A
$$

An example of a formal transform is the unary partition transform $\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in$ $\mathcal{T}_{U, \mathrm{f}, 1}$ which is always formal, formal $\left(A,\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}\right)$. All effective unit functional transforms are formal if the histogram is independent, $A=A^{\mathrm{X}} \Longrightarrow A * T=$ $A^{\mathrm{X}} * T$. A value full functional transform is formal only if the histogram is independent, formal $\left(A^{\mathrm{X}},\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in V\right\}^{\mathrm{T}}\right)$.

A contentisation is size-conserving if the derived histogram is as effective as the formal histogram, $(A * T)^{\mathrm{F}} \geq\left(A^{\mathrm{X}} * T\right)^{\mathrm{F}} \Longrightarrow \operatorname{size}\left(A^{\mathrm{X}} * T * T^{\odot A}\right)=\operatorname{size}(A)$. Otherwise the size of the contentisation is less than the size of the histogram, $(A * T)^{\mathrm{F}}<\left(A^{\mathrm{X}} * T\right)^{\mathrm{F}} \Longrightarrow \operatorname{size}\left(A^{\mathrm{X}} * T * T^{\odot A}\right)<\operatorname{size}(A)$. A formal transform is necessarily size-conserving.

The effective contentisation of an independent equals the independent

$$
A^{\mathrm{X}} * T * T^{\odot A^{\mathrm{X}}} \equiv A^{\mathrm{X}}
$$

The contentisation equals the histogram if the transform is formal, formal $(A, T)$, by definition

$$
A * T \equiv A^{\mathrm{X}} * T \Longrightarrow A^{\mathrm{x}} * T * T^{\odot A} \equiv A
$$

The independent of a contentisation equals the independent of the given histogram if the transform is formal, formal $(A, T)$

$$
A * T \equiv A^{\mathrm{x}} * T \Longrightarrow\left(A^{\mathrm{X}} * T * T^{\odot A}\right)^{\mathrm{X}} \equiv A^{\mathrm{X}}
$$

because the contentisation is equivalent to the histogam, $A^{\mathrm{X}} * T * T^{\odot} A^{\mathrm{x}} \equiv A$.
The contentisation equals the surrealisation if the formal histogram is equivalent to the abstract histogram, $A^{\mathrm{X}} * T \equiv(A * T)^{\mathrm{X}}$

$$
A^{\mathrm{X}} * T \equiv(A * T)^{\mathrm{X}} \Longrightarrow A^{\mathrm{X}} * T * T^{\odot A} \equiv(A * T)^{\mathrm{X}} * T^{\odot A}
$$

In the case where the formal histogram is independent, $A^{\mathrm{X}} * T \equiv\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, then the surrealisation of the independent, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}} * T^{\odot A^{\mathrm{X}}}$, equals contentisation of the independent, $A^{\mathrm{X}} * T * T^{\odot} A^{\mathrm{x}}$, which equals the independent,
$A^{\mathrm{X}}$

$$
A^{\mathrm{X}} * T \equiv\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}} \Longrightarrow\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}} * T^{\odot A^{\mathrm{X}}} \equiv A^{\mathrm{X}} * T * T^{\odot A^{\mathrm{X}}} \equiv A^{\mathrm{x}}
$$

This is the case where the transform is non-overlapping, $\neg \operatorname{overlap}(T) \Longrightarrow$ $A^{\mathrm{X}} * T \equiv\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$.

The actual converse of unit functional transform $T \in \mathcal{T}_{\mathrm{f}, \mathrm{U}}$ of the independent histogram $A^{\mathrm{X}}$ applied to the derived histogram $A * T$ is called the neutralisation, $A * T * T^{\odot A^{\mathrm{X}}}$. A neutralisation is size-conserving, $\operatorname{size}\left(A * T * T^{\odot} A^{\mathrm{x}}\right)=$ $\operatorname{size}(A)$. If the transform is a unary partition transform $\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, \mathrm{f}, 1}$ then the neutralisation equals the independent, $A *\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} *\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T} \odot A^{\mathrm{X}}}=A^{\mathrm{X}}$. If the transform is a full functional transform, for example a value full functional transform $\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in V\right\}^{\mathrm{T}}$, then the neutralisation equals the histogram only if the histogram is independent, $A^{\mathrm{X}} *\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in\right.$ $V\}^{\mathrm{T}} *\left\{\{w\}^{\operatorname{CS}\{ \} \mathrm{T}}: w \in V\right\}^{\mathrm{T} \odot A^{\mathrm{X}}}=A^{\mathrm{X}}$.

The effective neutralisation of an independent equals the independent

$$
A^{\mathrm{X}} * T * T^{\odot A^{\mathrm{X}}} \equiv A^{\mathrm{X}}
$$

The effective neutralisation equals the independent if the transform is formal, formal $(A, T)$,

$$
A * T \equiv A^{\mathrm{X}} * T \Longrightarrow A * T * T^{\odot A^{\mathrm{X}}} \equiv A^{\mathrm{X}}
$$

So the independent of a neutralisation equals the independent if the transform is formal

$$
A * T \equiv A^{\mathrm{x}} * T \Longrightarrow\left(A * T * T^{\odot A^{\mathrm{x}}}\right)^{\mathrm{x}} \equiv A^{\mathrm{X}}
$$

If a transform $T$ is formal, formal $(A, T)$, then the contentisation equals the histogram, $A^{\mathrm{X}} * T * T^{\odot A} \equiv A$, and the neutralisation equals the independent, $A * T * T^{\odot A^{\mathrm{X}}} \equiv A^{\mathrm{X}}$

$$
A^{\mathrm{X}} * T * T^{\odot A} \equiv A \Longleftrightarrow A * T * T^{\odot A^{\mathrm{X}}} \equiv A^{\mathrm{X}}
$$

The neutralisation equals the idealisation when each of the components of the independent equals the independent component of the histogram

$$
\forall C \in T^{\mathrm{P}}\left(A^{\mathrm{X}} * C^{\mathrm{U}}=\left(A * C^{\mathrm{U}}\right)^{\mathrm{x}}\right) \Longleftrightarrow A * T * T^{\odot A^{\mathrm{x}}}=A * T * T^{\dagger A}
$$

In the case where the transform is a substrate transform $T \in \mathcal{T}_{U, V}$ and the formal independent equals the abstract, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$, then the
neutralisations of the partition transforms equal the independent,

$$
\begin{aligned}
& \left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}=(A * T)^{\mathrm{x}} \Longleftrightarrow \\
& \quad \forall P \in W\left(A * P^{\mathrm{T}}=A^{\mathrm{x}} * P^{\mathrm{T}}\right) \\
& \quad=\forall P \in W\left(A * P^{\mathrm{T}} * P^{\mathrm{T} \odot A^{\mathrm{x}}}=A^{\mathrm{X}}\right)
\end{aligned}
$$

and the contentisations of the partition transforms equal the histogram,

$$
\begin{aligned}
& \left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}=(A * T)^{\mathrm{x}} \Longleftrightarrow \\
& \quad \forall P \in W\left(A * P^{\mathrm{T}}=A^{\mathrm{x}} * P^{\mathrm{T}}\right) \\
& \quad=\forall P \in W\left(A=A^{\mathrm{X}} * P^{\mathrm{T}} * P^{\mathrm{T} \odot A}\right)
\end{aligned}
$$

Of the idealisation and actualisations, the idealisation, $A * T * T^{\dagger A}$, and the surrealisation, $(A * T)^{\mathrm{X}} * T^{\odot A}$, may be grouped together as abstract converse actions which depend on the derived histogram, $A * T$, and the independent of the derived histogram, or abstract histogram, $(A * T)^{\mathrm{X}}$. The neutralisation, $A * T * T^{\odot A^{\mathrm{X}}}$, and the contentisation, $A^{\mathrm{X}} * T * T^{\odot A}$, may be grouped together as formal converse actions which depend on the histogram, $A$, and the independent of the histogram, $A^{\mathrm{X}}$.

### 3.12.4 Converse action entropy

Consider the histogram-transform pair $(A, T) \in \mathcal{A} \times \mathcal{T}_{U, \mathrm{f}, 1}$ in variables $V=\operatorname{vars}(A)$ where (i) the independent histogram is completely effective, $A^{\mathrm{XF}}=V^{\mathrm{C}}$, (ii) the one functional transform has underlying variables equal to the histogram variables, $\operatorname{und}(T)=V$, and (iii) the derived histogram is as effective as the formal histogram, $(A * T)^{\mathrm{F}} \geq\left(A^{\mathrm{X}} * T\right)^{\mathrm{F}}$, so that the contentisation is size-conserving, $\operatorname{size}\left(A^{\mathrm{X}} * T * T^{\odot} \bar{A}\right)=\operatorname{size}(A)$.

The formal converse actions, which depend on the histogram, $A$, and the independent of the histogram, $A^{\mathrm{X}}$, are related. Conjecture that the sum of the contentisation and the neutralisation is approximately equal to the sum of the histogram and the independent

$$
A^{\mathrm{x}} * T * T^{\odot A}+A * T * T^{\odot A^{\mathrm{x}}} \cong A+A^{\mathrm{X}}
$$

The sizes sum exactly, $\operatorname{size}\left(A^{\mathrm{X}} * T * T^{\odot A}\right)+\operatorname{size}\left(A * T * T^{\odot} A^{\mathrm{x}}\right)=\operatorname{size}(A)+$ $\operatorname{size}\left(A^{\mathrm{X}}\right)$. In the case when the transform is formal with respect to the histogram, formal $(A, T):=A * T \equiv A^{\mathrm{X}} * T$, then (i) the contentisation is equivalent to the histogram, $A^{\mathrm{X}} * T * T^{\odot A} \equiv A$, and (ii) the neutralisation is equivalent to the independent, $A * T * T^{\odot A^{\mathrm{x}}} \equiv A^{\mathrm{X}}$, and so the sum of
the contentisation and the neutralisation is exactly equal to the sum of the histogram and the independent, $A * T * T^{\odot A}+A^{\mathrm{X}} * T * T^{\odot A^{\mathrm{X}}} \equiv A+A^{\mathrm{X}}$.

If the transform is a unary partition transform $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, \mathrm{f}, 1}$ then (i) the neutralisation equals the independent, $A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\odot} A^{\mathrm{x}} \equiv A^{\mathrm{X}}$, and (ii) the contentisation equals the histogram, $A^{\mathrm{X}} * T_{\mathrm{u}} * T_{\mathrm{u}}^{\odot A} \equiv A$, and so in this case the sums are exactly equal, $A^{\mathrm{X}} * T_{\mathrm{u}} * T_{\mathrm{u}}^{\odot A}+A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\odot A^{\mathrm{X}}} \equiv A+A^{\mathrm{X}}$.

If the transform is a full functional transform, for example a value full functional transform $T_{\mathrm{s}}=\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in V\right\}^{\mathrm{T}}$, then (i) the neutralisation equals the histogram, $A * T_{\mathrm{s}} * T_{\mathrm{s}}^{\odot A^{\mathrm{X}}} \equiv A$, and (ii) the contentisation equals the independent because the histogram is as effective as the independent, $\left(A * T_{\mathrm{s}}\right)^{\mathrm{F}} \geq\left(A^{\mathrm{X}} * T_{\mathrm{s}}\right)^{\mathrm{F}} \Longrightarrow A^{\mathrm{F}}=A^{\mathrm{XF}} \Longrightarrow A^{\mathrm{X}} * T_{\mathrm{s}} * T_{\mathrm{s}}^{\odot A} \equiv A^{\mathrm{X}}$, and so in this case the sums are exactly equal, $A^{\mathrm{X}} * T_{\mathrm{s}} * T_{\mathrm{s}}^{\odot A}+A * T_{\mathrm{s}} * T_{\mathrm{s}}^{\odot} A^{\mathrm{X}} \equiv A^{\mathrm{X}}+A$.

In the special case where the independent equals the scaled cartesian, $A^{\mathrm{X}}=$ $V_{z}^{\mathrm{C}}$, where $z=\operatorname{size}(A), v=\left|V^{\mathrm{C}}\right|$ and $V_{z}^{\mathrm{C}}=\operatorname{scalar}(z / v) * V^{\mathrm{C}}$, then the sum of the unnaturalisation and the naturalisation is approximately equal to the sum of the histogram and the scaled cartesian

$$
V_{z}^{\mathrm{C}} * T * T^{\odot A}+A * T * T^{\dagger} \cong A+V_{z}^{\mathrm{C}}
$$

Conjecture that the sum of the entropies of the contentisation and the neutralisation varies as the sum of the entropies of the histogram and the independent
$\operatorname{entropy}\left(A^{\mathrm{X}} * T * T^{\odot A}\right)+\operatorname{entropy}\left(A * T * T^{\odot} A^{\mathrm{x}}\right) \sim \operatorname{entropy}(A)+\operatorname{entropy}\left(A^{\mathrm{X}}\right)$
In the special case where the independent equals the scaled cartesian, $A^{\mathrm{x}}=$ $V_{z}^{\mathrm{C}}$, then the entropies are such that

$$
\operatorname{entropy}\left(V_{z}^{\mathrm{C}} * T * T^{\odot A}\right)+\operatorname{entropy}\left(A * T * T^{\dagger}\right) \sim \operatorname{entropy}(A)+\operatorname{entropy}\left(V_{z}^{\mathrm{C}}\right)
$$

The relationship between the entropies of the formal converse actions can be lifted to the abstract converse actions. In the case where the formal histogram is equivalent to the abstract histogram, $A^{\mathrm{X}} * T \equiv(A * T)^{\mathrm{X}}$, then insofar as the idealisation approximates to the neutralisation, $A * T * T^{\dagger A} \cong$ $A * T * T^{\odot A^{\mathrm{X}}}$, conjecture that the sum of the entropies of the surrealisation and the idealisation varies as the sum of the entropies of the histogram and the independent

$$
\operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)+\operatorname{entropy}\left(A * T * T^{\dagger A}\right) \sim \operatorname{entropy}(A)+\operatorname{entropy}\left(A^{\mathrm{X}}\right)
$$

In the case where the formal equals the abstract, $A^{\mathrm{X}} * T \equiv(A * T)^{\mathrm{X}}$, conjecture that the entropies of the converse action histograms are subject to the following inequalities. First via the actual converse of the independent,

$$
\begin{aligned}
& \operatorname{entropy}\left(V_{z}^{\mathrm{C}} * T * T^{\dagger}\right)=\operatorname{entropy}\left(V_{z}^{\mathrm{C}}\right) \\
\geq & \operatorname{entropy}\left(V_{z}^{\mathrm{C}} * T * T^{\odot A^{\mathrm{x}}}\right) \\
\geq & \operatorname{entropy}\left(A^{\mathrm{X}} * T * T^{\odot A^{\mathrm{x}}}\right)=\operatorname{entropy}\left(A^{\mathrm{x}}\right) \\
\geq & \operatorname{entropy}\left(A^{\mathrm{X}} * T * T^{\odot A}\right)=\operatorname{entropy}\left((A * T)^{\mathrm{x}} * T^{\odot A}\right) \\
\geq & \operatorname{entropy}(A) \\
\geq & \operatorname{entropy}\left(Z_{A}\right)=0
\end{aligned}
$$

and

$$
\begin{aligned}
& \operatorname{entropy}\left(V_{z}^{\mathrm{C}} * T * T^{\dagger}\right)=\operatorname{entropy}\left(V_{z}^{\mathrm{C}}\right) \\
\geq & \operatorname{entropy}\left(V_{z}^{\mathrm{C}} * T * T^{\odot A^{\mathrm{x}}}\right) \\
\geq & \operatorname{entropy}\left(A^{\mathrm{X}} * T * T^{\odot A^{\mathrm{x}}}\right)=\operatorname{entropy}\left(A^{\mathrm{x}}\right) \\
\geq & \operatorname{entropy}\left(A * T * T^{\odot A^{\mathrm{x}}}\right) \\
\geq & \operatorname{entropy}\left(A * T * T^{\dagger A}\right) \\
\geq & \operatorname{entropy}(A) \\
\geq & \operatorname{entropy}\left(Z_{A}\right)=0
\end{aligned}
$$

where $Z_{A}=A \% \emptyset=\operatorname{scalar}(\operatorname{size}(A))$.
Now via the natural converse,

$$
\begin{aligned}
& \operatorname{entropy}\left(V_{z}^{\mathrm{C}} * T * T^{\dagger}\right)=\operatorname{entropy}\left(V_{z}^{\mathrm{C}}\right) \\
\geq & \operatorname{entropy}\left(A^{\mathrm{X}} * T * T^{\dagger}\right)=\operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\dagger}\right) \\
\geq & \operatorname{entropy}\left(A * T * T^{\dagger}\right) \\
\geq & \operatorname{entropy}\left(A * T * T^{\odot A^{\mathrm{x}}}\right) \\
\geq & \operatorname{entropy}\left(A * T * T^{\dagger A}\right) \\
\geq & \operatorname{entropy}(A) \\
\geq & \quad \operatorname{entropy}\left(Z_{A}\right)=0
\end{aligned}
$$

Now via the actual converse,

```
    \(\operatorname{entropy}\left(V_{z}^{\mathrm{C}} * T * T^{\dagger}\right)=\operatorname{entropy}\left(V_{z}^{\mathrm{C}}\right)\)
\(\geq \operatorname{entropy}\left(\left(V_{z}^{\mathrm{C}} * T\right)^{\mathrm{X}} * T^{\dagger}\right)\)
\(\geq \operatorname{entropy}\left(\left(V_{z}^{\mathrm{C}} * T\right)^{\mathrm{X}} * T^{\odot A}\right)\)
\(\geq \operatorname{entropy}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}} * T^{\odot A}\right)\)
\(\geq \operatorname{entropy}\left(A^{\mathrm{X}} * T * T^{\odot A}\right)=\operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)\)
\(\geq\) entropy \((A)\)
\(\geq \operatorname{entropy}\left(Z_{A}\right)=0\)
```

In section 'Minimum alignment', below, it is shown that the relative entropy of the independent with respect to the histogram equals the difference between the independent entropy and the histogram entropy,

$$
\operatorname{entropyRelative}\left(A, A^{\mathrm{X}}\right)=\operatorname{entropy}\left(A^{\mathrm{X}}\right)-\operatorname{entropy}(A)
$$

and so the independent entropy is greater than or equal to the histogram entropy, entropy $\left(A^{\mathrm{X}}\right) \geq \operatorname{entropy}(A)$. Therefore the surrealisation derived entropy is greater than or equal to the idealisation derived entropy,

$$
\begin{aligned}
& \operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\odot A} * T\right)=\operatorname{entropy}\left((A * T)^{\mathrm{x}}\right) \\
\geq & \operatorname{entropy}\left(A * T * T^{\dagger} * T\right)=\operatorname{entropy}(A * T)
\end{aligned}
$$

The idealisation independent equals the histogram independent, so the idealisation entropy is less than or equal to the independent entropy, entropy $\left(A^{\mathrm{X}}\right)=$ entropy $\left(\left(A * T * T^{\dagger A}\right)^{\mathrm{X}}\right) \geq \operatorname{entropy}\left(A * T * T^{\dagger A}\right)$. The idealisation entropy is greater than or equal to the histogram entropy, entropy $\left(A * T * T^{\dagger A}\right) \geq$ entropy $(A)$. Therefore the idealisation entropy is between the independent entropy and the histogram entropy,

$$
\operatorname{entropy}\left(A^{\mathrm{X}}\right) \geq \operatorname{entropy}\left(A * T * T^{\dagger A}\right) \geq \operatorname{entropy}(A)
$$

### 3.12.5 Iso-sets

A histogram $A$ and its independent $A^{\mathrm{X}}$ are congruent. Let the set of complete congruent histograms in system $U$, of variables $V$ and size $z$ be

$$
\mathcal{A}_{U, V, z}=\left\{A: A \in \mathcal{A}_{U}, A^{\mathrm{U}}=V^{\mathrm{C}}, \operatorname{size}(A)=z\right\}
$$

The set of complete congruent histograms is also known as the set of substrate histograms. The set of complete congruent histograms, $\mathcal{A}_{U, V, z}$, is infinite if
the volume is greater than one, $\left|V^{\mathrm{C}}\right|>1$. Let histogram $A$ be a complete congruent histogram, $A \in \mathcal{A}_{U, V, z}$. Then the independent histogram, $A^{\mathrm{X}}$, is a complete congruent histogram, $A^{\mathrm{X}} \in \mathcal{A}_{U, V, z}$. The independent function partitions $\mathcal{A}_{U, V, z}$ into equivalence classes of iso-independents. Let $Y_{U, V, z} \in$ $\mathcal{A}_{U, V, z} \rightarrow \mathcal{A}_{U, V, z}$ be the subset of the independent function,

$$
Y_{U, V, z}=\left\{\left(A, A^{\mathrm{X}}\right): A \in \mathcal{A}_{U, V, z}\right\} \subset \text { independent }
$$

Then inverse $\left(Y_{U, V, z}\right) \in \mathcal{A}_{U, V, z} \rightarrow \mathrm{P}\left(\mathcal{A}_{U, V, z}\right)$ and ran(inverse $\left.\left(Y_{U, V, z}\right)\right) \in \mathrm{B}\left(\mathcal{A}_{U, V, z}\right)$. Thus the set of iso-independents of histogram $A \in \mathcal{A}_{U, V, z}$ is

$$
\operatorname{inverse}\left(Y_{U, V, z}\right)\left(A^{\mathrm{x}}\right)=\left\{B: B \in \mathcal{A}_{U, V, z}, B^{\mathrm{X}}=A^{\mathrm{X}}\right\}
$$

The set of iso-independents is infinite if more than one of its perimeter histograms is not an effective singleton, $\left|\left\{w: w \in V,\left|\left(A^{\mathrm{X}} \%\{w\}\right)^{\mathrm{F}}\right|>1\right\}\right|>$ $1 \Longleftrightarrow\left|Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|=\infty$. Otherwise the set of iso-independents is a singleton, $\left|\left\{w: w \in V,\left|\left(A^{\mathrm{X}} \%\{w\}\right)^{\mathrm{F}}\right|>1\right\}\right| \leq 1 \Longleftrightarrow Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)=\left\{A^{\mathrm{X}}\right\}$.

Both the histogram, $A$, and the independent histogram, $A^{\mathrm{X}}$, are iso-independents, $A, A^{\mathrm{X}} \in \operatorname{inverse}\left(Y_{U, V, z}\right)\left(A^{\mathrm{X}}\right)$.

The idealisation of a histogram given an effective transform, $A * T * T^{\dagger A}$, is also in the iso-independents, $A * T * T^{\dagger A} \in Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, because the independent of the idealisation equals the independent histogram, $\left(A * T * T^{\dagger A}\right)^{\mathrm{X}}=A^{\mathrm{X}}$.

Let the set of complete congruent integral histograms, also called the integral congruent support, in system $U$, of variables $V$ and size $z$ be

$$
\mathcal{A}_{U, \mathrm{i}, V, z}=\left\{A: A \in \mathcal{A}_{U, \mathrm{i}}, A^{\mathrm{U}}=V^{\mathrm{C}}, \operatorname{size}(A)=z\right\}
$$

The set of complete congruent integral histograms is also known as the set of integral substrate histograms. The integral congruent support is a finite subset of the complete congruent histograms, $\mathcal{A}_{U, \mathrm{i}, V, z} \subset \mathcal{A}_{U, V, z}$. Its cardinality is the cardinality of weak compositions $\left|\mathrm{C}^{\prime}\left(V^{\mathrm{C}}, z\right)\right|$

$$
\left|\mathcal{A}_{U, i, V, z}\right|=\frac{(z+v-1)!}{z!(v-1)!}
$$

where $v=\left|V^{\mathrm{C}}\right|$. The independent function also partitions the integral congruent support, $\mathcal{A}_{U, \mathrm{i}, V, z}$, into equivalence classes of integral iso-independents. Let $Y_{U, \mathrm{i}, V, z} \in \mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathcal{A}_{U, V, z}$ be such that $Y_{U, \mathrm{i}, V, z}=\left\{\left(A, A^{\mathrm{X}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\} \subset$
$Y_{U, V, z} \subset$ independent. Thus the finite set of integral iso-independents of histogram $A \in \mathcal{A}_{U, \mathbf{i}, V, z}$ is

$$
\operatorname{inverse}\left(Y_{U, \mathrm{i}, V, z}\right)\left(A^{\mathrm{X}}\right)=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{X}}=A^{\mathrm{X}}\right\}
$$

The integral histogram $A \in \mathcal{A}_{U, i, V, z}$ is an integral iso-independent, $A \in$ inverse $\left(Y_{U, \mathrm{i}, V, z}\right)\left(A^{\mathrm{X}}\right)$. The independent histogram, $A^{\mathrm{X}}$, is not necessarily integral. If it is integral then it is a member of the integral iso-independents, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}} \Longleftrightarrow A^{\mathrm{X}} \in \operatorname{inverse}\left(Y_{U, \mathrm{i}, V, z}\right)\left(A^{\mathrm{X}}\right)$.

The range of the integral congruent independent function, $\operatorname{ran}\left(Y_{U, i, V, z}\right)$, consists of the set of all of the independent histograms in the complete congruent histograms which have integral perimeter, $\operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)=\left\{A^{\mathrm{X}}: A \in\right.$ $\left.\mathcal{A}_{U, V, z}, \forall w \in V\left(A^{\mathrm{X}} \%\{w\} \in \mathcal{A}_{U, \mathrm{i},\{w\}, z}\right)\right\}$, because (i) each of the histograms of the domain, $\operatorname{dom}\left(Y_{U, \mathrm{i}, V, z}\right)$, has integral perimeter, $\forall A \in \mathcal{A}_{U, \mathrm{i}, V, z} \forall w \in$ $V\left(A \%\{w\} \in \mathcal{A}_{U, \mathrm{i},\{w\}, z}\right)$, (ii) the perimeter of an independent histogram equals the perimeter of its histogram, $\forall A \in \mathcal{A}_{U, \mathrm{i}, V, z} \forall w \in V\left(A^{\mathrm{X}} \%\{w\}=\right.$ $A \%\{w\}$ ), and (iii) all integral perimeters imply the existence of at least one integral histogram having that perimeter, $\forall Q \in V \rightarrow \mathcal{A}_{U}((|Q|=$ $\left.|V| \wedge\left(\forall(w, B) \in Q\left(B \in \mathcal{A}_{U, \mathbf{i},\{w\}, z}\right)\right)\right) \Longrightarrow\left(\exists A \in \mathcal{A}_{U, \mathrm{i}, V, z}(\{(w, A \%\{w\}):\right.$ $w \in V\}=Q))$ ). This can be shown by constructing the set of integral iso-independents explicitly given an integral perimeter. Define iiso $\in(\mathcal{V} \rightarrow$ $\left.\mathcal{A}_{\mathrm{i}}\right) \rightarrow \mathrm{P}\left(\mathcal{A}_{\mathrm{i}}\right)$ as $\operatorname{iiso}(Q):=\operatorname{iiso}(Q, \emptyset)$, and iiso $\in\left(\mathcal{V} \rightarrow \mathcal{A}_{\mathrm{i}}\right) \times \mathcal{A}_{\mathrm{i}} \rightarrow \mathrm{P}\left(\mathcal{A}_{\mathrm{i}}\right)$ as

$$
\begin{aligned}
& \operatorname{iiso}(Q, A):= \\
& \begin{array}{l}
\cup \\
\quad\left\{\operatorname{iiso}\left(Q^{\prime}, A^{\prime}\right): X \in \prod \operatorname{ran}(Q), \operatorname{minr}(X)>0, S=\bigcup \operatorname{dom}(X),\right. \\
\\
\left.\quad A^{\prime}=A+\{S\}^{\mathrm{U}}, Q^{\prime}=\left\{\left(w, B-\{S \%\{w\}\}^{\mathrm{U}}\right):(w, B) \in Q\right\}\right\} \\
\cup \quad\{A: \operatorname{maxr}(\operatorname{ran}(Q))=0\}
\end{array} .
\end{aligned}
$$

where $(\Pi)$ is the monoidal product of a set of sets. The function, iiso, is such that $\operatorname{iiso}(Q) \subset \mathcal{A}_{U, \mathrm{i}, V, z}$ where $\forall(w, B) \in Q\left(B \in \mathcal{A}_{U, \mathrm{i},\{w\}, z}\right)$. It is also the case that $|\operatorname{iiso}(Q)|>0$. Thus there always exists at least one integral iso-independent histogram having the given integral perimeter. Therefore the range of the integral congruent independent function is bijective with the integral congruent perimeters and the cardinality is

$$
\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)\right|=\prod_{w \in V} \frac{\left(z+\left|U_{w}\right|-1\right)!}{z!\left(\left|U_{w}\right|-1\right)!}
$$

Thus, $\operatorname{iiso}\left(\left\{\left(w, A^{\mathrm{X}} \%\{w\}\right): w \in V\right\}\right)=Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$.

The cardinality of the integral congruent perimeters must be less than or equal to the cardinality of the integral congruent support

$$
\left|\operatorname{ran}\left(Y_{U, i, V, z}\right)\right| \leq\left|\operatorname{dom}\left(Y_{U, i, V, z}\right)\right|=\left|\mathcal{A}_{U, \mathbf{i}, V, z}\right|
$$

and so

$$
\prod_{w \in V} \frac{\left(z+\left|U_{w}\right|-1\right)!}{z!}\left(\left|U_{w}\right|-1\right)!\quad \leq \frac{(z+v-1)!}{z!(v-1)!}
$$

In the case of regular variables $V$ having dimension $n=|V|$ and valency $\{d\}=\left\{\left|U_{w}\right|: w \in V\right\}$ the cardinality is

$$
\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)\right|=\left(\frac{(z+d-1)!}{z!(d-1)!}\right)^{n}
$$

The average cardinality of the integral iso-independents is

$$
\frac{\left|\mathcal{A}_{U,, \mathrm{i}, V, z}\right|}{\left|\operatorname{ran}\left(Y_{U, i, V, z}\right)\right|}=\frac{(z+v-1)!}{z!(v-1)!} / \prod_{w \in V} \frac{\left(z+\left|U_{w}\right|-1\right)!}{z!\left(\left|U_{w}\right|-1\right)!}
$$

The average cardinality of the integral iso-independents varies with both size, $z$, and volume, $v$. For a given volume, $v$, the average cardinality of the integral iso-independents varies with the entropy of the valencies, entropy $\left(\left\{\left(w,\left|U_{w}\right|\right): w \in V\right\}\right)$. Thus the average cardinality of the integral iso-independents tends to increase with dimension, $n=|V|$. Regular histograms tend to have higher average cardinality than irregular.

Integral iso-independents sets cannot be singletons of a non-independent histogram, $A \neq A^{\mathrm{X}} \Longrightarrow Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right) \neq\{A\}$. Thus $A \neq A^{\mathrm{X}} \Longrightarrow$ $\left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|>1$. Integral iso-independents sets are singletons only if no more than one of its perimeter histograms is not an effective singleton, $\mid\{w$ : $\left.w \in V,\left|\left(A^{\mathrm{X}} \%\{w\}\right)^{\mathrm{F}}\right|>1\right\} \mid \leq 1 \Longleftrightarrow Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)=\left\{A^{\mathrm{X}}\right\}$.

Given any integral subset of the substrate histograms $I \subseteq \mathcal{A}_{U, \mathrm{i}, V, z}$ that contains the histogram $A \in I$, the degree to which the subset is said to be aligned-like is called the iso-independence. The iso-independence is defined as the ratio of (i) the cardinality of the intersection between the integral substrate histograms subset and the set of integral iso-independents, and (ii) the cardinality of the union,

$$
\frac{1}{\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right|} \leq \frac{\left|I \cap Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|I \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|} \leq 1
$$

If the iso-independence is low, for example in the case of the integral substrate histograms, $I=\mathcal{A}_{U, i, V, z}$, the subset is said to be classical-like. If the isoindependence is high, for example in the case of the integral iso-independents, $I=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, the subset is said to be aligned-like.

Let histogram $A \in \mathcal{A}_{U, V, z}$ be in system $U$ and have variables $V$ and size $z$. Consider the iso-independents given some one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ where $\operatorname{und}(T)=V$. Let $W=\operatorname{der}(T)$. Let the formal-valued function of the substrate histograms $Y_{U, T, \mathrm{~V}, z} \in \mathcal{A}_{U, V, z} \rightarrow \mathcal{A}_{U, W, z}$ be defined

$$
Y_{U, T, \mathrm{~V}, z}=\left\{\left(A, A^{\mathrm{X}} * T\right): A \in \mathcal{A}_{U, V, z}\right\}
$$

Note that $Y_{U, T, \mathrm{~V}, z}$ is not a subset of the independent function, $Y_{U, T, \mathrm{~V}, z} \cap$ independent $=\emptyset$. The infinite set of iso-formals of $A^{\mathrm{X}} * T$ is

$$
\operatorname{inverse}\left(Y_{U, T, \mathrm{~V}, z}\right)\left(A^{\mathrm{X}} * T\right)=\left\{B: B \in \mathcal{A}_{U, V, z}, B^{\mathrm{X}} * T=A^{\mathrm{X}} * T\right\}
$$

Iso-formals have the same formal histogram, $\forall B \in Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)\left(B^{\mathrm{X}} * T=\right.$ $\left.A^{\mathrm{X}} * T\right)$. The equivalence classes implied by $Y_{U, T, \mathrm{~V}, z}$ partition the complete congruent histograms, $\operatorname{ran}\left(Y_{U, T, \mathrm{~V}, z}^{-1}\right) \in \mathrm{B}\left(\mathcal{A}_{U, V, z}\right)$. The equivalence classes implied by $Y_{U, T, \mathrm{~V}, z}$ form a parent partition of equivalence classes implied by the subset of the independent function $Y_{U, V, z}, \operatorname{parent}\left(\operatorname{ran}\left(Y_{U, T, V, z}^{-1}\right), \operatorname{ran}\left(Y_{U, V, z}^{-1}\right)\right)$, so that $Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right) \subseteq Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)$. Thus both the histogram and its independent are iso-formals, $A, A^{\mathrm{X}} \in Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)$. The iso-formals is a superset of the iso-independents, $Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \supseteq Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, so the isoindependence, or degree of aligned-likeness, is

$$
\frac{\left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|}{\left|Y_{U, \mathbf{i}, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{x}} * T\right)\right|}
$$

In the case where the transform is a substrate transform, $T \in \mathcal{T}_{U, V}$, and the formal is independent, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, the iso-formals can be written in terms of the partition variables,

$$
\begin{aligned}
& A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}} \Longrightarrow \\
& \quad Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)=\left\{B: B \in \mathcal{A}_{U, V, z}, \forall P \in W\left(B^{\mathrm{X}} * P^{\mathrm{T}}=A^{\mathrm{x}} * P^{\mathrm{T}}\right)\right\}
\end{aligned}
$$

This is the case if the transform is non-overlapping, $\neg \operatorname{overlap}(T) \Longrightarrow A^{\mathrm{X}} *$ $T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$.

Let the formal independent-valued function of the substrate histograms $Y_{U, T, \mathrm{~V}, \mathrm{x}, z} \in \mathcal{A}_{U, V, z} \rightarrow \mathcal{A}_{U, W, z}$ be defined

$$
Y_{U, T, \mathrm{~V}, \mathrm{x}, z}=\left\{\left(A,\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right): A \in \mathcal{A}_{U, V, z}\right\}
$$

The infinite set of iso-formal-independents of $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$ is

$$
\operatorname{inverse}\left(Y_{U, T, \mathrm{~V}, \mathrm{x}, z}\right)\left(\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}\right)=\left\{B: B \in \mathcal{A}_{U, V, z},\left(B^{\mathrm{x}} * T\right)^{\mathrm{x}}=\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}\right\}
$$

Iso-formal-independents have the same formal independent, $\forall B \in Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{x}} *\right.\right.$ $\left.T)^{\mathrm{X}}\right)\left(\left(B^{\mathrm{X}} * T\right)^{\mathrm{X}}=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right)$. The equivalence classes implied by $Y_{U, T, \mathrm{~V}, \mathrm{x}, z}$ partition the complete congruent histograms, $\operatorname{ran}\left(Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\right) \in \mathrm{B}\left(\mathcal{A}_{U, V, z}\right)$. The equivalence classes implied by $Y_{U, T, \mathrm{~V}, \mathrm{x}, z}$ form a parent partition of equivalence classes implied by the subset of the formal function $Y_{U, T, \mathrm{~V}, z}$,

$$
\operatorname{parent}\left(\operatorname{ran}\left(Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\right), \operatorname{ran}\left(Y_{U, T, \mathrm{~V}, z}^{-1}\right)\right)
$$

so that $Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right) \subseteq Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \subseteq Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right)$. Thus both the histogram and its independent are iso-formal-independents, $A, A^{\mathrm{X}} \in$ $Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right)$. The iso-independence of the integral iso-formal independents is less than or equal to the iso-independence of the integral iso-formals, $\left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right| /\left|Y_{U, \mathrm{i}, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right)\right| \leq\left|Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right| /\left|Y_{U, i, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)\right|$.

In the case where the transform is a substrate transform, $T \in \mathcal{T}_{U, V}$, the iso-formal-independents equals the subset of the substrate histograms having the same set of partition formals,
$Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}}\right)=\left\{B: B \in \mathcal{A}_{U, V, z}, \forall P \in W\left(B^{\mathrm{X}} * P^{\mathrm{T}}=A^{\mathrm{X}} * P^{\mathrm{T}}\right)\right\}$
In fact the iso-partition-formal sets are bijective to the iso-formal-independents sets,

$$
\left\{\left\{A^{\mathrm{x}} * P^{\mathrm{T}}: P \in W\right\}: A \in \mathcal{A}_{U, V, z}\right\} \quad: \leftrightarrow: \quad \operatorname{ran}\left(Y_{U, T, \mathrm{~V}, \mathrm{x}, z}\right)
$$

Similarly to the definition of the iso-formals, let the abstract-valued function of the substrate histograms $Y_{U, T, \mathrm{~W}, z} \in \mathcal{A}_{U, V, z} \rightarrow \mathcal{A}_{U, W, z}$ be defined

$$
Y_{U, T, \mathrm{~W}, z}=\left\{\left(A,(A * T)^{\mathrm{X}}\right): A \in \mathcal{A}_{U, V, z}\right\}
$$

The infinite set of iso-abstracts of $(A * T)^{\mathrm{X}}$ is

$$
\text { inverse }\left(Y_{U, T, \mathrm{~W}, z}\right)\left((A * T)^{\mathrm{x}}\right)=\left\{B: B \in \mathcal{A}_{U, V, z},(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}\right\}
$$

Iso-abstracts have the same abstract histogram, $\forall B \in Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)((B *$ $\left.T)^{\mathrm{X}}=(A * T)^{\mathrm{X}}\right)$. The equivalence classes implied by $Y_{U, T, \mathrm{~W}, z}$ partition the complete congruent histograms, $\operatorname{ran}\left(Y_{U, T, \mathrm{~W}, z}^{-1}\right) \in \mathrm{B}\left(\mathcal{A}_{U, V, z}\right)$. The lifted isoabstracts is a subset of the iso-independents of the derived,

$$
\left\{B * T: B \in Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right\} \subseteq Y_{U, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)
$$

If the transform is non-overlapping then the lifted iso-abstracts equals the derived iso-independents

$$
\neg \operatorname{overlap}(T) \Longrightarrow\left\{B * T: B \in Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right\}=Y_{U, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)
$$

because the transform is right total when non-overlapping, $(X \% W)^{\mathrm{F}}=W^{\mathrm{C}}$ where $(X, W)=T$.

The derived iso-independence of the integral lifted iso-abstracts is

$$
\frac{\left|\left\{B * T: B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right\}\right|}{\left.\mid Y_{U, \mathrm{i}, \mathrm{i}, \mathrm{i}, z}^{-1}(A * T)^{\mathrm{X}}\right) \mid}
$$

The histogram is an iso-abstract, $A \in Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$. If the formal independent histogram equals the abstract histogram, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$, then the independent is an iso-abstract,

$$
\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}=(A * T)^{\mathrm{x}} \Longrightarrow A^{\mathrm{x}} \in Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)
$$

This is also the case if the formal histogram equals the abstract histogram

$$
\left(A^{\mathrm{X}} * T\right)=(A * T)^{\mathrm{x}} \Longrightarrow A^{\mathrm{x}} \in Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)
$$

In the case where the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, and an integral isoabstract, $A^{\mathrm{X}} \in Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$, the iso-independence of the iso-abstracts,

$$
\frac{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}
$$

is greater than would otherwise be the case because the independent is in the intersection, $A^{\mathrm{X}} \in Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$.

In the case where the transform is a substrate transform, $T \in \mathcal{T}_{U, V}$, the set of iso-abstracts can be written in terms of the partition variables,

$$
\begin{aligned}
Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) & =\left\{B: B \in \mathcal{A}_{U, V, z}, \forall P \in W\left(B * P^{\mathrm{T}}=A * P^{\mathrm{T}}\right)\right\} \\
& =\bigcap_{P \in W} D_{U, P^{\mathrm{T}}, z}^{-1}\left(A * P^{\mathrm{T}}\right)
\end{aligned}
$$

where $D_{U, T, z}^{-1}(A * T)$ is the set of iso-deriveds, defined below.
In fact the iso-partition-derived sets are bijective to the iso-abstract sets,

$$
\left\{\left\{A * P^{\mathrm{T}}: P \in W\right\}: A \in \mathcal{A}_{U, V, z}\right\} \quad: \leftrightarrow: \quad \operatorname{ran}\left(Y_{U, T, \mathrm{~W}, z}\right)
$$

For this reason, all subsets of the iso-abstracts that include the histogram,

$$
\left\{I: I \subseteq Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right), A \in I\right\}
$$

are called entity-like iso-sets of the histogram, A.

The lifted iso-sets of all entity-like integral iso-sets are subsets of the integral iso-independents of the derived,

$$
\{B * T: B \in I\} \subseteq Y_{U, i, W, z}^{-1}\left((A * T)^{\mathrm{x}}\right)
$$

where $I \subseteq Y_{U,, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$ and $A \in I$. So the derived iso-independence is

$$
\frac{|\{B * T: B \in I\}|}{\left|Y_{U, i, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
$$

In some cases the derived iso-independence of entity-like integral iso-sets may be greater than the iso-independence,

$$
\frac{|\{B * T: B \in I\}|}{\left|Y_{U, i, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|} \geq \frac{\left|I \cap Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|}{\left|I \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}
$$

because the lifted iso-sets of entity-like integral iso-sets are subsets of the derived iso-independents, $\{B * T: B \in I\} \subseteq Y_{U, i, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$, and not just intersections.

The degree to which an integral iso-set $I \subseteq \mathcal{A}_{U, \mathrm{i}, V, z}$ that contains the histogram, $A \in I$, is said to be entity-like is called the iso-abstractence. The iso-abstractence is defined as the ratio of (i) the cardinality of the intersection between the integral iso-set and the set of integral iso-abstracts, and (ii) the cardinality of the union,

$$
\frac{1}{\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right|} \leq \frac{\left|I \cap Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}{\left|I \cup Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|} \leq 1
$$

Consider the iso-deriveds subset of the iso-abstracts. Let the derivedvalued function of the substrate histograms $D_{U, T, z} \in \mathcal{A}_{U, V, z} \rightarrow \mathcal{A}_{U, W, z}$ be defined

$$
D_{U, T, z}=\left\{(A, A * T): A \in \mathcal{A}_{U, V, z}\right\}
$$

The infinite set of iso-deriveds of $A * T$ is

$$
\operatorname{inverse}\left(D_{U, T, z}\right)(A * T)=\left\{B: B \in \mathcal{A}_{U, V, z}, B * T=A * T\right\}
$$

The set of equivalence classes implied by $D_{U, T, z}$ is a child partition of the set of equivalence classes implied by $Y_{U, T, \mathrm{~W}, z}, \operatorname{parent}\left(\operatorname{ran}\left(Y_{U, T, \mathrm{~W}, z}^{-1}\right), \operatorname{ran}\left(D_{U, T, z}^{-1}\right)\right)$. The lifted iso-deriveds is a singleton, $\left\{B * T: B \in D_{U, T, z}^{-1}(A * T)\right\}=\{A * T\}$. The naturalisation is in the iso-deriveds, $A * T * T^{\dagger} \in D_{U, T, z}^{-1}(A * T)$, because the derived of the naturalisation equals the derived, $\left(A * T * T^{\dagger}\right) * T=A * T$. The iso-deriveds might equally well be called the iso-naturalisations, since all have the same naturalisation, $\forall B \in D_{U, T, z}^{-1}(A * T)\left(B * T * T^{\dagger}=A * T * T^{\dagger}\right)$.

The iso-abstractence or degree of entity-likeness is

$$
\frac{\left|D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right|}{\left|Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right|} \leq 1
$$

All subsets of the iso-derived that include the histogram,

$$
\left\{I: I \subseteq D_{U, T, z}^{-1}(A * T), A \in I\right\}
$$

are called law-like iso-sets of the histogram, A. All law-like iso-sets are entitylike iso-sets, $D_{U, T, z}^{-1}(A * T) \subseteq Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$.

The iso-independence of the integral iso-derived is

$$
\frac{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T) \cap Y_{U U, \mathrm{i}, z}^{-1}\left(A^{\mathrm{x}}\right)\right|}{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}
$$

The lifted iso-set of any law-like iso-set is a singleton of the derived, $\{A * T\}$, so the derived iso-independence of the integral lifted iso-derived is

$$
\frac{1}{\left|Y_{U, i, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
$$

The degree to which an integral iso-set $I \subseteq \mathcal{A}_{U, \mathrm{i}, V, z}$ that contains the histogram, $A \in I$, is said to be law-like is called the iso-derivedence. The
iso-derivedence is defined as the ratio of (i) the cardinality of the intersection between the integral iso-set and the set of integral iso-deriveds, and (ii) the cardinality of the union,

$$
\frac{1}{\left|\mathcal{A}_{U, i, V, z}\right|} \leq \frac{\left|I \cap D_{U U, i, T, z}^{-1}(A * T)\right|}{\left|I \cup D_{U, i, T, z}^{-1}(A * T)\right|} \leq 1
$$

The iso-derivedence of the iso-abstracts equals the iso-abstractence of the iso-deriveds,

$$
\frac{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
$$

That is, the iso-deriveds is as entity-like as the iso-abstracts is law-like.
In the case where (i) the transform is a substrate transform, $T \in \mathcal{T}_{U, V}$, and (ii) the derived is independent, and so equals the abstract, $A * T=(A * T)^{\mathrm{X}}$, the set of iso-deriveds equals the set of iso-partition-deriveds and so equals the set of iso-abstracts,

$$
\begin{aligned}
D_{U, T, z}^{-1}(A * T) & =D_{U, T, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \\
& =\bigcap_{P \in W} D_{U, P^{\mathrm{T}}, z}^{-1}\left(A * P^{\mathrm{T}}\right) \\
& =Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)
\end{aligned}
$$

So in this case the iso-abstractence, or degree of entity-likeness, of the integral iso-deriveds is maximal.

In fact the iso-deriveds equals the iso-abstracts if and only if the derived is independent,

$$
A * T=(A * T)^{\mathrm{x}} \Longleftrightarrow D_{U, T, z}^{-1}(A * T)=Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)
$$

So if the derived is not independent, the iso-deriveds is a proper subset of the iso-abstracts,

$$
A * T \neq(A * T)^{\mathrm{x}} \Longrightarrow D_{U, T, z}^{-1}(A * T) \subset Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)
$$

and the iso-abstractence of the integral iso-deriveds is sub-maximal,

$$
A * T \neq(A * T)^{\mathrm{X}} \Longrightarrow \frac{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}<1
$$

The cardinality of the set of integral iso-deriveds is the product of the weak compositions of the components,

$$
\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|=\prod_{(R, C) \in T^{-1}} \frac{\left((A * T)_{R}+|C|-1\right)!}{(A * T)_{R}!(|C|-1)!}
$$

The cardinality of the set of integral iso-abstracts is constrained,
$\forall P \in W\left(\left|Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right| \leq \prod_{(R, C) \in\left(P^{\mathrm{T}}\right)^{-1}} \frac{\left(\left(A * P^{\mathrm{T}}\right)_{R}+|C|-1\right)!}{\left(A * P^{\mathrm{T}}\right)_{R}!(|C|-1)!}\right)$
In the case where the derived is independent, $A * T=(A * T)^{\mathrm{X}}$, the cardinality of the set of integral iso-abstracts can also be stated explicitly,

$$
\left|Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|=\prod_{(R, C) \in T^{-1}} \frac{\left((A * T)_{R}^{\mathrm{X}}+|C|-1\right)!}{(A * T)_{R}^{\mathrm{X}}!(|C|-1)!}
$$

Corresponding to the derived valued function of the substrate histograms, $D_{U, T, z}$, the normalised components valued function of the substrate histograms is $C_{U, T, z} \in \mathcal{A}_{U, V, z} \rightarrow \mathrm{P}\left(\mathcal{A}_{U, V, z}\right)$, defined

$$
C_{U, T, z}=\left\{\left(A,\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right): A \in \mathcal{A}_{U, V, z}\right\}
$$

where ()$^{\wedge} \in \mathcal{A} \rightarrow \mathcal{A}$ is defined $\hat{A}:=\operatorname{normalise}(A)$ if $\operatorname{size}(A)>0$ otherwise $\hat{A}:=A$, and $T^{-1}:=\operatorname{inverse}(T)$. The infinite set of iso-components of $\{(A *$ $\left.\left.C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}$ is

$$
\begin{aligned}
& \text { inverse }\left(C_{U, T, z}\right)\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right)= \\
& \quad\left\{B: B \in \mathcal{A}_{U, V, z}, \forall C \in T^{\mathrm{P}}\left(\left(B * C^{\mathrm{U}}\right)^{\wedge}=\left(A * C^{\mathrm{U}}\right)^{\wedge}\right)\right\}
\end{aligned}
$$

The unnaturalisation is in the iso-components, $V_{z}^{\mathrm{C}} * T * T^{\odot A} \in C_{U, T, z}^{-1}(\{(A *$ $\left.\left.\left.C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right)$. The iso-components might equally well be called the isounnaturalisations, since all have the same unnaturalisation, $\forall B \in C_{U, T, z}^{-1}(\{(A *$ $\left.\left.\left.C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right)\left(V_{z}^{\mathrm{C}} * T * T^{\odot B}=V_{z}^{\mathrm{C}} * T * T^{\odot A}\right)$.

The normalised components of the independent valued function of the substrate histograms is $C_{U, \mathbf{x}, T, z} \in \mathcal{A}_{U, V, z} \rightarrow \mathrm{P}\left(\mathcal{A}_{U, V, z}\right)$, defined

$$
C_{U, \mathbf{x}, T, z}=\left\{\left(A,\left\{\left(A^{\mathrm{X}} * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right): A \in \mathcal{A}_{U, V, z}\right\}
$$

The infinite set of iso-independent-components of $\left\{\left(A^{\mathrm{X}} * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}$ is

$$
\begin{aligned}
& \operatorname{inverse}\left(C_{U, \mathrm{x}, T, z}\right)\left(\left\{\left(A^{\mathrm{X}} * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right)= \\
& \quad\left\{B: B \in \mathcal{A}_{U, V, z}, \forall C \in T^{\mathrm{P}}\left(\left(B^{\mathrm{X}} * C^{\mathrm{U}}\right)^{\wedge}=\left(A^{\mathrm{X}} * C^{\mathrm{U}}\right)^{\wedge}\right)\right\}
\end{aligned}
$$

The normalised independent components valued function of the substrate histograms is $C_{U, T, \mathrm{x}, z} \in \mathcal{A}_{U, V, z} \rightarrow \mathrm{P}\left(\mathcal{A}_{U, V, z}\right)$, defined

$$
C_{U, T, \mathrm{x}, z}=\left\{\left(A,\left\{\left(A * C^{\mathrm{U}}\right)^{\mathrm{x} \wedge}: C \in T^{\mathrm{P}}\right\}\right): A \in \mathcal{A}_{U, V, z}\right\}
$$

The infinite set of iso-component-independents of $\left\{\left(A * C^{\mathrm{U}}\right)^{\mathrm{X} \wedge}: C \in T^{\mathrm{P}}\right\}$ is

$$
\begin{aligned}
& \operatorname{inverse}\left(C_{U, T, \mathrm{x}, z}\right)\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\mathrm{x} \wedge}: C \in T^{\mathrm{P}}\right\}\right)= \\
& \quad\left\{B: B \in \mathcal{A}_{U, V, z}, \forall C \in T^{\mathrm{P}}\left(\left(B * C^{\mathrm{U}}\right)^{\mathrm{x} \wedge}=\left(A * C^{\mathrm{U}}\right)^{\mathrm{x} \wedge}\right)\right\}
\end{aligned}
$$

Now consider the iso-formals and the iso-abstracts together. Let the formal-abstract pair valued function of the substrate histograms $Y_{U, T, z} \in$ $\mathcal{A}_{U, V, z} \rightarrow\left(\mathcal{A}_{U, W, z} \times \mathcal{A}_{U, W, z}\right)$ be defined

$$
Y_{U, T, z}=\left\{\left(A,\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right): A \in \mathcal{A}_{U, V, z}\right\}
$$

The infinite set of iso-transform-independents of $\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)$ is

$$
\begin{aligned}
& \text { inverse }\left(Y_{U, T, z}\right)\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)= \\
& \quad\left\{B: B \in \mathcal{A}_{U, V, z}, B^{\mathrm{X}} * T=A^{\mathrm{x}} * T,(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}\right\}
\end{aligned}
$$

Iso-transform-independents have (i) the same formal histogram and (ii) the same abstract histogram, $\forall B \in Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\left(\left(B^{\mathrm{X}} * T=A^{\mathrm{X}} *\right.\right.$ $\left.T) \wedge\left((B * T)^{\mathrm{X}}=(A * T)^{\mathrm{X}}\right)\right)$. The formal histogram, $A^{\mathrm{X}} * T$, is not necessarily equal to the abstract histogram, $(A * T)^{\mathrm{X}}$. The equivalence classes implied by $Y_{U, T, z}$ partition the complete congruent histograms, $\operatorname{ran}\left(Y_{U, T, z}^{-1}\right) \in \mathrm{B}\left(\mathcal{A}_{U, V, z}\right)$. The equivalence classes implied by both $Y_{U, T, \mathrm{~V}, z}$ and $Y_{U, T, \mathrm{~W}, z}$ form parent partitions of the partition implied by $Y_{U, T, z}, \operatorname{parent}\left(\operatorname{ran}\left(Y_{U, T, \mathrm{~V}, z}^{-1}\right), \operatorname{ran}\left(Y_{U, T, z}^{-1}\right)\right)$ and $\operatorname{parent}\left(\operatorname{ran}\left(Y_{U, T, \mathrm{~W}, z}^{-1}\right), \operatorname{ran}\left(Y_{U, T, z}^{-1}\right)\right)$. So the set of iso-transform-independents is the intersection of the iso-formals and iso-abstracts

$$
Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{x}}\right)\right)=Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{x}} * T\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)
$$

The histogram is an iso-transform-independent, $A \in Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A *\right.\right.$ $\left.T)^{\mathrm{X}}\right)$ ).

The idealisation of the histogram with the given transform, $A * T * T^{\dagger A}$, is also in the iso-transform-independents, $A * T * T^{\dagger A} \in Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)$. This is because (i) the idealisation is in the iso-abstracts, $A * T * T^{\dagger A} * T=$ $A * T \Longrightarrow\left(A * T * T^{\dagger A} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$, and (ii) idealisation is in the iso-formals, $\left(A * T * T^{\dagger A}\right)^{\mathrm{X}}=A^{\mathrm{X}} \Longrightarrow\left(A * T * T^{\dagger A}\right)^{\mathrm{X}} * T=A^{\mathrm{X}} * T$.

The set of iso-transform-independents is a subset of the iso-abstracts, so it is an entity-like iso-set of the histogram, A,

$$
Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{x}}\right)\right) \subseteq Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)
$$

The iso-abstractence or degree of entity-likeness is

$$
\frac{\left|Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{x}}\right)\right)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right|} \leq 1
$$

The set of iso-transform-independents is not necessarily more entity-like than the iso-deriveds, which has an iso-abstractence of

$$
\frac{\left|D_{U, i, T, z}^{-1}(A * T)\right|}{\left|Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
$$

because the iso-transform-independents is not necessarily a superset of the iso-deriveds, $\left|D_{U, i, T, z}^{-1}(A * T) \backslash Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right| \geq 0$.

The iso-derivedence or degree of law-likeness is

$$
\begin{aligned}
& \frac{\left|Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{x}}\right)\right) \cap D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}{\left|Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cup D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}= \\
& \\
& \quad \frac{\left|Y_{U, \mathrm{i}, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{x}} * T\right) \cap D_{U U, \mathrm{i}, T, z}^{-1}(A * T)\right|}{\left|\left(Y_{U, \mathrm{i}, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cup D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right) \cap Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
\end{aligned}
$$

So the set of iso-transform-independents is not necessarily more law-like than the iso-abstracts, which has an iso-derivedence of

$$
\frac{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right|}
$$

The set of iso-transform-independents is entity-like so the lifted iso-transformindependents is a subset of the iso-independents of the derived,

$$
\begin{aligned}
\left\{B * T: B \in Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right)\right.\right.\right. & \left.\left.\left.(A * T)^{\mathrm{X}}\right)\right)\right\} \\
& \subseteq\left\{B * T: B \in Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right\} \\
& \subseteq Y_{U, W, z}^{-1}\left((A * T)^{\mathrm{x}}\right)
\end{aligned}
$$

So the derived iso-independence of the integral lifted iso-transform-independents is

$$
\frac{\left|\left\{B * T: B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right\}\right|}{\left|Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
$$

The derived iso-independence of the integral lifted iso-transform-independents is less than or equal to the derived iso-independence of the integral lifted isoabstracts,

$$
\begin{aligned}
& \frac{\left|\left\{B * T: B \in Y_{U U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right\}\right|}{\left|Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|} \leq \\
& \frac{\left|\left\{B * T: B \in Y_{U \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right\}\right|}{\left|Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
\end{aligned}
$$

The iso-independence of the iso-transform-independents is

$$
\begin{aligned}
& \frac{\left|Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cap Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}= \\
& \frac{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|\left(Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right) \cap Y_{U, \mathrm{i}, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)\right|}
\end{aligned}
$$

So the set of iso-transform-independents is not necessarily more aligned-like than the iso-formals, which has an iso-independence of

$$
\frac{\left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|}{\left|Y_{U, i, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)\right|}
$$

depending on the relative intersection cardinality.
If the formal independent histogram equals the abstract histogram then the independent is an iso-abstract, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}} \Longrightarrow A^{\mathrm{X}} \in Y_{U, T, \mathrm{~W}, z}^{-1}((A *$ $T)^{\mathrm{X}}$ ), and hence is an iso-transform-independent,

$$
\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}}=(A * T)^{\mathrm{x}} \Longrightarrow A^{\mathrm{X}} \in Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{x}}\right)\right)
$$

This is also the case where the formal histogram equals the abstract histogram,

$$
A^{\mathrm{x}} * T=(A * T)^{\mathrm{x}} \Longrightarrow A^{\mathrm{x}} \in Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{X}}\right)\right)
$$

In the case where the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, and an integral iso-transform-independent, $A^{\mathrm{X}} \in Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)$, the iso-independence of the iso-transform-independents,

$$
\frac{\left|Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|}{\left|Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|}
$$

is greater than would otherwise be the case because the independent is in the intersection, $A^{\mathrm{X}} \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cap Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$.

If the formal histogram equals the abstract histogram then the lifted iso-transform-independents contains the abstract histogram

$$
(A * T)^{\mathrm{x}}=A^{\mathrm{x}} * T \in\left\{B * T: B \in Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right\}
$$

In this case, if the abstract is also integral, $(A * T)^{\mathrm{X}} \in \mathcal{A}_{\mathbf{i}}$, the derived isoindependence of the iso-transform-independents,

$$
\frac{\left|\left\{B * T: B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right\}\right|}{\left|Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
$$

is greater than would otherwise be the case because the abstract is in the intersection, $(A * T)^{\mathrm{X}} \in\left\{B * T: B \in Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right\} \cap Y_{U, i, W, z}^{-1}((A *$ $T)^{\mathrm{X}}$.

Note that it is only in the subset where the formal histogram equals the $a b$ stract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, that the lifted iso-transform-independent relation is functional

$$
\begin{aligned}
& \left\{\left(A * T,\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{x}}\right)\right): A \in \mathcal{A}_{U, V, z}, A^{\mathrm{x}} * T=(A * T)^{\mathrm{x}}\right\} \\
\in & \mathcal{A}_{U, W, z} \rightarrow\left(\mathcal{A}_{U, W, z} \times \mathcal{A}_{U, W, z}\right)
\end{aligned}
$$

That is, the lifted iso-transform-independent sets do not partition the complete congruent histograms in the derived variables
$\operatorname{ran}\left(\left\{\left(A * T,\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right):\left(A,\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \in Y_{U, T, z}\right\}^{-1}\right) \notin \mathrm{B}\left(\mathcal{A}_{U, W, z}\right)$
except where the formal histogram equals the abstract histogram

$$
\begin{aligned}
& \operatorname{ran}\left(\left\{\left(A * T,\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right):\right.\right. \\
&\left.\left.\left(A,\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \in Y_{U, T, z}, A^{\mathrm{x}} * T=(A * T)^{\mathrm{x}}\right\}^{-1}\right) \\
& \in \quad \mathrm{B}\left(\left\{B * T: B \in \mathcal{A}_{U, V, z}, B^{\mathrm{X}} * T=(B * T)^{\mathrm{X}}\right\}\right)
\end{aligned}
$$

Similarly it is only in the subset where the formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, that the formal domained relation of the iso-transform-independents is functional

$$
\begin{aligned}
& \left\{\left(A^{\mathrm{X}} * T,\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right): A \in \mathcal{A}_{U, V, z}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right\} \\
\in & \mathcal{A}_{U, W, z} \rightarrow\left(\mathcal{A}_{U, W, z} \times \mathcal{A}_{U, W, z}\right)
\end{aligned}
$$

If the transform is a self partition transform, $T=V^{\mathrm{CS}\{ \} \mathrm{T}}$, or it is value full functional, $T=\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in V\right\}^{\mathrm{T}}$, then the set of iso-transformindependents equals the set of iso-independents in the underlying variables, $Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)=Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)$. In this case the iso-independence is maximised and the iso-transform-independents is aligned-like.

If the transform is a unary partition, $T^{\mathrm{P}}=\left\{V^{\mathrm{CS}}\right\}$, then the set of iso-transform-independents equals the set of complete congruent histograms in the underlying variables, $Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)=\mathcal{A}_{U, V, z} . \quad$ In this case the iso-independence is minimised and the iso-transform-independents is classical-like.

In the case where the transform is a substrate transform, $T \in \mathcal{T}_{U, V}$, and the formal is independent, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, the iso-transform-independents can be written in terms of the partition variables,

$$
\begin{aligned}
& A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}} \Longrightarrow \\
& Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)=\left\{B: B \in \mathcal{A}_{U, V, z},\right. \\
& \left.\quad \forall P \in W\left(B^{\mathrm{X}} * P^{\mathrm{T}}=A^{\mathrm{X}} * P^{\mathrm{T}} \wedge B * P^{\mathrm{T}}=A * P^{\mathrm{T}}\right)\right\}
\end{aligned}
$$

In the stricter case where the formal equals the abstract, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, this is,

$$
\begin{aligned}
& A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}} \Longrightarrow \\
& \quad Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)=\left\{B: B \in \mathcal{A}_{U, V, z}\right. \\
& \left.\quad \forall P \in W\left(B^{\mathrm{X}} * P^{\mathrm{T}}=A^{\mathrm{X}} * P^{\mathrm{T}}=B * P^{\mathrm{T}}=A * P^{\mathrm{T}}\right)\right\}
\end{aligned}
$$

because $\forall P \in W\left(A * P^{\mathrm{T}}=A^{\mathrm{X}} * P^{\mathrm{T}}\right)$.

The set of iso-partition-independents is the intersection of the iso-formalindependents and iso-abstracts

$$
Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)
$$

In the case where the transform is a substrate transform, $T \in \mathcal{T}_{U, V}$, each iso-partition-independent has the same set of partition formals and partition deriveds,

$$
\begin{aligned}
& \forall B \in Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \\
& \quad \forall P \in W\left(B^{\mathrm{X}} * P^{\mathrm{T}}=A^{\mathrm{X}} * P^{\mathrm{T}} \wedge B * P^{\mathrm{T}}=A * P^{\mathrm{T}}\right)
\end{aligned}
$$

In the case where the formal independent equals the abstract each of the partition transforms is formal, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}} \Longrightarrow \forall P \in W\left(A * P^{\mathrm{T}}=\right.$ $A^{\mathrm{X}} * P^{\mathrm{T}}$ ), so

$$
\begin{aligned}
& \left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}=(A * T)^{\mathrm{x}} \Longrightarrow \\
& \forall B \in Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \\
& \quad \forall P \in W\left(B^{\mathrm{x}} * P^{\mathrm{T}}=A^{\mathrm{x}} * P^{\mathrm{T}}=B * P^{\mathrm{T}}=A * P^{\mathrm{T}}\right)
\end{aligned}
$$

In this case the independent is an iso-partition-independent too,
$\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}} \Longrightarrow A^{\mathrm{X}} \in Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$
The set of iso-partition-independents is a subset of the iso-abstracts, so it is an entity-like iso-set of the histogram, A,

$$
Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \subseteq Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)
$$

The iso-transform-independents is a subset of the iso-partition-independents,

$$
\begin{aligned}
& Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \subseteq \\
& Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)
\end{aligned}
$$

The iso-abstractence of the set of iso-partition-independents is greater than or equal to the iso-abstractence of the set of iso-transform-independents

$$
\begin{aligned}
& \frac{\left|Y_{U, \mathrm{i}, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}\right) \cap Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|} \geq \\
& \frac{\left|Y_{U, \mathrm{i}, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{x}} * T\right) \cap Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right|}
\end{aligned}
$$

So the iso-partition-independents is more entity-like than the iso-transformindependents.

The set of iso-neutralisations is the intersection of the iso-independentcomponents and iso-deriveds

$$
C_{U, \mathbf{x}, T, z}^{-1}\left(\left\{\left(A^{\mathrm{X}} * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right) \cap D_{U, T, z}^{-1}(A * T)
$$

Each iso-neutralisation has the same neutralisation,
$\forall B \in C_{U, \mathrm{x}, T, z}^{-1}\left(\left\{\left(A^{\mathrm{X}} * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right) \cap D_{U, T, z}^{-1}(A * T)\left(B * T * T^{\odot B^{\mathrm{x}}}=A * T * T^{\odot A^{\mathrm{x}}}\right)$

The neutralisation is necessarily in the iso-deriveds, $A * T * T^{\odot} A^{\mathrm{x}} * T=A * T$, but not necessarily in the iso-neutralisations. In the case where the transform is formal, formal $(A, T)$, the neutralisation is in the iso-neutralisations because it is in the iso-independent-components
$A * T=A^{\mathrm{X}} * T \Longrightarrow\left\{\left(\left(A * T * T^{\odot} A^{\mathrm{x}}\right)^{\mathrm{X}} * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}=\left\{\left(A^{\mathrm{X}} * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}$
The set of iso-neutralisations is a subset of the iso-deriveds, so it is a law-like iso-set of the histogram, A,

$$
C_{U, \mathbf{x}, T, z}^{-1}\left(\left\{\left(A^{\mathrm{X}} * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right) \cap D_{U, T, z}^{-1}(A * T) \subseteq D_{U, T, z}^{-1}(A * T)
$$

The set of iso-contentisations is the intersection of the iso-components and iso-formals

$$
C_{U, T, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right) \cap Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)
$$

Each iso-contentisation has the same contentisation,
$\forall B \in C_{U, T, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right) \cap Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)\left(B^{\mathrm{X}} * T * T^{\odot B}=A^{\mathrm{X}} * T * T^{\odot A}\right)$
The contentisation is necessarily in the iso-components, $\left(A^{\mathrm{X}} * T * T^{\odot} A *\right.$ $\left.C^{\mathrm{U}}\right)^{\wedge}=\left(A * C^{\mathrm{U}}\right)^{\wedge}$, but not necessarily in the iso-contentisations. In the case where the transform is formal, formal $(A, T)$, the contentisation is in the iso-contentisations because it is in the iso-formals,

$$
A^{\mathrm{x}} * T=A * T \Longrightarrow\left(A^{\mathrm{x}} * T * T^{\odot A}\right)^{\mathrm{x}} * T=A^{\mathrm{x}} * T
$$

The set of iso-liftisations is the intersection of the iso-formals and isoderiveds

$$
Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap D_{U, T, z}^{-1}(A * T)
$$

The iso-liftisations is a subset of the iso-transform-independents which is the intersection of the iso-formals and iso-abstracts

$$
\begin{aligned}
Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap D_{U, T, z}^{-1}(A * T) & \subseteq Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \\
& =Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)
\end{aligned}
$$

In the case of formal histogram, formal $(A, T)$, the naturalisation is in the iso-liftisations,

$$
A * T=A^{\mathrm{x}} * T \Longrightarrow A * T * T^{\dagger} \in Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{x}} * T\right) \cap D_{U, T, z}^{-1}(A * T)
$$

The set of iso-liftisations is a subset of the iso-deriveds, so it is a law-like iso-set of the histogram, A,

$$
Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap D_{U, T, z}^{-1}(A * T) \subseteq D_{U, T, z}^{-1}(A * T)
$$

The iso-derivedence of the set of iso-liftisations is greater than or equal to the iso-derivedence of the set of iso-transform-independents

$$
\begin{aligned}
& \frac{\left|Y_{U, i, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}{\left|D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right|} \geq \\
& \quad \frac{\left|Y_{U, \mathbf{i}, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{x}} * T\right) \cap D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}{\left|\left(Y_{U, \mathbf{i}, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap Y_{U, \mathbf{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right) \cup D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right|}
\end{aligned}
$$

So the iso-liftisations is more law-like than the iso-transform-independents.
Let the iso-idealisation function $Y_{U, T, \dagger, z} \in \mathcal{A}_{U, V, z} \rightarrow \mathrm{P}\left(\mathcal{A}_{U, V, z}\right)$ be defined $Y_{U, T, \uparrow, z}=\left\{\left(A, A * T * T^{\dagger A}\right): A \in \mathcal{A}_{U, V, z}\right\}$. The infinite set of iso-idealisations of $A * T * T^{\dagger A}$ is

$$
\begin{aligned}
& \operatorname{inverse}\left(Y_{U, T, \dagger, z}\right)\left(A * T * T^{\dagger A}\right)= \\
& \quad\left\{B: B \in \mathcal{A}_{U, V, z}, B * T * T^{\dagger B}=A * T * T^{\dagger A}\right\}
\end{aligned}
$$

Each iso-idealisation has the same set of component independents as the given histogram $A$,

$$
\forall B \in Y_{U, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right) \forall C \in T^{\mathrm{P}}\left(\left(B * C^{\mathrm{U}}\right)^{\mathrm{x}}=\left(A * C^{\mathrm{U}}\right)^{\mathrm{x}}\right)
$$

The iso-idealisations equals the intersection of the iso-component-independents and the iso-derived,

$$
Y_{U, T, t, z}^{-1}\left(A * T * T^{\dagger A}\right)=C_{U, T, \mathrm{x}, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\mathrm{x} \wedge}: C \in T^{\mathrm{P}}\right\}\right) \cap D_{U, T, z}^{-1}(A * T)
$$

The set of iso-idealisations is a subset of the iso-deriveds, so it is a law-like iso-set of the histogram, A,

$$
Y_{U, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right) \subseteq D_{U, T, z}^{-1}(A * T)
$$

The iso-derivedence or degree of law-likeness is

$$
\frac{\left|Y_{U, i, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)\right|}{\left|D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right|} \leq 1
$$

The set of iso-idealisations is a subset of the iso-abstracts, so it is an entitylike iso-set of the histogram, A,

$$
Y_{U, T, \mathrm{t}, z}^{-1}\left(A * T * T^{\dagger A}\right) \subseteq Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)
$$

The iso-abstractence or degree of entity-likeness is less than or equal to the iso-derivedence

$$
\frac{\left|Y_{U, i, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|} \leq \frac{\left|Y_{U, \mathrm{i}, T, \mathrm{t}, z}^{-1}\left(A * T * T^{\dagger A}\right)\right|}{\left|D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right|}
$$

so the set of iso-idealisations is more law-like than entity-like.
The equivalence classes implied by $Y_{U, T, \uparrow, z}$ partition the complete congruent histograms, $\operatorname{ran}\left(Y_{U, T, \uparrow, z}^{-1}\right) \in \mathrm{B}\left(\mathcal{A}_{U, V, z}\right)$. The set of iso-idealisations is (i) the intersection of the iso-component-independents and the iso-derived which is (ii) a subset of the intersection of the iso-independents and iso-deriveds which is (iii) a subset of the iso-liftisations which is (iv) a subset of the iso-transformindependents which is (v) a subset of the iso-partition-independents which is (vi) a subset of the iso-abstracts,

$$
\begin{aligned}
Y_{U, T, \mathrm{t}, z}^{-1}\left(A * T * T^{\dagger A}\right) & =C_{U, T, \mathrm{x}, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\mathrm{X} \wedge}: C \in T^{\mathrm{P}}\right\}\right) \cap D_{U, T, z}^{-1}(A * T) \\
& \subseteq Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right) \cap D_{U, T, z}^{-1}(A * T) \\
& \subseteq Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{x}} * T\right) \cap D_{U, T, z}^{-1}(A * T) \\
& \subseteq Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{x}} * T\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \\
& \subseteq Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \\
& \subseteq Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)
\end{aligned}
$$

The lifted iso-idealisations is a singleton, $\left\{B * T: B \in Y_{U, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)\right\}=$ $\{A * T\}$.

The histogram is an iso-idealisation, $A \in Y_{U, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)$. The histogram idealisation is an iso-idealisation, $A * T * T^{\dagger A} \in Y_{U, T, \mathrm{t}, z}^{-1}\left(A * T * T^{\dagger A}\right)$.

There is a bijection between the sets of component independents and the idealisations of the histograms of the complete congruent histograms, $\left\{\left\{\left(A * C^{\mathrm{U}}\right)^{\mathrm{X}}\right.\right.$ : $\left.\left.C \in T^{\mathrm{P}}\right\}: A \in \mathcal{A}_{U, V, z}\right\}: \leftrightarrow: \operatorname{ran}\left(Y_{U, T, \uparrow, z}^{-1}\right)$.

The set of iso-idealisations is a subset of the iso-independents, $Y_{U, T, \mathrm{t}, z}^{-1}(A * T *$ $\left.T^{\dagger A}\right) \subseteq Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, so the degree to which the iso-idealisations is aligned-like,
or the iso-independence, is $\left|Y_{U, \mathrm{i}, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)\right| /\left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|$.
The iso-independence of the intersection of the iso-derived and the isoindependents is greater than or equal to the iso-independence of the isoderived,

$$
\frac{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|} \geq \frac{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}
$$

The set of iso-idealisations is a subset of the intersection of the iso-derived and the iso-independents, $Y_{U, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right) \subseteq D_{U, T, z}^{-1}(A * T) \cap Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, so in some cases the iso-independence of the iso-idealisations is greater than or equal to the iso-independence of the iso-derived,

$$
\frac{\left|Y_{U,,, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)\right|}{\left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|} \geq \frac{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}
$$

The set of iso-idealisations is also a subset of the intersection of the isoabstracts and the iso-independents, $Y_{U, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right) \subseteq Y_{U, T, \mathrm{~W}, z}^{-1}((A *$ $\left.T)^{\mathrm{X}}\right) \cap Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, so in some cases the iso-independence of the iso-idealisations is greater than or equal to the iso-independence of the iso-abstract,

$$
\frac{\left|Y_{U, i, T, \mathrm{t}, z}^{-1}\left(A * T * T^{\dagger A}\right)\right|}{\left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|} \geq \frac{\left|Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}
$$

If the transform is a self partition transform, $T=V^{\mathrm{CS}\{ \} \mathrm{T}}$, or it is value full functional, $T=\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in V\right\}^{\mathrm{T}}$, then the set of iso-idealisations equals a singleton of the histogram, $Y_{U, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)=\{A\}$. In this case the iso-idealisations is neither aligned-like nor classical-like.

If the transform is a unary partition, $T^{\mathrm{P}}=\left\{V^{\mathrm{CS}}\right\}$, then the set of isoidealisations equals the set of iso-independents in the underlying variables, $Y_{U, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)=Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)$. In this case the iso-independence is maximised and the iso-idealisations is aligned-like.

The set of iso-surrealisations is the intersection of the iso-abstracts and iso-components

$$
Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \cap C_{U, T, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right)
$$

Each iso-surrealisation has the same surrealisation,

$$
\begin{aligned}
\forall B \in Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \cap & C_{U, T, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right) \\
& \left((B * T)^{\mathrm{x}} * T^{\odot B}=(A * T)^{\mathrm{X}} * T^{\odot A}\right)
\end{aligned}
$$

The set of iso-surrealisations is a subset of the iso-abstracts, so it is an entitylike iso-set of the histogram, $A$,

$$
Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \cap C_{U, T, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right) \subseteq Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)
$$

The iso-abstractence or degree of entity-likeness is

$$
\frac{\left|C_{U, i, T, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right) \cap Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|} \leq 1
$$

Define the iso-extremes as the union of the iso-liftisations and the isosurrealisations,

$$
\begin{array}{rll}
\left(Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)\right. & \cap & \left.D_{U, T, z}^{-1}(A * T)\right) \cup \\
\left(Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right. & \cap & \left.C_{U, T, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right)\right)
\end{array}
$$

The iso-extremes are required to be members of the iso-liftisations or the isosurrealisations, but not necessarily both. So the set of iso-extremes is not, strictly speaking, an iso-set, because there is no function of the substrate histograms that implies a partition for which the set of iso-extremes is a component. The iso-extremes can be re-arranged as the intersection of (i) the union of the iso-formals and the iso-abstracts, and (ii) the union of the iso-deriveds and the iso-components,

$$
\begin{array}{rll}
\left(Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)\right. & \cup & \left.Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right) \cap \\
\left(D_{U, T, z}^{-1}(A * T)\right. & \cup & \left.C_{U, T, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right)\right)
\end{array}
$$

So, although the iso-transform-independents is the intersection of the isoformals and the iso-abstracts, the iso-extreme set is not a superset of the set of iso-transform-independents. That is, the iso-transform-independents that are neither iso-deriveds nor iso-components are not iso-extreme,

$$
\begin{aligned}
& \left(Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right) \backslash \\
& \quad\left(D_{U, T, z}^{-1}(A * T) \cup C_{U, T, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right)\right)
\end{aligned}
$$

The iso-idealisations, which is a subset of the iso-liftisations, is a subset of the iso-extremes.

The set of iso-extremes is a subset of the iso-abstracts, so it is an entitylike iso-set of the histogram, $A$,

$$
\begin{aligned}
\left(Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap\right. & \left.D_{U, T, z}^{-1}(A * T)\right) \cup \\
\left(Y _ { U , T , \mathrm { W } , z } ^ { - 1 } ( ( A * T ) ^ { \mathrm { X } } ) \cap C _ { U , T , z } ^ { - 1 } \left(\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C\right.\right.\right. & \left.\left.\left.\in T^{\mathrm{P}}\right\}\right)\right) \\
& \\
& \subseteq Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)
\end{aligned}
$$

The integral subset of the iso-transform-independents is formally defined as follows. Let $Y_{U, \mathbf{i}, T, z} \in \mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow\left(\mathcal{A}_{U, W, z} \times \mathcal{A}_{U, W, z}\right)$ be defined, $Y_{U, \mathbf{i}, T, z}=$ $\left\{\left(A,\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}$. The finite set of integral iso-transform-independents of $\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)$ is

$$
\begin{aligned}
& \operatorname{inverse}\left(Y_{U, \mathbf{i}, T, z}\right)\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)= \\
& \quad\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{X}} * T=A^{\mathrm{X}} * T,(B * T)^{\mathrm{X}}=(A * T)^{\mathrm{X}}\right\}
\end{aligned}
$$

The equivalence classes implied by $Y_{U, \mathbf{i}, T, z}$ partition the integral congruent support, $\operatorname{ran}\left(Y_{U, \mathbf{i}, T, z}^{-1}\right) \in \mathrm{B}\left(\mathcal{A}_{U, \mathrm{i}, V, z}\right)$. The histogram is an integral iso-transformindependent, $A \in Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)$. If the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, and the formal independent histogram equals the abstract histogram, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$, then the independent is an integral iso-abstract and hence an integral iso-transform-independent,
$\left(A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right) \wedge\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}\right) \Longrightarrow A^{\mathrm{X}} \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)$
The cardinality of the set of integral iso-formal sets is such that

$$
\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, T, \mathrm{~V}, z}\right)\right| \leq \prod_{w \in V} \frac{\left(z+\left|U_{w}\right|-1\right)!}{z!\left(\left|U_{w}\right|-1\right)!}
$$

The cardinality of the set of integral iso-abstract sets is

$$
\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, T, \mathrm{~W}, z}\right)\right| \leq \prod_{w \in W} \frac{\left(z+\left|U_{w}\right|-1\right)!}{z!\left(\left|U_{w}\right|-1\right)!}
$$

Therefore the cardinality of the set of integral iso-transform-independent sets is such that

$$
\left|\operatorname{ran}\left(Y_{U, \mathbf{i}, T, z}\right)\right| \leq \prod_{w \in V} \frac{\left(z+\left|U_{w}\right|-1\right)!}{z!} \times \prod_{w} \frac{\left(z+\left|U_{w}\right|-1\right)!}{z!\left(\left|U_{w}\right|-1\right)!}
$$

The cardinality of the set of integral iso-transform-independent sets is also such that

$$
\left|\operatorname{ran}\left(Y_{U, \mathbf{i}, T, z}\right)\right| \leq\left|\operatorname{dom}\left(Y_{U, \mathbf{i}, T, z}\right)\right|=\frac{(z+v-1)!}{z!(v-1)!}
$$

In the derived-valued function of the substrate histograms, $D_{U, T, z}$, the model is a transform. Now consider extending the model to (i) fuds, (ii) decompositions, and (iii) fud decompositions.

Let substrate histogram $A \in \mathcal{A}_{U, V, z}$ be in system $U$ and have variables $V$
and size $z$. Given the one functional definition set $F \in \mathcal{F}_{U, 1}$, such that $\operatorname{und}(F) \subseteq V$, let the derived set valued function of the substrate histograms $D_{U, F, z} \in \mathcal{A}_{U, V, z} \rightarrow \mathrm{P}\left(\mathcal{A}_{U}\right)$ be defined

$$
D_{U, F, z}=\left\{\left(A,\left\{A * T_{F}: T \in F\right\}\right): A \in \mathcal{A}_{U, V, z}\right\}
$$

where $T_{F}:=\operatorname{depends}(F, \operatorname{der}(T))^{\mathrm{T}}$.
The set of iso-fuds is the intersection of the iso-deriveds of each transform

$$
D_{U, F, z}^{-1}\left(\left\{A * T_{F}: T \in F\right\}\right)=\bigcap_{T \in F} D_{U, T_{F}, z}^{-1}\left(A * T_{F}\right)
$$

If the top transform exists the set of iso-fuds is a subset of the iso-deriveds, $\exists T \in F(\operatorname{der}(T)=\operatorname{der}(F)) \Longrightarrow D_{U, F, z}^{-1}\left(\left\{A * T_{F}: T \in F\right\}\right) \subseteq D_{U, F \mathrm{~T}, z}^{-1}\left(A * F^{\mathrm{T}}\right)$

In this case the set of iso-fuds is law-like with an iso-derivedence of

$$
\frac{\left|D_{U, \mathrm{i}, F, z}^{-1}\left(\left\{A * T_{F}: T \in F\right\}\right)\right|}{\left|D_{U, \mathrm{i}, F^{\mathrm{T}}, z}^{-1}\left(A * F^{\mathrm{T}}\right)\right|}
$$

In the case where the $f u d$ is a singleton, $F=\{T\}$, the iso-fuds equals the iso-deriveds,

$$
D_{U,\{T\}, z}^{-1}(\{A * T\})=D_{U, T, z}^{-1}(A * T)
$$

and the iso-fuds is maximally law-like.
The set of iso-fuds is a subset of the iso-abstracts,

$$
D_{U, F, z}^{-1}\left(\left\{A * T_{F}: T \in F\right\}\right) \subseteq Y_{U, F}^{-1}, \mathrm{~W}, z\left(\left(A * F^{\mathrm{T}}\right)^{\mathrm{x}}\right)
$$

so the set of iso-fuds is entity-like with an iso-abstractence of

$$
\frac{\left|D_{U, \mathbf{i}, F, z}^{-1}\left(\left\{A * T_{F}: T \in F\right\}\right)\right|}{\left|Y_{U, \mathrm{i}, F^{\mathrm{T}}, \mathrm{~W}, z}^{-1}\left(\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}\right)\right|}
$$

In the case where the fud consists of a single layer of partition transforms, $F \in \mathcal{F}_{U, \mathrm{P}}$ such that $|\operatorname{der}(F)|=|F|$, the iso-fuds equals the iso-abstracts, which is the intersection of the iso-deriveds of the partition transforms,

$$
\begin{aligned}
D_{U, F, z}^{-1}\left(D_{U, F, z}(A)\right) & =Y_{U, F^{\mathrm{T}}, \mathrm{~W}, z}^{-1}\left(\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}\right) \\
& =\bigcap_{T \in F} D_{U, T, z}^{-1}(A * T)
\end{aligned}
$$

In this case the iso-fuds is maximally entity-like.
Given the decomposition of one functional transforms $D \in \mathcal{D}_{U}=\mathcal{D} \cap$ $\operatorname{trees}\left(\mathcal{S}_{U} \times \mathcal{T}_{U, f, 1}\right)$, such that und $(D) \subseteq V$, let the component-derived function valued function of the substrate histograms $D_{U, D, z} \in \mathcal{A}_{U, V, z} \rightarrow\left(\mathcal{A}_{U} \rightarrow \mathcal{A}_{U}\right)$ be defined

$$
D_{U, D, z}=\left\{(A,\{(C, A * C * T):(C, T) \in \operatorname{cont}(D)\}): A \in \mathcal{A}_{U, V, z}\right\}
$$

where $\operatorname{cont}(D)=\operatorname{elements}(\operatorname{contingents}(D))$.
The set of iso-decompositions can be related to the set iso-deriveds for each slice,
$\forall B \in D_{U, D, z}^{-1}\left(D_{U, D, z}(A)\right) \forall(C, T) \in \operatorname{cont}(D)\left(B * C \in D_{U, T, z_{C}}^{-1}(A * C * T)\right)$
where $z_{C}=\operatorname{size}(A * C)$. So each set of slice iso-decompositions is law-like,

$$
\forall(C, T) \in \operatorname{cont}(D)\left(D_{U, D, z_{C}}^{-1}\left(D_{U, D, z_{C}}(A * C)\right) \subseteq D_{U, T, z_{C}}^{-1}(A * C * T)\right)
$$

The set of iso-decompositions is a subset of the iso-deriveds of the transform of the decomposition,

$$
D_{U, D, z}^{-1}\left(D_{U, D, z}(A)\right) \subseteq D_{U, D^{\mathrm{T}}, z}^{-1}\left(A * D^{\mathrm{T}}\right)
$$

so the set of iso-decompositions is law-like with an iso-derivedence of

$$
\frac{\left|D_{U, \mathrm{i}, D, z}^{-1}\left(D_{U, D, z}(A)\right)\right|}{\left|D_{U, \mathbf{i}, D^{\mathrm{T}}, z}^{-1}\left(A * D^{\mathrm{T}}\right)\right|}
$$

In the case where the decomposition consists of a root node only, $D=$ $\{((\emptyset, T), \emptyset)\}$, the iso-decompositions equals the iso-deriveds,

$$
D_{U, D, z}^{-1}\left(D_{U, D, z}(A)\right)=D_{U, T, z}^{-1}(A * T)
$$

In this case the set of iso-decompositions is maximally law-like.
Given the fud decomposition of one functional definition sets $D \in \mathcal{D}_{\mathrm{F}, U}=$ $\mathcal{D}_{\mathrm{F}} \cap \operatorname{trees}\left(\mathcal{S}_{U} \times \mathcal{F}_{U, 1}\right)$, such that $\operatorname{und}(D) \subseteq V$, let the component-derivedset function valued function of the substrate histograms $D_{U, D, \mathrm{~F}, z} \in \mathcal{A}_{U, V, z} \rightarrow$ $\left(\mathcal{A}_{U} \rightarrow \mathrm{P}\left(\mathcal{A}_{U}\right)\right)$ be defined
$D_{U, D, \mathrm{~F}, z}=\left\{\left(A,\left\{\left(C,\left\{A * C * T_{F}: T \in F\right\}\right):(C, F) \in \operatorname{cont}(D)\right\}\right): A \in \mathcal{A}_{U, V, z}\right\}$

The set of iso-fud-decompositions can be related to the set of intersections of iso-deriveds for each slice

$$
\begin{aligned}
\forall B \in D_{U, D, \mathrm{~F}, z}^{-1}\left(D_{U, D, \mathrm{~F}, z}(A)\right) & \forall(C, F) \in \operatorname{cont}(D) \\
& \left(B * C \in \bigcap_{T \in F} D_{U, T_{F}, z_{C}}^{-1}\left(A * C * T_{F}\right)\right)
\end{aligned}
$$

or
$\forall(C, F) \in \operatorname{cont}(D)\left(D_{U, D, \mathrm{~F}, z_{C}}^{-1}\left(D_{U, D, \mathrm{~F}, z_{C}}(A * C)\right) \subseteq \bigcap_{T \in F} D_{U, T_{F}, z_{C}}^{-1}\left(A * C * T_{F}\right)\right)$
If the top transform exists the set of slice iso-fud-decompositions is a subset of the slice iso-deriveds,

$$
\begin{aligned}
\forall(C, F) \in \operatorname{cont}(D)(\exists T & \in F(\operatorname{der}(T)=\operatorname{der}(F)) \Longrightarrow \\
& \left.D_{U, D, \mathrm{~F}, z_{C}}^{-1}\left(D_{U, D, \mathrm{~F}, z_{C}}(A * C)\right) \subseteq D_{U, F^{\mathrm{T}}, z_{C}}^{-1}\left(A * C * F^{\mathrm{T}}\right)\right)
\end{aligned}
$$

so in some cases the set of slice iso-fud-decompositions is law-like with an iso-derivedence of

$$
\frac{\left|D_{U, \mathrm{i}, D, \mathrm{~F}, z_{C}}^{-1}\left(D_{U, D, \mathrm{~F}, z_{C}}(A * C)\right)\right|}{\left|D_{U, \mathrm{i}, F^{\mathrm{T}}, z_{C}}^{-1}\left(A * C * F^{\mathrm{T}}\right)\right|}
$$

If the top transform exists for all of the fuds, then the set of iso-fud decompositions is a subset of the iso-deriveds,

$$
\begin{aligned}
& \forall F \in \operatorname{fuds}(D) \exists T \in F(\operatorname{der}(T)=\operatorname{der}(F)) \Longrightarrow \\
& D_{U, D, \mathrm{~F}, z}^{-1}\left(D_{U, D, \mathrm{~F}, z}(A)\right) \subseteq D_{U, D^{\mathrm{T}}, z}^{-1}\left(A * D^{\mathrm{T}}\right)
\end{aligned}
$$

In this case the set of iso-fud-decompositions is law-like with an iso-derivedence of

$$
\frac{\left|D_{U, \mathrm{i}, D, \mathrm{~F}, z}^{-1}\left(D_{U, D, \mathrm{~F}, z}(A)\right)\right|}{\left|D_{U, \mathrm{i}, D^{\mathrm{T}}, z}^{-1}\left(A * D^{\mathrm{T}}\right)\right|}
$$

The set of slice iso-fud-decompositions is a subset of the slice iso-abstracts $\forall(C, F) \in \operatorname{cont}(D)\left(D_{U, D, \mathrm{~F}, z_{C}}^{-1}\left(D_{U, D, \mathrm{~F}, z_{C}}(A * C)\right) \subseteq Y_{U, F^{\mathrm{T}}, \mathrm{W}, z_{C}}^{-1}\left(\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{X}}\right)\right)$ so the set of slice iso-fud-decompositions is entity-like with an iso-abstractence of

$$
\frac{\left|D_{U, i, D, \mathrm{~F}, z_{C}}^{-1}\left(D_{U, D, \mathrm{~F}, z_{C}}(A * C)\right)\right|}{\left|Y_{U, i, F^{\mathrm{T}}, \mathrm{~W}, z_{C}}^{-1}\left(\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{X}}\right)\right|}
$$

Thus when the model is extended to fuds or fud decompositions, the iso-set or slice iso-set corresponding to the iso-deriveds is only sometimes law-like, although it is always at least entity-like.

Similarly, in the formal-abstract-pair-valued function of the substrate histograms, $Y_{U, T, z}$, the model is a transform. Again consider extending the model to (i) fuds, (ii) decompositions, and (iii) fud decompositions.

Let substrate histogram $A \in \mathcal{A}_{U, V, z}$ be in system $U$ and have variables $V$ and size $z$. Given the one functional definition set $F \in \mathcal{F}_{U, 1}$, such that $\operatorname{und}(F) \subseteq V$, let the abstract set valued function of the substrate histograms $Y_{U, F, \mathrm{~W}, z} \in \mathcal{A}_{U, V, z} \rightarrow \mathrm{P}\left(\mathcal{A}_{U}\right)$ be defined

$$
Y_{U, F, \mathrm{~W}, z}=\left\{\left(A,\left\{\left(A * T_{F}\right)^{\mathrm{X}}: T \in F\right\}\right): A \in \mathcal{A}_{U, V, z}\right\}
$$

where $T_{F}:=\operatorname{depends}(F, \operatorname{der}(T))^{\mathrm{T}}$.
The set of iso-fud-abstracts is the intersection of the iso-abstracts of each transform

$$
Y_{U, F, \mathrm{~W}, z}^{-1}\left(\left\{\left(A * T_{F}\right)^{\mathrm{X}}: T \in F\right\}\right)=\bigcap_{T \in F} Y_{U, T_{F}, \mathrm{~W}, z}^{-1}\left(\left(A * T_{F}\right)^{\mathrm{X}}\right)
$$

The set of iso-fud-abstracts is a subset of the iso-abstracts,

$$
Y_{U, F, \mathrm{~W}, z}^{-1}\left(\left\{\left(A * T_{F}\right)^{\mathrm{X}}: T \in F\right\}\right) \subseteq Y_{U, F^{\mathrm{T}}, \mathrm{~W}, z}^{-1}\left(\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}\right)
$$

So the set of iso-fud-abstracts is entity-like with an iso-abstractence of

$$
\frac{\left|Y_{U, F, \mathrm{~W}, z}^{-1}\left(\left\{\left(A * T_{F}\right)^{\mathrm{X}}: T \in F\right\}\right)\right|}{\left|Y_{U, \mathrm{i}, F^{\mathrm{T}}, \mathrm{~W}, z}^{-1}\left(\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}\right)\right|}
$$

In the case where the $f u d$ is a singleton, $F=\{T\}$, the iso-fud-abstracts equals the iso-abstracts,

$$
Y_{U,\{T\}, \mathrm{W}, z}^{-1}\left(\left\{(A * T)^{\mathrm{X}}\right\}\right)=Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)
$$

and the iso-fud-abstracts is maximally entity-like.
In the case where the fud consists of a single layer of partition transforms, $F \in \mathcal{F}_{U, \mathrm{P}}$ such that $|\operatorname{der}(F)|=|F|$, the iso-fud-abstracts equals the isoabstracts, which is the intersection of the iso-deriveds of the partition transforms,

$$
\begin{aligned}
Y_{U, F, \mathrm{~W}, z}^{-1}\left(\left\{\left(A * T_{F}\right)^{\mathrm{X}}: T \in F\right\}\right) & =Y_{U, F^{\mathrm{T}}, \mathrm{~W}, z}^{-1}\left(\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}\right) \\
& =\bigcap_{T \in F} D_{U, T, z}^{-1}(A * T)
\end{aligned}
$$

In this case the iso-fud-abstracts is maximally entity-like.
Let the formal set valued function of the substrate histograms $Y_{U, F, \mathrm{~V}, z} \in$ $\mathcal{A}_{U, V, z} \rightarrow \mathrm{P}\left(\mathcal{A}_{U}\right)$ be defined

$$
Y_{U, F, \mathrm{~V}, z}=\left\{\left(A,\left\{A^{\mathrm{X}} * T_{F}: T \in F\right\}\right): A \in \mathcal{A}_{U, V, z}\right\}
$$

where $T_{F}:=\operatorname{depends}(F, \operatorname{der}(T))^{\mathrm{T}}$.
The set of iso-fud-formals is the intersection of the iso-formals of each transform

$$
Y_{U, F, \mathrm{~V}, z}^{-1}\left(\left\{A^{\mathrm{X}} * T_{F}: T \in F\right\}\right)=\bigcap_{T \in F} Y_{U, T_{F}, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T_{F}\right)
$$

If the top transform exists the set of iso-fud-formals is a subset of the isoformals,

$$
\begin{aligned}
\exists T \in F(\operatorname{der}(T)=\operatorname{der}(F)) & \Longrightarrow \\
Y_{U, F, \mathrm{~V}, z}^{-1} & \left(\left\{A^{\mathrm{x}} * T_{F}: T \in F\right\}\right) \subseteq Y_{U, F^{\mathrm{T}}, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * F^{\mathrm{T}}\right)
\end{aligned}
$$

Let the formal-abstract-pair set valued function of the substrate histograms $Y_{U, F, z} \in \mathcal{A}_{U, V, z} \rightarrow \mathrm{P}\left(\mathcal{A}_{U} \times \mathcal{A}_{U}\right)$ be defined

$$
Y_{U, F, z}=\left\{\left(A,\left\{\left(A^{\mathrm{X}} * T_{F},\left(A * T_{F}\right)^{\mathrm{X}}\right): T \in F\right\}\right): A \in \mathcal{A}_{U, V, z}\right\}
$$

where $T_{F}:=\operatorname{depends}(F, \operatorname{der}(T))^{\mathrm{T}}$.
The set of iso-fud-independents is the intersection of the iso-transform independents of each transform
$Y_{U, F, z}^{-1}\left(\left\{\left(A^{\mathrm{X}} * T_{F},\left(A * T_{F}\right)^{\mathrm{X}}\right): T \in F\right\}\right)=\bigcap_{T \in F} Y_{U, T_{F}, z}^{-1}\left(\left(A^{\mathrm{X}} * T_{F},\left(A * T_{F}\right)^{\mathrm{X}}\right)\right)$
The set of iso-fud-independents is the intersection of the iso-fud-formals and the iso-fud-abstracts

$$
\begin{aligned}
& Y_{U, F, z}^{-1}\left(\left\{\left(A^{\mathrm{X}} * T_{F},\left(A * T_{F}\right)^{\mathrm{X}}\right): T \in F\right\}\right)= \\
& \quad Y_{U, F, \mathrm{~V}, z}^{-1}\left(\left\{A^{\mathrm{x}} * T_{F}: T \in F\right\}\right) \cap Y_{U, F, \mathrm{~W}, z}^{-1}\left(\left\{\left(A * T_{F}\right)^{\mathrm{x}}: T \in F\right\}\right)
\end{aligned}
$$

If the top transform exists the set of iso-fud-independents is a subset of the iso-transform independents,

$$
\begin{aligned}
& \exists T \in F(\operatorname{der}(T)=\operatorname{der}(F)) \Longrightarrow \\
& \quad Y_{U, F, z}^{-1}\left(\left\{\left(A^{\mathrm{X}} * T_{F},\left(A * T_{F}\right)^{\mathrm{x}}\right): T \in F\right\}\right) \subseteq Y_{U, F^{\mathrm{T}}, z}^{-1}\left(\left(A^{\mathrm{X}} * F^{\mathrm{T}},\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}\right)\right)
\end{aligned}
$$

The set of iso-fud-independents is a subset of the iso-abstracts,

$$
Y_{U, F, z}^{-1}\left(\left\{\left(A^{\mathrm{X}} * T_{F},\left(A * T_{F}\right)^{\mathrm{x}}\right): T \in F\right\}\right) \subseteq Y_{U, F^{\mathrm{T}}, \mathrm{~W}, z}^{-1}\left(\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}\right)
$$

So the set of iso-fud-independents is entity-like with an iso-abstractence of

$$
\frac{\left|Y_{U, F, z}^{-1}\left(\left\{\left(A^{\mathrm{X}} * T_{F},\left(A * T_{F}\right)^{\mathrm{x}}\right): T \in F\right\}\right)\right|}{\left|Y_{U, \mathrm{i}, F^{\mathrm{T}}, \mathrm{~W}, z}^{-1}\left(\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}\right)\right|}
$$

In the case where the fud is a singleton, $F=\{T\}$, the iso-fud-independents equals the iso-transform-independents,

$$
Y_{U,\{T\}, z}^{-1}\left(\left\{\left(A^{\mathrm{x}} * T,(A * T)^{\mathrm{x}}\right)\right\}\right)=Y_{U, T, z}^{-1}\left(\left(A^{\mathrm{x}} * T,(A * T)^{\mathrm{x}}\right)\right)
$$

Given the decomposition of one functional transforms $D \in \mathcal{D}_{U}=\mathcal{D} \cap$ $\operatorname{trees}\left(\mathcal{S}_{U} \times \mathcal{T}_{U, \mathrm{f}, 1}\right)$, such that $\operatorname{und}(D) \subseteq V$, let the component-formal-abstractpair function valued function of the substrate histograms $Y_{U, D, z} \in \mathcal{A}_{U, V, z} \rightarrow$ $\left(\mathcal{A}_{U} \rightarrow\left(\mathcal{A}_{U} \times \mathcal{A}_{U}\right)\right)$ be defined
$Y_{U, D, z}=\left\{\left(A,\left\{\left(C,\left((A * C)^{\mathrm{X}} * T,(A * C * T)^{\mathrm{X}}\right)\right):(C, T) \in \operatorname{cont}(D)\right\}\right): A \in \mathcal{A}_{U, V, z}\right\}$
where $\operatorname{cont}(D)=\operatorname{elements}(\operatorname{contingents}(D))$.
The set of iso-decomposition-independents can be related to the set iso-transform-independents for each slice,

$$
\begin{aligned}
\forall B \in Y_{U, D, z}^{-1}\left(Y_{U, D, z}(A)\right) \forall(C, T) & \in \operatorname{cont}(D) \\
& \left(B * C \in Y_{U, T, z_{C}}^{-1}\left(\left((A * C)^{\mathrm{X}} * T,(A * C * T)^{\mathrm{X}}\right)\right)\right)
\end{aligned}
$$

where $z_{C}=\operatorname{size}(A * C)$.
In the case where the decomposition consists of a root node only, $D=$ $\{((\emptyset, T), \emptyset)\}$, the iso-decomposition-independents equals the iso-transformindependents,

$$
Y_{U, D, z}^{-1}\left(Y_{U, D, z}(A)\right)=Y_{U, T, z}^{-1}\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right)
$$

Given the fud decomposition of one functional definition sets $D \in \mathcal{D}_{\mathrm{F}, U}=$ $\mathcal{D}_{\mathrm{F}} \cap \operatorname{trees}\left(\mathcal{S}_{U} \times \mathcal{F}_{U, 1}\right)$, such that und $(D) \subseteq V$, let the component-formal-abstract-pair set function valued function of the substrate histograms $Y_{U, D, \mathrm{~F}, z} \in$ $\mathcal{A}_{U, V, z} \rightarrow\left(\mathcal{A}_{U} \rightarrow \mathrm{P}\left(\mathcal{A}_{U} \times \mathcal{A}_{U}\right)\right)$ be defined

$$
\begin{aligned}
& Y_{U, D, \mathrm{~F}, z}= \\
& \qquad \begin{array}{l}
\left\{\left(A,\left\{\left(C,\left\{\left((A * C)^{\mathrm{x}} * T_{F},\left(A * C * T_{F}\right)^{\mathrm{x}}\right): T \in F\right\}\right):\right.\right.\right. \\
\\
\left.\quad(C, F) \in \operatorname{cont}(D)\}): A \in \mathcal{A}_{U, V, z}\right\}
\end{array}
\end{aligned}
$$

The set of iso-fud-decomposition-independents can be related to the set of intersections of iso-transform-independents for each slice

$$
\begin{aligned}
& \forall B \in Y_{U, D, \mathrm{~F}, z}^{-1}\left(Y_{U, D, \mathrm{~F}, z}(A)\right) \forall(C, F) \in \operatorname{cont}(D) \\
& \qquad\left(B * C \in \bigcap_{T \in F} Y_{U, T_{F}, z_{C}}^{-1}\left(\left((A * C)^{\mathrm{x}} * T_{F},\left(A * C * T_{F}\right)^{\mathrm{X}}\right)\right)\right)
\end{aligned}
$$

or

$$
\begin{aligned}
& \forall(C, F) \in \operatorname{cont}(D) \\
& \qquad\left(Y_{U, D, \mathrm{~F}, z_{C}}^{-1}\left(Y_{U, D, \mathrm{~F}, z_{C}}(A * C)\right) \subseteq \bigcap_{T \in F} Y_{U, T_{F}, z_{C}}^{-1}\left(\left((A * C)^{\mathrm{x}} * T_{F},\left(A * C * T_{F}\right)^{\mathrm{x}}\right)\right)\right)
\end{aligned}
$$

The set of slice iso-fud-decomposition-independents is a subset of the slice iso-abstracts
$\forall(C, F) \in \operatorname{cont}(D)\left(Y_{U, D, \mathrm{~F}, z_{C}}^{-1}\left(Y_{U, D, \mathrm{~F}, z_{C}}(A * C)\right) \subseteq Y_{U, F^{\mathrm{T}}, \mathrm{W}, z_{C}}^{-1}\left(\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{X}}\right)\right)$
so the set of slice iso-fud-decomposition-independents is entity-like with an iso-abstractence of

$$
\frac{\left|Y_{U, i, D, \mathrm{~F}, z_{C}}^{-1}\left(Y_{U, D, \mathrm{~F}, z_{C}}(A * C)\right)\right|}{\left|Y_{U, \mathrm{i}, \mathrm{~F}^{\mathrm{T}}, \mathrm{~W}, z_{C}}^{-1}\left(\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{x}}\right)\right|}
$$

### 3.12.6 Integral iso-sets and entropy

The set of integral substrate histograms in system $U$, of variables $V$ and size $z$ is defined in section 'Iso-sets', above, as

$$
\mathcal{A}_{U, \mathrm{i}, V, z}=\left\{A: A \in \mathcal{A}_{U, \mathrm{i}}, A^{\mathrm{U}}=V^{\mathrm{C}}, \operatorname{size}(A)=z\right\}
$$

Its cardinality is the cardinality of weak compositions $\left|\mathrm{C}^{\prime}\left(V^{\mathrm{C}}, z\right)\right|$

$$
\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right|=\frac{(z+v-1)!}{z!(v-1)!}
$$

where $v=\left|V^{\mathrm{C}}\right|$.
In the case where the size is less than or equal to the volume, $z \leq v$, the logarithm of the cardinality of weak compositions may be approximated

$$
\begin{aligned}
\ln \frac{(z+v-1)!}{z!(v-1)!} & =\bar{z} \ln v-\underline{z} \ln z \\
& \approx z \ln \frac{v}{z}
\end{aligned}
$$

by abuse of notation. If the size, $z$, is fixed, $\log$-cardinality varies with the logarithm of the volume, $\ln v$.

In the case where the size is greater than the volume, $z>v$, the logcardinality approximates

$$
\begin{aligned}
\ln \frac{(z+v-1)!}{z!(v-1)!} & \approx \bar{v} \ln z-\underline{v} \ln v \\
& \approx v \ln \frac{z}{v}
\end{aligned}
$$

If the volume, $v$, is fixed, the log-cardinality varies with the logarithm of the size, $\ln z$.

The logarithm of the cardinality of weak compositions may also be analysed by means of Stirling's approximation in the case where $z \gg \ln z$ and $v \gg \ln v$,

$$
\begin{aligned}
\ln \frac{(z+v-1)!}{z!(v-1)!} \approx & (z+v) \ln (z+v)-z \ln z-v \ln v \\
= & z \ln \frac{z+v}{z}+v \ln \frac{z+v}{v} \\
\approx & \left(z \ln \frac{v}{z}: z<v\right)+ \\
& (2 z \ln 2: z=v)+ \\
& \left(v \ln \frac{z}{v}: z>v\right)
\end{aligned}
$$

The cardinality of the set of integral iso-deriveds is the product of the weak compositions of the components,

$$
\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|=\prod_{(R, C) \in T^{-1}} \frac{\left((A * T)_{R}+|C|-1\right)!}{(A * T)_{R}!(|C|-1)!}
$$

The integral iso-deriveds is a subset of the integral substrate histograms, $D_{U, \mathrm{i}, T, z}^{-1}(A * T) \subseteq \mathcal{A}_{U, \mathrm{i}, V, z}$, so the cardinality of the set of integral iso-deriveds is bounded

$$
1 \leq\left|D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right| \leq \frac{(z+v-1)!}{z!(v-1)!}
$$

The logarithm of the cardinality of the set of integral iso-deriveds is

$$
\begin{aligned}
\ln \left|D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right| & =\sum_{(R, C) \in T^{-1}} \ln \frac{\left((A * T)_{R}+|C|-1\right)!}{(A * T)_{R}!(|C|-1)!} \\
& =\sum_{(R, \cdot) \in T^{-1}} \ln \frac{\left((A * T)_{R}+\left(V^{\mathrm{C}} * T\right)_{R}-1\right)!}{(A * T)_{R}!\left(\left(V^{\mathrm{C}} * T\right)_{R}-1\right)!} \\
& =\sum_{(, C) \in T^{-1}} \ln \frac{(\operatorname{size}(A * C)+|C|-1)!}{\operatorname{size}(A * C)!(|C|-1)!}
\end{aligned}
$$

The integral iso-deriveds log-cardinality is approximately bounded

$$
0 \leq \ln \left|D_{U, i, T, z}^{-1}(A * T)\right| \leq(z+v) \ln (z+v)-z \ln z-v \ln v
$$

In the case where the volume is much greater than one, $v \gg 1$, the integral iso-deriveds log-cardinality is approximately proportional to the negative size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
& \ln \left|D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right| \\
& \approx \sum_{(R, \cdot) \in T^{-1}}\left(A * T+V^{\mathrm{C}} * T\right)_{R} \ln \left(A * T+V^{\mathrm{C}} * T\right)_{R} \\
& \quad-\sum_{(R, \cdot) \in T^{-1}}(A * T)_{R} \ln (A * T)_{R}-\sum_{(R, \cdot) \in T^{-1}}\left(V^{\mathrm{C}} * T\right)_{R} \ln \left(V^{\mathrm{C}} * T\right)_{R} \\
& =\quad(z+v) \ln (z+v)-z \ln z-v \ln v \\
& \quad-\left((z+v) \times \operatorname{entropy}\left(A * T+V^{\mathrm{C}} * T\right)\right. \\
& \left.\quad-z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)\right)
\end{aligned}
$$

In the domain where the size is less than or equal to the volume, $z \leq v$, where the derived counts or component sizes are generally less than their component cardinalities, $A * T<V^{\mathrm{C}} * T$ or $\forall(\cdot, C) \in T^{-1}(\operatorname{size}(A * C)<|C|)$, then the integral iso-deriveds log-cardinality varies against the size scaled component size cardinality relative entropy,

$$
\begin{aligned}
\ln \left|D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right| & \sim \sum_{(R, \cdot) \in T^{-1}}(A * T)_{R} \ln \frac{\left(V^{\mathrm{C}} * T\right)_{R}}{(A * T)_{R}} \\
& \sim-z \times \operatorname{entropyRelative}\left(A * T, V^{\mathrm{C}} * T\right)
\end{aligned}
$$

Similarly, in the domain where the size is greater than the volume, $z>v$, where the derived counts or component sizes are generally greater than their component cardinalities, $A * T>V^{\mathrm{C}} * T$ or $\forall(\cdot, C) \in T^{-1}(\operatorname{size}(A * C)>|C|)$,
then the integral iso-deriveds log-cardinality varies against the volume scaled component cardinality size relative entropy,

$$
\begin{aligned}
\ln \left|D_{U, i, T, z}^{-1}(A * T)\right| & \sim \sum_{(R, \cdot) \in T^{-1}}\left(V^{\mathrm{C}} * T\right)_{R} \ln \frac{(A * T)_{R}}{\left(V^{\mathrm{C}} * T\right)_{R}} \\
& \sim-v \times \text { entropyRelative }\left(V^{\mathrm{C}} * T, A * T\right)
\end{aligned}
$$

In both domains the integral iso-deriveds log-cardinality varies against the relative entropy. That is, integral iso-deriveds log-cardinality is minimised when (a) the cross entropy is maximised and (b) the component entropy is minimised. The cross entropy is maximised when high size components are low cardinality components and low size components are high cardinality components.

In the case where the derived is independent, $A * T=(A * T)^{\mathrm{X}}$, the cardinality of the set of integral iso-abstracts equals the cardinality of the set of integral iso-deriveds,

$$
\begin{aligned}
\left|Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right| & =\left|D_{U, \mathbf{i}, T, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right| \\
& =\prod_{(R, C) \in T^{-1}} \frac{\left((A * T)_{R}^{\mathrm{X}}+|C|-1\right)!}{(A * T)_{R}^{\mathrm{X}}!(|C|-1)!}
\end{aligned}
$$

and so in this case the integral iso-abstracts log-cardinality is approximately proportional to the negative abstract size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
& \ln \left|Y_{U, 1, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right| \\
& \begin{array}{l}
\approx(z+v) \ln (z+v)-z \ln z-v \ln v \\
\quad-\left((z+v) \times \operatorname{entropy}\left((A * T)^{\mathrm{X}}+V^{\mathrm{C}} * T\right)\right. \\
\\
\left.\quad-z \times \operatorname{entropy}\left((A * T)^{\mathrm{X}}\right)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)\right)
\end{array}
\end{aligned}
$$

Conjecture that the logarithm of the cardinality of the integral iso independents corresponding to $A^{\mathrm{X}}$ varies with the size scaled independent entropy,

$$
\ln \left|Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right| \sim z \times \operatorname{entropy}\left(A^{\mathrm{X}}\right)
$$

The conjecture is suggested by considering the state $S \in V^{\mathrm{CS}}$ having minimum count in the independent, $S \in \operatorname{mind}\left(A^{\mathrm{X}}\right)$, which therefore is also the minimum of the perimeter, $\forall w \in V\left(S \cap \operatorname{mind}\left(Q_{A}(w)\right) \neq \emptyset\right)$. The minimum
count of the minimum state, $\operatorname{minr}\left(\left\{\left(w, Q_{A}(w)(S \%\{w\}): w \in V\right\}\right) \in \mathbf{N}\right.$, limits the number of ways the iso-independents can be cumulatively constructed. See 'Deltas and Perturbations', below, for a discussion of the construction of the iso-independents from a sequence of circuit deltas.

The positive correlation between the integral iso-independents log-cardinality and the independent entropy is consistent with the negative correlation between the integral iso-abstracts log-cardinality and the relative entropy,

$$
\begin{aligned}
& \ln \left|Y_{U, 1, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right| \\
& \quad \sim \quad-\left((z+v) \times \operatorname{entropy}\left((A * T)^{\mathrm{X}}+V^{\mathrm{C}} * T\right)\right. \\
& \left.\quad \sim \quad-z \times \operatorname{entropy}\left((A * T)^{\mathrm{X}}\right)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)\right) \\
& \quad \sim\left((A * T)^{\mathrm{x}}\right)
\end{aligned}
$$

As the transform tends to value full functional, $T_{\mathrm{s}}=\left\{\{w\}^{\operatorname{CS}\{ \} \mathrm{T}}: w \in V\right\}^{\mathrm{T}}$, the abstract tends to the independent, $\left(A * T_{\mathrm{s}}\right)^{\mathrm{X}}=A^{\mathrm{X}}$, and the abstract entropy, entropy $\left((A * T)^{\mathrm{X}}\right)$, tends to the independent entropy, entropy $\left(A^{\mathrm{X}}\right)$.

The integral iso-transform-independents is a subset of the integral isoabstracts, $Y_{U,, T, T, z}^{-1}\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right) \subseteq Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$, so the integral iso-transform-independents log-cardinality varies with the integral iso-abstracts log-cardinality,

$$
\ln \left|Y_{U, i, T, z}^{-1}\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right)\right| \sim \ln \left|Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|
$$

Conjecture that, in the case where formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, the integral iso-transform-independents logcardinality varies against the abstract size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
& \ln \left|Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)\right)\right| \\
& -\left((z+v) \times \operatorname{entropy}\left((A * T)^{\mathrm{X}}+V^{\mathrm{C}} * T\right)\right. \\
& \left.\quad-z \times \operatorname{entropy}\left((A * T)^{\mathrm{X}}\right)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)\right)
\end{aligned}
$$

and with the size scaled abstract entropy,

$$
\ln \left|Y_{U, i, T, z}^{-1}\left(\left(A^{\mathrm{x}} * T,(A * T)^{\mathrm{x}}\right)\right)\right| \sim z \times \operatorname{entropy}\left((A * T)^{\mathrm{x}}\right)
$$

### 3.12.7 Shuffled history

Closely related to the independent histogram are the shuffles of the nonempty history $H$ of histogram $A=$ histogram $(H)$ of size $z=|H|>0$, having
at least one variable $n \geq 1$ where $V=\operatorname{vars}(H)$ and $n=|V|$. The result is a set of histories of the same size $z$ where the variable values are shuffled between the states.

Define shuffles $\in \mathcal{H} \rightarrow \mathrm{P}(\mathcal{H})$ as the monoidal concatenation of the set of reduced histories having shuffle prefixed event identifiers

$$
\begin{aligned}
& \operatorname{shuffles}(H):= \\
& \qquad \prod\{\{\{((X, x), T):(x,(\cdot, T)) \in X\}: X \in \operatorname{ids}(H) \cdot(H \%\{v\})\}: v \in V\}
\end{aligned}
$$

where $(\%) \in \mathcal{H} \times \mathrm{P}(\mathcal{V}) \rightarrow \mathcal{H}$ is defined $H \% W:=\{(x, S \% W)):(x, S) \in H\}$, the monoidal product is defined $\Pi X=\operatorname{fold} 1((*), \operatorname{flip}(Q))$ for some $Q \in$ enums $(X)$, and the monoidal product operator $(*) \in \mathcal{H} \times \mathcal{H} \rightarrow \mathcal{H}$ is

$$
G * I:=\{((X \cup Y, x), S \cup T):((X, x), S) \in G, \quad((Y, y), T) \in I, x=y\}
$$

The shuffles function is defined where $n \geq 1$.
The shuffles all have the same size, $\forall G \in \operatorname{shuffles}(H)(|G|=z)$. The histograms of the shuffles include the histogram of the given history, $A \in$ $\{\operatorname{his}(G): G \in \operatorname{shuffles}(H)\}$, where his $=$ histogram. If histogram $A$ is singleton, $\left|A^{\mathrm{F}}\right|=1$, then there is only one shuffle histogram, $\{\operatorname{his}(G): G \in$ $\operatorname{shuffles}(H)\}=\{A\}$. The cardinality of the shuffles is $|\operatorname{shuffles}(H)|=z!^{n}$. The cardinality of the shuffle histograms is less than or equal to the cardinality of the shuffles, $|\{\operatorname{his}(G): G \in \operatorname{shuffles}(H)\}| \leq|\operatorname{shuffles}(H)|$. If history $H$ is mono-variate, $n=1$, then there is only one shuffle histogram, $\{\operatorname{his}(G): G \in \operatorname{shuffles}(H)\}=\{A\}$. All histograms of the shuffles of $H$ are congruent,

$$
\forall G \in \operatorname{shuffles}(H) \diamond B=\operatorname{his}(H)(\operatorname{congruent}(B, A))
$$

All the histograms of the shuffles of $H$ have the same independent histogram

$$
\forall G \in \operatorname{shuffles}(H) \diamond B=\operatorname{his}(G)\left(B^{\mathrm{X}} \equiv A^{\mathrm{X}}\right)
$$

The scaled sum of the histograms of any subset of the shuffled histories also has the same independent

$$
\forall P \subseteq \operatorname{shuffles}(H) \diamond B=\operatorname{scalar}(1 /|P|) * \sum_{G \in P} \operatorname{his}(G)\left(B^{\mathrm{x}} \equiv A^{\mathrm{x}}\right)
$$

The scaled sum of the histograms of the shuffled histories equals the independent

$$
\operatorname{scalar}\left(1 / z!^{n}\right) * \sum(\operatorname{his}(G): G \in \operatorname{shuffles}(H)) \equiv A^{\mathrm{X}}
$$

### 3.13 Rolls

A roll, $R \in \mathcal{S} \rightarrow \mathcal{S}$, is a function on the cartesian set of states of some set of variables $V$ in system $U, R \in V^{\mathrm{CS}} \rightarrow V^{\mathrm{CS}}$.

Define the set of rolls as rolls $\subset \mathcal{S} \rightarrow \mathcal{S}$. Define vars $\in(\mathcal{S} \rightarrow \mathcal{S}) \rightarrow \mathrm{P}(\mathcal{V})$ as $\operatorname{vars}(R):=\{v: S \in \operatorname{dom}(R) \cup \operatorname{ran}(R), v \in \operatorname{vars}(S)\}$. Rolls are constrained such that $\forall R \in$ rolls $\forall S \in \operatorname{dom}(R) \cup \operatorname{ran}(R)(\operatorname{vars}(S)=\operatorname{vars}(R))$.

Define the application of a roll $R$ in variables $V$ to a histogram $A$ having the same variables $\operatorname{vars}(R)=\operatorname{vars}(A)=V$ as roll $\in \operatorname{rolls} \times \mathcal{A} \rightarrow \mathcal{A}$

$$
\begin{array}{r}
\operatorname{roll}(R, A):=\{(S, c):(S, c) \in A, S \notin \operatorname{dom}(R)\}+\sum_{S \in A^{\mathrm{S}} \cap \operatorname{dom}(R)}\left\{\left(R_{S}, A_{S}\right)\right\} \\
=\sum_{S \in A^{\mathrm{S}} \backslash \operatorname{dom}(R)}\left\{\left(S, A_{S}\right)\right\}+\sum_{S \in A^{\mathrm{S}} \cap \operatorname{dom}(R)}\left\{\left(R_{S}, A_{S}\right)\right\}
\end{array}
$$

Define $(*) \in \mathcal{A} \times$ rolls $\rightarrow \mathcal{A}$ as $A * R:=\operatorname{roll}(R, A)$. The application of the empty roll is defined $A * \emptyset=A$. (Note that the operator has a type ambiguity between the empty roll, $\emptyset \in$ rolls, and the empty histogram, $\emptyset \in$ $\mathcal{A}$.) $A * R$ is undefined if $\operatorname{vars}(R) \neq \operatorname{vars}(A)$. If $A$ is scalar then the only applicable roll, apart from the empty roll, is $\{(\emptyset, \emptyset)\}$ and so a scalar rolls to itself, $\operatorname{scalar}(z) *\{(\emptyset, \emptyset)\}=\operatorname{scalar}(z)$. The rolled histogram $A * R$ is congruent to the underlying histogram $A$, congruent $(A, A * R)$. That is, the application is size-conserving, $\operatorname{size}(A * R)=\operatorname{size}(A)$ and in the same variables, $\operatorname{vars}(A * R)=\operatorname{vars}(A)$. The part of $A$ for which the states $Q \subset \operatorname{states}(A)$ are neither in the domain nor range of $R, Q=\operatorname{states}(A) \backslash \operatorname{dom}(R) \backslash \operatorname{ran}(R)$, is unchanged under application, $A * Q^{\mathrm{U}} * R=A * R * Q^{\mathrm{U}}=A * Q^{\mathrm{U}}$. If $A \in \mathcal{A}_{U}$ and $R \in \operatorname{cartesian}(U)(\operatorname{vars}(A)) \rightarrow \operatorname{cartesian}(U)(\operatorname{vars}(A)) \subset$ rolls then $A * R \in\left(A^{\mathrm{CS}} \rightarrow \mathbf{Q}_{\geq 0}\right) \subset \mathcal{A}_{U}$.

Define the identity roll $\operatorname{id}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow$ rolls as $\operatorname{id}(U)(V):=\{(S, S):$ $\left.S \in V^{\mathrm{CS}}\right\}$. Application of the identity roll leaves a histogram $A$ unchanged, $A * \operatorname{id}(U)(\operatorname{vars}(A))=A$.

A roll $R \in$ rolls is circular if there exists a source state which is also a target state, $\operatorname{dom}(R) \cap \operatorname{ran}(R) \neq \emptyset$. The identity roll on variables $V$, $\operatorname{id}(U)(V)$, is circular.

The set of rolls in substrate variables $V$ of system $U, V^{\mathrm{CS}} \rightarrow V^{\mathrm{CS}} \subset$ rolls, can be constructed

$$
V^{\mathrm{CS}} \rightarrow V^{\mathrm{CS}}=\left\{R: R \subseteq V^{\mathrm{CS}} \times V^{\mathrm{CS}},|\operatorname{dom}(R)|=|R|\right\}=\prod_{S \in V^{\mathrm{CS}}}\{S\} \times V^{\mathrm{CS}}
$$

The substrate rolls includes the empty roll, $\emptyset \in V^{\mathrm{CS}} \rightarrow V^{\mathrm{CS}}$. The cardinality of the set of substrate rolls is bounded $\left|V^{\mathrm{CS}} \rightarrow V^{\mathrm{CS}}\right| \leq 2^{y} y^{y}$ where $y=\left|V^{\mathrm{C}}\right|$. The subset of the substrate rolls which have cardinality equal to the volume are the substrate complete rolls, $\left\{R \in V^{\mathrm{CS}} \rightarrow V^{\mathrm{CS}},|R|=\left|V^{\mathrm{CS}}\right|\right\}$. The cardinality of the substrate complete rolls is $\left|V^{\mathrm{CS}}: \rightarrow V^{\mathrm{CS}}\right|=y^{y}$.

A list of rolls, for example $L \in \mathcal{L}\left(V^{\mathrm{CS}} \rightarrow V^{\mathrm{CS}}\right)$, in variables $V$, can be applied to a histogram $A$ in sequence, because the application of each roll results in a congruent histogram to which a successive roll may be applied. Define roll $\in \mathcal{L}$ (rolls) $\times \mathcal{A} \rightarrow \mathcal{A}$ as $\operatorname{roll}(L, A):=\operatorname{roll}($ sequence $(L), A)$ and roll $\in \mathcal{K}$ (rolls) $\times \mathcal{A} \rightarrow \mathcal{A}$ as

$$
\begin{aligned}
\operatorname{roll}((R, X), A) & :=\operatorname{roll}(X, A * R) \\
\operatorname{roll}(\emptyset, A) & :=A
\end{aligned}
$$

$\operatorname{roll}(L, A)$ is undefined unless all of the rolls are in the same variables as the histogram, $\forall R \in \operatorname{set}(L)(\operatorname{vars}(R)=\operatorname{vars}(A))$. Define $(*) \in \mathcal{A} \times \mathcal{L}$ (rolls) $\rightarrow \mathcal{A}$ as $A * L:=\operatorname{roll}(L, A)$. The application of the empty list of rolls is defined $A * \emptyset=A$. (Again note the operator type ambiguity between $\emptyset \in \mathcal{L}$ (rolls) and $\emptyset \in \mathcal{A}$.) The application of a list of rolls to a histogram is left associative, $A * L=A * L_{1} * L_{2} \ldots * L_{l}=\left(A * L_{1}\right) * L_{2} \ldots * L_{l}=\left(\left(A * L_{1}\right) * L_{2}\right) \ldots * L_{l}$, where $l=|L|$. The list rolled histogram $A * L$ is congruent to the underlying histogram $A$, congruent $(A, A * L)$. If $A \in \mathcal{A}_{U}$ and $L \in \mathcal{L}\left(A^{\mathrm{CS}} \rightarrow A^{\mathrm{CS}}\right) \subset$ $\mathcal{L}$ (rolls) then $A * L \in\left(A^{\mathrm{CS}} \rightarrow \mathbf{Q}_{\geq 0}\right) \subset \mathcal{A}_{U}$.

A pair of rolls, $R_{1}, R_{2} \in$ rolls, in the same variables, $\operatorname{vars}\left(R_{1}\right)=\operatorname{vars}\left(R_{2}\right)=$ $V$, is a pair of endomorphic functions and hence can be composed to form a single roll $R_{2} \circ R_{1}=\operatorname{compose}\left(R_{1}, R_{2}\right) \in$ rolls (see Appendix 'Function composition'). The function composition is here defined as an outer join $R_{2} \circ R_{1}$. Define compose $\in(\mathcal{S} \rightarrow \mathcal{S}) \times(\mathcal{S} \rightarrow \mathcal{S}) \rightarrow(\mathcal{S} \rightarrow \mathcal{S})$ as

$$
\begin{aligned}
& \operatorname{compose}\left(R_{1}, R_{2}\right):= \\
& \quad\left\{\left(S_{1}, T_{2}\right):\left(S_{1}, T_{1}\right) \in R_{1},\left(S_{2}, T_{2}\right) \in R_{2}, S_{2}=T_{1}\right\} \cup \\
& \quad\left\{\left(S_{1}, T_{1}\right):\left(S_{1}, T_{1}\right) \in R_{1}, T_{1} \notin \operatorname{dom}\left(R_{2}\right)\right\} \cup \\
& \quad\left\{\left(S_{2}, T_{2}\right):\left(S_{2}, T_{2}\right) \in R_{2}, S_{2} \notin \operatorname{dom}\left(R_{1}\right)\right\}
\end{aligned}
$$

Define $R_{2} \circ R_{1}:=$ compose $\left(R_{1}, R_{2}\right)$. compose $\left(R_{1}, R_{2}\right)$ is undefined if $\operatorname{vars}\left(R_{1}\right) \neq$ $\operatorname{vars}\left(R_{2}\right)$. The domain of a composition is the union of the domains of the arguments, $\operatorname{dom}\left(R_{2} \circ R_{1}\right)=\operatorname{dom}\left(R_{1}\right) \cup \operatorname{dom}\left(R_{2}\right)$. A sequence of compositions of rolls is right associative, $R_{3} \circ R_{2} \circ R_{1}=R_{3} \circ\left(R_{2} \circ R_{1}\right)$.

If the composition of a roll $R$ in variables $V$ and the identity roll $\operatorname{id}(U)(V)$ is equal to the identity roll, $R \circ \mathrm{id}(U)(V)=\operatorname{id}(U)(V)$, then $R$ is said to be an identity equivalent roll.

A list of rolls, $L \in \mathcal{L}$ (rolls), in variables $V, \forall R \in \operatorname{set}(L)(\operatorname{vars}(R)=$ $V)$, can be composed recursively, compose $\in \mathcal{L}($ rolls $) \rightarrow$ rolls. For example, compose $\left(\left\{\left(1, R_{1}\right),\left(2, R_{2}\right),\left(3, R_{3}\right)\right\}\right)=R_{3} \circ R_{2} \circ R_{1}$. The application of a roll list to a histogram $A \operatorname{roll}(L, A)$, is equal to the application of the joined list, $A * L=A * \operatorname{compose}(L)$. For example, let roll list $L=\left\{\left(1, R_{1}\right),\left(2, R_{2}\right),\left(3, R_{3}\right)\right\}$, then $A * L=A * R_{1} * R_{2} * R_{3}=A *\left(R_{3} \circ R_{2} \circ R_{1}\right)$.

A roll list $L$ is unique where the unioned list has the same cardinality as the sum of the cardinalities of the rolls, $|\bigcup \operatorname{set}(L)|=\sum_{i \in\{1 \ldots \mid L\}\}}\left|R_{i}\right|$. That is, each map of the rolls appears only once, $\forall i \in\{1 \ldots|L|-1\} \forall i \in$ $\{i+1 \ldots|L|\}\left(L_{i} \cap L_{j}=\emptyset\right)$.

A roll list $L$ is functional where the unioned list is functional, $\bigcup \operatorname{set}(L) \in$ $\mathcal{S} \rightarrow \mathcal{S}$.

A roll list $L$ is non-circular where no source state subsequently appears as a target state,

$$
\forall i \in\{1 \ldots|L|\} \forall S \in \operatorname{dom}\left(L_{i}\right)\left(S \notin\left\{S_{2}: R \in \operatorname{set}\left(L_{\{i \ldots|L|\}}\right),\left(S_{1}, S_{2}\right) \in R\right\}\right)
$$

The composition of a non-circular functional roll list, $L \in \mathcal{L}\left(V^{\mathrm{CS}} \rightarrow V^{\mathrm{CS}}\right)$, has disjoint domain and range, $\operatorname{dom}(R) \cap \operatorname{ran}(R)=\emptyset$ where $R=\operatorname{compose}(L)$. Thus $R \in \operatorname{dom}(R) \rightarrow\left(V^{\mathrm{CS}} \backslash \operatorname{dom}(R)\right)$.

A unique non-circular functional roll list $L$ is such that no source state subsequently appears as either a source or target state,

$$
\begin{aligned}
& \forall i \in\{1 \ldots|L|\} \diamond X=\bigcup \operatorname{set}\left(L_{\{i+1 \ldots|L|\}}\right) \\
& \quad\left(\operatorname{dom}\left(L_{i}\right) \cap\left(\operatorname{ran}\left(L_{i}\right) \cup \operatorname{dom}(X) \cup \operatorname{ran}(X)\right)=\emptyset\right)
\end{aligned}
$$

A roll $R \in$ rolls having variables $V$ can be converted to a partition $P \in \mathcal{R}_{U}$, by taking the functional inverse of the roll stuffed with the identity roll, $P=\operatorname{ran}\left(\operatorname{inverse}\left(R^{\prime}\right)\right)$ where $R^{\prime}=R \circ \operatorname{id}(U)(V)$. A roll list, $L \in$
$\mathcal{L}\left(V^{\mathrm{CS}} \rightarrow V^{\mathrm{CS}}\right)$, can be mapped to a reverse partition sequence. That is, a list of partitions such that each is succeeded by parent partitions. Let $K=$ $\left\{\left(i, \operatorname{ran}\left(\right.\right.\right.$ inverse $\left.\left.\left.\left(\operatorname{compose}\left(L_{\{1 \ldots i\}}\right) \circ \operatorname{id}(U)(V)\right)\right)\right): i \in\{1 \ldots|L|\}\right\} \in \mathcal{L}\left(\mathcal{R}_{U}\right)$. Then $|K| \geq 2 \Longrightarrow \forall i \in\{1 \ldots|K|\} \forall j \in\{i+1 \ldots|K|\}\left(\operatorname{parent}\left(K_{j}, K_{i}\right)\right)$.

A roll $R \in$ rolls having variables $V$ can converted to a transform in $\mathcal{T}_{U, V}$. One method is to create a partition transform $P^{\mathrm{T}} \in \mathcal{T}_{U, V}$ on the partition $P \in \mathcal{R}_{U}$ of the cartesian states of the variables, $P \in \mathrm{~B}\left(V^{\mathrm{CS}}\right)$, implied by the functional inverse, $P=\operatorname{ran}(\operatorname{inverse}(R \circ \operatorname{id}(U)(V)))$. This transform has a single derived variable, $\left|\operatorname{der}\left(P^{\mathrm{T}}\right)\right|=1$, and therefore the derived histogram is independent, $A * P^{\mathrm{T}}=\left(A * P^{\mathrm{T}}\right)^{\mathrm{X}}$, when applied to some underlying histogram $A$ in variables $V$.

Another method is create a partition-set and thence a fud of partition transforms. Each partition transform corresponds to an underlying variable, $v \in V$, by reducing the target state to that variable. Each derived variable partitions the entire cartesian set of states of all the variables, $V^{\mathrm{CS}}$, not just the cartesian of the underlying variable, $\{v\}^{\mathrm{CS}}$. Define $\operatorname{transform}(U, V) \in$ rolls $\rightarrow \mathcal{T}_{U, \mathrm{f}, 1}$ as

$$
\begin{aligned}
& \operatorname{transform}(U, V)(R):= \\
& \qquad\left\{P^{\mathrm{T}}: v \in V, P=\operatorname{ran}\left(\operatorname{inverse}\left(\left\{\left(S_{1}, S_{2} \%\{v\}\right):\left(S_{1}, S_{2}\right) \in R^{\prime}\right\}\right)\right)\right\}^{\mathrm{T}}
\end{aligned}
$$

where $\operatorname{vars}(R)=V$ or $R=\emptyset$, and $R^{\prime}=R \circ \operatorname{id}(U)(V)$ is the given roll stuffed with the identity roll. Define $R^{\mathrm{T}}:=\operatorname{transform}(U)(R)$ where the system $U$ and the substrate variables $V$ are implicit. The transforms of rolls in variables $V$ form a subset of the substrate transforms set, $\left\{R^{\mathrm{T}}: R \in V^{\mathrm{CS}} \rightarrow\right.$ $\left.V^{\mathrm{CS}}\right\} \subset \mathcal{T}_{U, V}$. The cardinality of the derived variables of the transform of a roll is less than or equal to the cardinality of the underlying variables, $|W| \leq|V|$, where $W=\operatorname{der}\left(R^{\mathrm{T}}\right)$. The valency of each of the derived variables is less than or equal to that of its corresponding underlying variable, $\forall v \in V\left(\left|\operatorname{ran}\left(\operatorname{inverse}\left(\left\{\left(S_{1}, S_{2} \%\{v\}\right):\left(S_{1}, S_{2}\right) \in R^{\prime}\right\}\right)\right)\right| \leq\left|U_{v}\right|\right)$. Thus the derived volume is less than or equal to the underlying volume $\left|W^{\mathrm{C}}\right| \leq\left|V^{\mathrm{C}}\right|$. In the case of non-empty substrate variables, $V \neq \emptyset$, if the cardinality of derived and underlying variables is the same, $|W|=|V|$, then the volume of the derived histogram is equal to the size of the effective cartesian subvolume formed by the independent of the roll of the cartesian histogram $\left|W^{\mathrm{C}}\right|=\left|\left(V^{\mathrm{C}} * R\right)^{\mathrm{XF}}\right|$. If the roll of the cartesian histogram is equal to the cartesian histogram, $\left(V^{\mathrm{C}} * R\right)^{\mathrm{XF}}=V^{\mathrm{C}}$, then the volume of the derived histogram is equal to the volume of the underlying, $\left|W^{\mathrm{C}}\right|=\left|V^{\mathrm{C}}\right|$. In this case, the roll transform is left total, $X \% V=V^{\mathrm{C}}$ where $X=\operatorname{his}\left(R^{\mathrm{T}}\right)$, and the
underlying volume equals the derived volume, $\left|W^{\mathrm{C}}\right|=\left|V^{\mathrm{C}}\right|$, so the roll transform is a frame transform. The transform is also right total, $X \% W=W^{\mathrm{C}}$, and hence frame full functional, if the roll is an identity equivalent roll, $R \circ \mathrm{id}(U)(V)=\operatorname{id}(U)(V)$, or if the roll is otherwise circular. If the roll is an identity equivalent roll, $R \circ \mathrm{id}(U)(V)=\operatorname{id}(U)(V)$, then the roll transform is a value full functional transform or reframe transform. In this case the roll transform is the singleton element of the strong self non-overlapping substrate self-cartesian transforms set, $\left\{R^{\mathrm{T}}\right\}=\left\{\left\{\{v\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: v \in V\right\}^{\mathrm{T}}\right\}=$ $\left\{N^{\mathrm{T}}: N \in \mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{s}}\right\} \subseteq \mathcal{T}_{U, V, \mathrm{c}} \cap \mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$.

The cardinality of the set of transforms of rolls is bounded by the cardinality of the subset of the substrate rolls which have cardinality equal to the volume, $\left|V^{\mathrm{CS}}: \rightarrow V^{\mathrm{CS}}\right|=y^{y}$. That is, $\left|\left\{R^{\mathrm{T}}: R \in V^{\mathrm{CS}} \rightarrow V^{\mathrm{CS}}\right\}\right| \leq y^{y}$. This may be compared to the cardinality of its superset, the substrate transforms set, $\left|\mathcal{T}_{U, V}\right|=2^{\operatorname{bell}(y)}$.

### 3.13.1 Value rolls

A value roll is equivalent to a special case of a roll $R \in V^{\mathrm{CS}} \rightarrow V^{\mathrm{CS}}$ on variables $V$. Let $v \in V$ be one of the variables, and $s, t \in U_{v}$ be source and target values of $v$. The value roll $(V, v, s, t)$ has a corresponding roll $R$ such that all states incident on the source value $s$ are mapped to the target value $t, R=\left\{(S, S \backslash\{(v, s)\} \cup\{(v, t)\}): S \in V^{\mathrm{CS}}, S_{v}=s\right\}$. Define the set of value rolls rollValues $(U) \subset \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{V}_{U} \times \mathcal{W}_{U} \times \mathcal{W}_{U}$ such that $\forall(V, v, s, t) \in \operatorname{rollValues}(U)\left((v \in V) \wedge\left(\{s, t\} \subseteq U_{v}\right)\right)$.

In order to construct a non-circular roll from a value roll, define $\operatorname{roll}(U) \in$ rollValues $(U) \rightarrow\left(\right.$ rolls $\left.\cap\left(\mathcal{S}_{U} \rightarrow \mathcal{S}_{U}\right)\right)$ as

$$
\begin{aligned}
& \operatorname{roll}(U)((V, v, s, t)):= \\
& \quad\{(S, S \backslash\{(v, s)\} \cup\{(v, t)\}): S \in \operatorname{cartesian}(U)(V),(v, s) \in S\} \backslash \operatorname{id}(U)(V)
\end{aligned}
$$

If $t=s$ then the roll is empty, $\operatorname{roll}(U)((V, v, s, s))=\emptyset$. Define $(V, v, s, t)^{\mathrm{R}}:=$ $\operatorname{roll}(U)((V, v, s, t))$.

The substrate value rolls set in variables $V$ of system $U$ is

$$
\left\{(V, v, s, t): v \in V, s, t \in U_{v}\right\} \subseteq \operatorname{rollValues}(U)
$$

The substrate value rolls set has cardinality $\left|\left\{(V, v, s, t): v \in V, s, t \in U_{v}\right\}\right|=$ $\sum_{v \in V}\left|U_{v}\right|^{2}$. In the case of regular variables of dimension $n=|V|$ and valency $\{d\}=\left\{\left|U_{v}\right|: v \in V\right\}$, the cardinality is $n d^{2}$.

The independent of the application of a value roll $(V, v, s, t)$ to a histogram $A$ is equal to the application of a value roll to the independent histogram

$$
\left(A *(V, v, s, t)^{\mathrm{R}}\right)^{\mathrm{X}}=A^{\mathrm{X}} *(V, v, s, t)^{\mathrm{R}}
$$

Thus the application of a value roll to an independent histogram is also independent,

$$
A^{\mathrm{X}} *(V, v, s, t)^{\mathrm{R}}=\left(A^{\mathrm{X}} *(V, v, s, t)^{\mathrm{R}}\right)^{\mathrm{X}}
$$

Let $\mathcal{J}_{U, V}$ be the infinite substrate value roll lists set in variables $V$ and system $U, \mathcal{J}_{U, V}=\{L: L \in \mathcal{L}(\operatorname{rollValues}(U)),(\forall(W, v, s, t) \in \operatorname{set}(L)(W=$ $V))\}$. The list of value rolls $J \in \mathcal{J}_{U, V}$ can be converted into a list of rolls, $\operatorname{map}(\operatorname{roll}(U), J)=\left\{\left(i,(V, v, s, t)^{\mathrm{R}}\right):(i,(V, v, s, t)) \in J\right\} \subset \mathcal{L}$ (rolls). Define $J^{\mathrm{R}}:=\operatorname{map}(\operatorname{roll}(U), J)$. A list of value rolls $J$ may be composed indirectly, compose $\left(J^{\mathrm{R}}\right)$. The application of a value roll list to a histogram $A, \operatorname{roll}\left(J^{\mathrm{R}}, A\right)$, is equal to the application of the joined list, $A * J^{\mathrm{R}}=A *$ compose $\left(J^{\mathrm{R}}\right)$. Rolled independent histograms remain independent $A^{\mathrm{X}} * J^{\mathrm{R}}=$ $\left(A^{\mathrm{X}} * J^{\mathrm{R}}\right)^{\mathrm{X}}$.

A list of value rolls $J \in \mathcal{J}_{U, V}$ in variables $V$ can be rearranged without altering its composition compose $\left(J^{\mathrm{R}}\right)$ so long as the order of the value rolls remains the same for each variable. That is, the set of lists filtered by variable can be concatenated in any order. Let filtv $(U) \in \mathcal{V}_{U} \times \mathcal{L}($ rollValues $(U)) \rightarrow$ $\mathcal{L}(\operatorname{rollValues}(U))$ be defined as filtv $(U)(v, J):=\operatorname{filter}(\{(N, w=v): N \in$ $\operatorname{rollValues}(U),(\cdot, w, \cdot, \cdot)=N\}, J)$. Then $\forall K \in \mathcal{L}(V)(|K|=|V| \wedge \operatorname{set}(K)=$ $\left.V \Longrightarrow \operatorname{compose}\left((\operatorname{concat}(\{(i, \operatorname{filtv}(U)(v, J)):(i, v) \in K\}))^{\mathrm{R}}\right)=\operatorname{compose}\left(J^{\mathrm{R}}\right)\right)$.

Consider a non-circular functional list of value rolls $J \in \mathcal{J}_{U, V}$ in the same variable $v \in V, J=\operatorname{filtv}(U)(v, J)$. The cumulative initial sub-lists of $J$ can be mapped to a reverse partition sequence. Let $l=|J|$. Let $K=$ $\{(i,\{(s, t)\}):(i,(\cdot, \cdot, s, t)) \in J\} \in \mathcal{L}\left(U_{v} \rightarrow U_{v}\right) . \operatorname{Let} \operatorname{id}(U)(v)=\{(u, u): u \in$ $\left.U_{v}\right\} \in U_{v} \rightarrow U_{v}$. Let $L=\left\{\left(i, \operatorname{ran}\left(\right.\right.\right.$ inverse $\left(\right.$ compose $\left.\left.\left.\left(K_{\{1 \ldots i\}}\right) \circ \operatorname{id}(U)(v)\right)\right)\right):$ $i \in\{1 \ldots l\}\} \in \mathcal{L}\left(\mathrm{B}\left(U_{v}\right)\right)$. Then $l \geq 1 \Longrightarrow \operatorname{parent}\left(L_{1}, \operatorname{id}(U)(v)\right)$ and $l \geq 2 \Longrightarrow \forall i \in\{1 \ldots l-1\}\left(\operatorname{parent}\left(L_{i+1}, L_{i}\right)\right)$. If, in addition, $J$ is constrained to be a list of non-identity value rolls, $\forall(\cdot, \cdot, s, t) \in \operatorname{set}(J)(s \neq t)$, then $l \geq 1 \Longrightarrow\left|L_{1}\right|=\left|U_{v}\right|-1$ and $l \geq 2 \Longrightarrow \forall i \in\{1 \ldots l-1\}\left(\left|L_{i+1}\right|=\right.$ $\left|L_{i}\right|-1$ ). The maximum length of such a list is $d-1$ where $d=\left|U_{v}\right|$. The cardinality of the set of all such value partition lists of maximum length is $d!(d-1)!/ 2^{d-1}$. The maximum length of a unique non-circular functional list of non-identity value rolls in regular variables $V$, having dimension $n=|V|$ and valency $\{d\}=\left\{\left|U_{w}\right|: w \in V\right\}$, is $n(d-1)$. The cardinality of the set of
possible value rolls at the head of such a list is $n d(d-1)$. The cardinality of the set of possible value partitions at the head is half of this, $n d(d-1) / 2$, because of the degeneracy of $\{(s, t)\}$ and $\{(t, s)\}$. The cardinality of the set of value partitions which correspond to the composed initial sublists of the lists in $\mathcal{J}_{U, V}$ is $\sum\left((\operatorname{bell}(d)-1)^{k}: k \in\{0 \ldots n\}\right)$.

A list of value rolls $J \in \mathcal{J}_{U, V}$ in variables $V$ can be converted into a transform, $\left.J^{\mathrm{RT}}=\operatorname{transform}(U)(\operatorname{map}(\operatorname{roll}(U), J))\right)$, by first converting each value roll to a roll, then composing and finally converting to a transform as defined above. An alternative method is to construct a fud $F \in \mathcal{F}_{U, \mathrm{P}}$ of partition transforms such that each partition variable corresponds to one of the underlying variables. That is, such that there is a surjective map between the underlying variables and the partition variables, und $(F) \rightarrow: \operatorname{der}(F)$. This method highlights the fact that the resultant fud $F$ is a non-overlapping partition of the underlying variables. First compose by variable by filtering the value roll list. Define $\operatorname{compv}(U) \in \mathcal{V}_{U} \times \mathcal{L}(\operatorname{rollValues}(U)) \rightarrow\left(\mathcal{W}_{U} \rightarrow \mathcal{W}_{U}\right)$ as $\operatorname{compv}(U)(v, J):=\operatorname{compose}(\{(i,\{(s, t)\}):(i,(\cdot, \cdot, s, t)) \in \operatorname{filtv}(U)(v, J)\})$, which is such that $\operatorname{compv}(U)(v, J) \in U_{v} \rightarrow U_{v}$. Then partition the values, define $\operatorname{partv}(U) \in \mathcal{V}_{U} \times \mathcal{L}(\operatorname{rollValues}(U)) \rightarrow \mathrm{P}\left(\mathrm{P}\left(\mathcal{W}_{U}\right)\right)$ as $\operatorname{partv}(U)(v, J):=$ $\operatorname{ran}($ inverse $(\operatorname{compv}(U)(v, J) \circ \operatorname{id}(U)(v)))$, which is such that $\operatorname{partv}(U)(v, J) \in$ $\mathrm{B}\left(U_{v}\right)$. Then $F=\left\{\{\{v\} \times C: C \in \operatorname{partv}(U)(v, J)\}^{\mathrm{T}}: v \in V\right\} \in \mathcal{F}_{U, \mathrm{P}}$. Define $\operatorname{transform}(U) \in \mathcal{L}($ rollValues $(U)) \rightarrow \mathcal{T}_{U, \mathrm{f}, 1}$ as
$\operatorname{transform}(U)(J):=\left\{\{\{\{(v, u)\}: u \in C\}: C \in \operatorname{partv}(U)(v, J)\}^{V \mathrm{~T}}: v \in V\right\}^{\mathrm{T}}$
which is defined when $J \in \mathcal{J}_{U, V}$ and $J \neq \emptyset$. Define $J^{\mathrm{T}}:=\operatorname{transform}(U)(J)$. Thus $J^{\mathrm{T}} \in \mathcal{T}_{U, V}$. Define $(V, v, s, t)^{\mathrm{T}}:=\{(1,(V, v, s, t))\}^{\mathrm{T}}$.

The value roll list transform equals the roll list transform, $J^{\mathrm{T}}=J^{\mathrm{RT}}$. Therefore the constraints on $J^{\mathrm{RT}}$ also apply to $J^{\mathrm{T}}$. That is, the cardinality of the derived variables is less than or equal to the cardinality of the underlying variables, $|W| \leq|V|$, where $W=\operatorname{der}\left(J^{\mathrm{T}}\right)$. The valency of each of the derived variables is less than or equal to that of its corresponding underlying variable, $\forall v \in V\left(|\operatorname{partv}(U)(v, J)| \leq\left|U_{v}\right|\right)$. The value roll list transform is non-overlapping, $\neg \operatorname{overlap}\left(J^{\mathrm{T}}\right)$. The transform is constructed from a nonoverlapping fud of partition transforms and hence the transform must be right total, $(X \% W)^{\mathrm{F}}=W^{\mathrm{C}}$ where $(X, W)=J^{\mathrm{T}}$. Thus the derived volume is less than or equal to the underlying volume, $\left|W^{\mathrm{C}}\right| \leq\left|V^{\mathrm{C}}\right|$. In the case of non-empty substrate variables, $V \neq \emptyset$, if the cardinalities of the derived and underlying variables is the same, $|W|=|V|$, then the volume of the derived histogram is equal to the size of the effective cartesian sub-volume formed
by the roll of the cartesian histogram $\left|W^{\mathrm{C}}\right|=\left|\left(V^{\mathrm{C}} * J^{\mathrm{R}}\right)^{\mathrm{F}}\right|$. The value roll list transform can only be full functional if the stuffed roll is the identity roll $J^{\mathrm{R}} \circ \operatorname{id}(U)(V)=\operatorname{id}(U)(V)$. In this case the value roll list transform is a value full functional transform or reframe transform. It is the singleton of the strong self non-overlapping substrate self-cartesian transforms set, $\left\{J^{\mathrm{T}}\right\}=$ $\left\{\left\{\{v\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: v \in V\right\}^{\mathrm{T}}\right\}=\left\{N^{\mathrm{T}}: N \in \mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}, \mathrm{s}}\right\} \subseteq \mathcal{T}_{U, V, \mathrm{c}} \cap \mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$.

The set of transforms of composed value rolls, $\left\{J^{\mathrm{T}}: J \in \mathcal{J}_{U, V}\right\} \subset \mathcal{T}_{U, V}$ is the self non-overlapping substrate transforms set $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$ which is a subset of the non-overlapping substrate transforms set,

$$
\left\{J^{\mathrm{T}}: J \in \mathcal{J}_{U, V}\right\}=\mathcal{T}_{U, V, \mathrm{n}, \mathrm{~s}} \subseteq \mathcal{T}_{U, V, \mathrm{n}}
$$

If $V$ is regular having dimension $n=|V|$ and valency $\{d\}=\left\{\left|U_{w}\right|: w \in V\right\}$, the cardinality of $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$ is bounded $\left|\mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}\right| \leq \operatorname{bell}(d)^{n}$. This may be compared to the cardinality of its superset, the non-overlapped substrate transforms set, $\left|\mathcal{T}_{U, V, \mathrm{n}}\right|<2 \times \operatorname{bell}(n) \times \operatorname{bell}\left(d^{n}\right)+1$, and thence to the cardinality of its superset, the substrate transforms set, $\left|\mathcal{T}_{U, V}\right|=2^{\text {bell }\left(d^{n}\right)}$

$$
\operatorname{bell}(d)^{n}<2 \times \operatorname{bell}(n) \times \operatorname{bell}\left(d^{n}\right) \leq 2^{\operatorname{bell}\left(d^{n}\right)}
$$

It may also be compared to the cardinality of its superset, the set of transforms of rolls, $\left|\left\{R^{\mathrm{T}}: R \in V^{\mathrm{CS}} \rightarrow V^{\mathrm{CS}}\right\}\right| \leq d^{n d^{n}}$

$$
\operatorname{bell}(d)^{n}<d^{n d^{n}}
$$

Finally compare it to the cardinality of its superset, the fixed dimension substrate transforms set, $\left|\left\{T: T \in \mathcal{T}_{U, V},|\operatorname{der}(T)|=n\right\}\right|=\operatorname{bell}\left(d^{n}\right)^{n} / n!$

$$
\operatorname{bell}(d)^{n}<\frac{1}{n!} \operatorname{bell}\left(d^{n}\right)^{\underline{n}}
$$

The subset of the transforms of composed value rolls, $\left\{J^{\mathrm{T}}: J \in \mathcal{J}_{U, V}\right\}=$ $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$, where the value roll list has only one value roll, $J=\{(1,(V, v, s, t))\}$ and $t \neq s$, is the intersection of the substrate decremented transforms set and the self non-overlapping substrate transforms set

$$
\begin{aligned}
& \left\{J^{\mathrm{T}}: J \in \mathcal{J}_{U, V},|J|=1,(\cdot, \cdot, s, t)=J_{1}, t \neq s\right\} \\
& \quad=\mathcal{T}_{U, V,-} \cap \mathcal{T}_{U, V, \mathrm{n}, \mathrm{~S}} \\
& \quad=\left\{\left(\left\{Q^{V \mathrm{~T}}\right\} \cup\left\{\{u\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: u \in V \backslash\{x\}\right\}\right)^{\mathrm{T}}: x \in V, Q \in \operatorname{decs}\left(\{x\}^{\mathrm{CS}\{ \}}\right)\right\}
\end{aligned}
$$

where decs $=$ decrements $\in \mathcal{R}_{U} \rightarrow \mathrm{P}\left(\mathcal{R}_{U}\right)$. If the substrate $V$ is regular having valency $d$, then $\left|\mathcal{T}_{U, V,-} \cap \mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}\right|=n d(d-1) / 2$, which is the cardinality
of the set of possible value partitions at the head of a non-circular functional list of non-identity value rolls.

As mentioned above, the set of transforms of composed value rolls is the self non-overlapping substrate transforms set, $\left\{J^{\mathrm{T}}: J \in \mathcal{J}_{U, V}\right\}=\mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$. In section 'Substrate structures', above, the self non-overlapping substrate transforms set, $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$, can be constructed from linear fuds of multi-partition transforms, $L \in \mathcal{L}\left(\mathcal{T}_{U, \mathrm{P}^{*}}\right)$, where the first transform is the value full functional transform and subsequent transforms are strong self non-overlapping substrate decremented transforms. In the case of non-empty substrate, $V \neq \emptyset$,

$$
\begin{aligned}
\mathcal{T}_{U, V, \mathrm{n}, \mathrm{~s}}=\left\{(\bigcup \operatorname{set}(L))^{\mathrm{TPT}}:\right. & M=\left\{\{v\}^{\mathrm{CS}\{ \}}: v \in V\right\} \\
& L \in \operatorname{subpaths}(\{(M, \operatorname{tdec}(U)(M))\})\}
\end{aligned}
$$

where the tree of self non-overlapping substrate decremented partition-sets is defined $\operatorname{tdec}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathrm{P}\left(\mathcal{R}_{U}\right)\right)$ as

$$
\begin{aligned}
& \operatorname{tdec}(U)(M):=\{(N, \operatorname{tdec}(U)(N)): \\
& \left.\quad w \in M, Q \in \operatorname{decs}\left(\{w\}^{\operatorname{CS}\{ \}}\right), N=\{Q\} \cup\left\{\{u\}^{\operatorname{CS}\{ \}}: u \in M, u \neq w\right\}\right\}
\end{aligned}
$$

A subset of the non-empty unique non-circular functional substrate value roll lists can be defined such that the source value is greater than the target value where there exists some order on the values of each of the variables $D_{v} \in \operatorname{enums}\left(U_{v}\right)$. Define the decrementing value roll lists

$$
\begin{aligned}
& \mathcal{J}_{U, V,-}=\left\{J: J \in \mathcal{J}_{U, V}, J \neq \emptyset, \forall(\cdot, \cdot, s, t) \in \operatorname{set}(J)(s>t)\right. \\
& \forall\left(i,\left(\cdot, v_{i}, s_{i}, t_{i}\right)\right),\left(j,\left(\cdot, v_{j}, s_{j}, t_{j}\right)\right) \in J \\
& \left.\quad\left(v_{i}=v_{j} \Longrightarrow\left(i \leq j \Longrightarrow t_{j} \neq s_{i}\right) \wedge\left(i \neq j \Longrightarrow s_{j} \neq s_{i}\right)\right)\right\}
\end{aligned}
$$

The decrementing value roll lists, $\mathcal{J}_{U, V,-}$, can be constructed recursively by means of a tree of value rolls $\operatorname{tdecrv}(U, V) \in \mathcal{J}_{U, V} \rightarrow \operatorname{trees}($ rollValues $(U))$, defined as

$$
\begin{aligned}
& \operatorname{tdecrv}(U, V)(J) \\
& \qquad \begin{aligned}
\{((V, v, s, t), & \operatorname{tdecrv}(U, V)(J \cup\{(|J|+1,(V, v, s, t))\})) \\
& v \in V, s, t \in U_{v}, s>t \\
& X=\{x:(\cdot, w, x, \cdot) \in \operatorname{set}(J), w=v\}, s \notin X, t \notin X\}
\end{aligned}
\end{aligned}
$$

Each source value may be rolled no more than once for each variable, and only to lesser target values. The decrementing value roll lists is $\mathcal{J}_{U, V,-}=$
subpaths $(\operatorname{tdecrv}(U, V)(\emptyset))$. The decrementing value roll lists, $\mathcal{J}_{U, V,-}$, is a finite set, corresponding bijectively to linear fuds of strong self non-overlapping substrate decremented transforms,

$$
\mathcal{J}_{U, V,-}: \leftrightarrow: \operatorname{subpaths}(\operatorname{tdec}(U)(V))
$$

because the construction trees map bijectively,

$$
\operatorname{places}(\operatorname{tdecrv}(U, V)(\emptyset)): \leftrightarrow: \operatorname{places}(\operatorname{tdec}(U)(V))
$$

To construct value rolls in a decrementing value roll list, $J \in \mathcal{J}_{U, V,-}$, given the application of the decrementing value roll list so far, $V^{\mathrm{C}} * J_{\{1 \ldots i\}}$, it is only necessary to test that the source and target values on the perimeter are nonzero. That is, putative value roll $(\cdot, v, s, t)$ may be added, $J_{i+1}=(V, v, s, t)$, if $\left(V^{\mathrm{C}} * J_{\{1 \ldots i\}}^{\mathrm{R}} \%\{v\}\right)(\{(v, s)\}) \neq 0$ and $\left(V^{\mathrm{C}} * J_{\{1 \ldots i\}}^{\mathrm{R}} \%\{v\}\right)(\{(v, t)\}) \neq 0$.

### 3.14 Deltas and Perturbations

A delta is a pair of histograms $(D, I) \in \mathcal{A} \times \mathcal{A}$ in the same variables $V$, $\operatorname{vars}(D)=\operatorname{vars}(I)=V$. The application of a delta to a histogram $A$ in variables $V$ is the subtraction of $D$ followed by the addition of $I$. The resultant histogram, $A-D+I$, is a perturbation of $A$. An effective delta is such that the perturbation is no more effective than the given histogram, $(A-D+I)^{\mathrm{F}} \leq A^{\mathrm{F}}$. A zero delta is such that $A-D+I \equiv A$.

If $D \leq A$ then $\operatorname{size}(A-D+I)=\operatorname{size}(A)-\operatorname{size}(D)+\operatorname{size}(I)$. If $D \leq A$ and the delta is congruent, $\operatorname{size}(D)=\operatorname{size}(I)$, then the histogram and its perturbation are congruent, congruent $(A, A-D+I)$.

If $D \leq A$ and the congruent delta histograms are effective singletons, $\left|D^{\mathrm{F}}\right|=$ $\left|I^{\mathrm{F}}\right|=1$, of unit size, $\operatorname{size}(D)=\operatorname{size}(I)=1$, then the congruent perturbation, $A-D+I$, is an event perturbation. The set of event perturbations of histogram $A$ in variables $V$ and system $U$ is

$$
\left\{A-\{R\}^{\mathrm{U}}+\{S\}^{\mathrm{U}}:(R, d) \in A, d \geq 1, S \in A^{\mathrm{CS}}\right\}
$$

The set of effective event perturbations is

$$
\left\{A-\{R\}^{\mathrm{U}}+\{S\}^{\mathrm{U}}:(R, d) \in A, d \geq 1,(S, c) \in A, c>0\right\}
$$

which is independent of system.

Let $(D, I) \in \mathcal{A} \times \mathcal{A}$ be a delta of histogram $A$ such that $D \leq A$. A one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ is a functor (or monoid homomorphism) of the delta application operator, $(A * T)-(D * T)+(I * T)=(A-D+I) * T$ where $\operatorname{vars}(D)=\operatorname{vars}(I)=\operatorname{und}(T)=\operatorname{vars}(A)$.

Let $N_{(D, I)} \in \mathcal{E}_{U}$ be a histogram expression of delta $(D, I) \in \mathcal{A} \times \mathcal{A}$ having variables $\operatorname{vars}(D)=\operatorname{vars}(I)=V$. The expression application to histogram $A$ in variables $V$ is such that $N_{(D, I)}(A)=A-D+I \in \mathcal{A}$. See appendix 'Histogram expressions' for a definition of $N_{(D, I)}$.

The application of a roll $R \in V^{\mathrm{CS}} \rightarrow V^{\mathrm{CS}} \subset$ rolls to a histogram $A$ is equivalent to the application of a congruent delta $(D, I) \in \mathcal{A} \times \mathcal{A}$ in variables $V$. Define delta $\in$ rolls $\times \mathcal{A} \rightarrow(\mathcal{A} \times \mathcal{A})$ as

$$
\operatorname{delta}(R, A):=\left(\sum_{S \in A^{\mathrm{S}} \cap \operatorname{dom}(R)}\left\{\left(S, A_{S}\right)\right\}, \sum_{S \in A^{\mathrm{S}} \cap \operatorname{dom}(R)}\left\{\left(R_{S}, A_{S}\right)\right\}\right)
$$

which is defined if $\operatorname{vars}(R)=\operatorname{vars}(A)$. Thus the congruent perturbation equals the rolled histogram, $A-D+I=A * R$, where $(D, I)=\operatorname{delta}(R, A)$.

A value roll $(V, w, s, t) \in \operatorname{rollValues}(U)$ is a special case of a roll, $(V, w, s, t)^{\mathrm{R}} \in$ $V^{\mathrm{CS}} \rightarrow V^{\mathrm{CS}} \subset$ rolls, and hence implies an equivalent congruent perturbation to the histogram, $A-D+I=A *(V, w, s, t)^{\mathrm{R}}$, where $(D, I)=$ $\operatorname{delta}\left((V, w, s, t)^{\mathrm{R}}, A\right)$. Similarly a value roll list $J \in \mathcal{J}_{U, V} \subset \mathcal{L}($ rollValues $(U))$ on variables $V$ in system $U$ implies an equivalent congruent perturbation, $A-D+I=A * J^{\mathrm{R}}$, where $(D, I)=\operatorname{delta}\left(J^{\mathrm{R}}, A\right)$.

Consider the subset of the substrate transforms set, $\mathcal{T}_{U, V}$, on variables $V$ in system $U$, which are transforms of value roll lists, $\left\{J^{\mathrm{T}}: J \in \mathcal{J}_{U, V}\right\} \subset \mathcal{T}_{U, V}$. The application of the delta $(D, I)$ corresponding the value roll list $J \in \mathcal{J}_{U, V}$, $(D, I)=\operatorname{delta}\left(J^{\mathrm{R}}, A\right)$, to the histogram $A$ is isomorphic to the application of the transform $J^{\mathrm{T}}, A * J=A-D+I \cong A * J^{\mathrm{T}}$, but not equal because the $d e-$ rived variables are not equal to the underlying variables, $\operatorname{der}\left(J^{\mathrm{T}}\right) \neq \operatorname{und}\left(J^{\mathrm{T}}\right)$, and hence $\operatorname{vars}(A * J) \neq \operatorname{vars}\left(A * J^{\mathrm{T}}\right)$.

As shown above, the application of a value roll $(V, w, s, t) \in \operatorname{rollValues}(U)$ to an independent histogram $A^{\mathrm{X}}$ in variables $V$, conserves independence, $A^{\mathrm{X}}{ }^{*}$ $(V, w, s, t)^{\mathrm{R}}=\left(A^{\mathrm{X}} *(V, w, s, t)^{\mathrm{R}}\right)^{\mathrm{X}}$. Thus the corresponding delta $(D, I)=$ $\operatorname{delta}\left((V, w, s, t)^{\mathrm{R}}, A\right)$ also conserves independence, $A^{\mathrm{X}}-D+I=\left(A^{\mathrm{X}}-D+\right.$ $I)^{\mathrm{X}}$. Similarly for value roll lists, $A^{\mathrm{X}} * J^{\mathrm{R}}=\left(A^{\mathrm{X}} * J^{\mathrm{R}}\right)^{\mathrm{X}}=A^{\mathrm{X}}-D+I=$

$$
\left(A^{\mathrm{X}}-D+I\right)^{\mathrm{X}} \text { where }(D, I)=\operatorname{delta}\left(J^{\mathrm{R}}, A\right) .
$$

Let $N_{R} \in \mathcal{E}_{U}$ be a histogram expression of roll $R \in$ rolls having variables $V$. The expression application to histogram $A$ in variables $V$ is such that $N_{R}(A)=A * R \in \mathcal{A}$. See appendix 'Histogram expressions' for a definition of $N_{R}$.

Let $Y_{U, \mathrm{i}, V, z} \in \mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathcal{A}_{U, V, z}$ be the subset of the independent function, $Y_{U, \mathrm{i}, V, z}=\left\{\left(A, A^{\mathrm{X}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\} \subset$ independent. The set of integral iso-independents of integral histogram $A \in \mathcal{A}_{U, \mathrm{i}, V, z}$ is $Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$. Let $Q_{A} \subset \mathcal{A}_{\mathrm{i}} \times \mathcal{A}_{\mathrm{i}}$ be the subset of the integral congruent deltas which conserve iso-independence, $\forall(D, I) \in Q_{A}\left(A-D+I \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right)$. The perimeters of each of the iso-independent perturbations are equal, $\forall(D, I) \in Q_{A} \forall w \in$ $V((A-D+I) \%\{w\}=A \%\{w\})$. None of the iso-independent deltas result in event perturbations except for the zero delta, $\forall(D, I) \in Q_{A}(\operatorname{size}(I) \neq 1)$.

Define the circuit deltas as the subset of iso-independent deltas having size less than or equal to two, $C_{A}=\left\{(D, I):(D, I) \in Q_{A}\right.$, size $\left.(I) \leq 2\right\}$. The circuit deltas may be defined explicitly,

$$
\begin{aligned}
C_{A}=\left\{\left(\{S, T\}^{\mathrm{U}},\{S \%(V \backslash W) \cup T \% W, T \%(V \backslash W) \cup S \% W\}^{\mathrm{U}}\right):\right. \\
\left.S, T \in A^{\mathrm{FS}}, W \subseteq V\right\}
\end{aligned}
$$

Conjecture that all of the iso-independent deltas are linear sums of the circuit deltas.

$$
\begin{aligned}
& \forall(D, I) \in Q_{A} \exists L \in \mathcal{L}\left(C_{A}\right) \\
& \qquad\left(\left(D=\sum X: i \in\{1 \ldots|L|\},(X, \cdot)=L_{i}\right) \wedge\right. \\
& \left.\quad\left(I=\sum Y: i \in\{1 \ldots|L|\},(\cdot, Y)=L_{i}\right)\right)
\end{aligned}
$$

Value roll deltas $A-D+I=A *(V, w, s, t)^{\mathrm{R}}$ cannot be iso-independent deltas, $A-D+I \notin Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, because the iso-independents are equivalence classes of the independent. That is, $A^{\mathrm{X}} *(V, w, s, t)^{\mathrm{R}} \notin Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$.

Similarly, given some one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ where $\operatorname{und}(T)=$ $V$ and $W=\operatorname{der}(T)$, define $Y_{U, \mathbf{i}, T, z} \in \mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow\left(\mathcal{A}_{U, W, z} \times \mathcal{A}_{U, W, z}\right)$ as $Y_{U, \mathbf{i}, T, z}=$ $\left\{\left(A,\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right): A \in \mathcal{A}_{U \mathrm{i}, V, z}\right\}$. The finite set of integral iso-transform-independents of $\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)$ is $Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)$. A delta $(D, I)$ is iso-transform-independence conserving with respect to $T$ if $A-D+I \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)$. In the stronger case of (i)
the delta is iso-independence conserving, $A-D+I \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, so that $(A-D+I)^{\mathrm{X}}=A^{\mathrm{X}}$ and $(A-D+I)^{\mathrm{X}} * T=A^{\mathrm{X}} * T$, and (ii) the transformed applied delta is iso-independence conserving, $(A-D+I) * T \in Y_{U, i, W, z}^{-1}\left((A * T)^{\mathrm{x}}\right)$, so that the delta is iso-abstract, $((A-D+I) * T)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$, then the delta is iso-transform-independence conserving.

If the transform is a self partition, $T^{\mathrm{P}}=V^{\mathrm{CS}\{ \}}$, then the set of integral iso-transform-independents equals the set of integral iso-independents in the underlying variables, $Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, and hence only iso-independent deltas, $A-D+I \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, are iso-transformindependence conserving in this case.

If the transform is a unary partition, $T^{\mathrm{P}}=\left\{V^{\mathrm{CS}}\right\}$, then the set of integral iso-transform-independents equals the integral congruent support in the underlying variables, $Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)=\mathcal{A}_{U, \mathrm{i}, V, z}$, and any congruent delta is iso-transform-independence conserving in this case.

If the transform is a value roll transform, $T=J^{\mathrm{T}}$ where $J=\{(1,(V, w, s, t))\} \in$ $\mathcal{J}_{U, V}$, then the value roll delta, $A-D+I=A *(V, w, s, t)^{\mathrm{R}}$, is iso-transformindependence conserving, $A *(V, w, s, t)^{\mathrm{R}} \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)$, because $(A-D+I) * T=A * T$ and $(A-D+I)^{\mathrm{X}} * T=A^{\mathrm{X}} * T$.

As discussed in section 'Transforms and Independent', above, given a substrate histogram $A \in \mathcal{A}_{U, V, z}$ and a substrate transform $T \in \mathcal{T}_{U, V}$, having derived variables $W=\operatorname{der}(T)$, the case where the formal equals the abstract, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, is equivalent to requiring each partition variable derived histogram to equal the partition variable derived histogram of the independent,

$$
\begin{aligned}
A^{\mathrm{x}} * T & =(A * T)^{\mathrm{x}} \Longleftrightarrow \\
& \forall P \in W\left(A * P^{\mathrm{T}}=A^{\mathrm{x}} * P^{\mathrm{T}}\right) \\
= & \forall P \in W \forall C \in P\left(\operatorname{size}\left(A * C^{\mathrm{U}}\right)=\operatorname{size}\left(A^{\mathrm{x}} * C^{\mathrm{U}}\right)\right)
\end{aligned}
$$

If the transform is also non-overlapping, then the constraint can be expressed in terms of the contraction of the partition variable,

$$
\begin{aligned}
& \neg \operatorname{overlap}(T) \wedge A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}} \Longleftrightarrow \\
& \quad \forall P \in W\left(A \% V_{P} * P^{\% \mathrm{~T}}=A^{\mathrm{X}} \% V_{P} * P^{\% \mathrm{~T}}\right)
\end{aligned}
$$

So the subset of substrate histograms which are such that the formal equals the abstract may be partly generated from the integral congruent deltas which
preserve iso-independence but which are constrained to the partition component. In the case where the transform is non-overlapping,

$$
\begin{aligned}
& \text { _overlap }(T) \wedge A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}} \Longrightarrow \\
& \quad\left\{A: A \in \mathcal{A}_{U, V, z}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{x}}\right\} \\
& \supseteq \quad\left\{\left(A^{\mathrm{X}} \% V_{P}-D+I\right) *\left(\hat{A}^{\mathrm{X}} \%\left(V \backslash V_{P}\right)\right): A \in \mathcal{A}_{U, V, z},\right. \\
& \left.\quad P \in W, C \in P,(D, I) \in Q_{A \% V_{P}}, D^{\mathrm{F}} \subseteq C^{\mathrm{U}}, I^{\mathrm{F}} \subseteq C^{\mathrm{U}}\right\}
\end{aligned}
$$

### 3.15 Histogram expression lists

A histogram expression list $M \in \mathcal{L}\left(\mathcal{E}_{U}\right)$ may be applied to an argument histogram $A \in \mathcal{A}_{U}$ in sequence to produce a list of histograms. Define histogram expression list application $M(A) \in \mathcal{L}\left(\mathcal{A}_{U}\right)$ such that $M(A)_{1}=A,|M(A)|=$ $|M|+1$ and $\forall i \in\{1 \ldots|M|\}\left(M(A)_{i+1}=M_{i}\left(M(A)_{i}\right)\right)$. The application of a histogram expression list, $M(A)$, is (i) size conserving if the histograms have the same size as the argument, $\forall B \in \operatorname{set}(M(A))(\operatorname{size}(B)=\operatorname{size}(A))$, (ii) variables conserving if the histograms have the same variables as the argument, $\forall B \in \operatorname{set}(M(A))(\operatorname{vars}(B)=\operatorname{vars}(A))$, (iii) congruent if the histograms are congruent to the argument, $\forall B \in \operatorname{set}(M(A))$ (congruent $(B, A)$ ), (iv) independence conserving if the histograms are all independent, $\forall B \in$ $\operatorname{set}(M(A))\left(B=B^{\mathrm{X}}\right),(\mathrm{v})$ iso-independence conserving if the histograms are all in the same iso-independent component, $\operatorname{set}(M(A)) \subseteq Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, (vi) circular if the last histogram is equal to the first, $M(A)_{l}=A$ where $l=|M|+1$.

Given the initial histogram $A \in \mathcal{A}_{U}$ and two histogram expression lists $R, S \in$ $\mathcal{L}\left(\mathcal{E}_{U}\right)$ which are such that the final histograms are equal, $R(A)_{l}=S(A)_{m}$, where $l=|R(A)|$ and $m=|S(A)|$, then the longer list may be said to have smaller histogram expressions. That is, if $m>l$ then $S$ has smaller histogram expressions than $R$, and vice-versa.

Given a list of histograms $L \in \mathcal{L}(\mathcal{A})$ in the same set of variables $V, \forall B \in$ $\operatorname{set}(L)(\operatorname{vars}(B)=V)$, a list of deltas can be implied, $P=\left\{\left(L_{i}-L_{i+1}, L_{i+1}-\right.\right.$ $\left.\left.L_{i}\right): i \in\{1 \ldots|L|-1\}\right\} \in \mathcal{L}(\mathcal{A} \times \mathcal{A})$. Let $N_{(D, I)} \in \mathcal{E}_{U}$ be a histogram expression of delta $(D, I) \in \mathcal{A} \times \mathcal{A}$ having variables $\operatorname{vars}(D)=\operatorname{vars}(I)=V$. If the histogram expression list of deltas, $N_{P}=\left\{\left(i, N_{(D, I)}\right):(i,(D, I)) \in P\right\} \in$ $\mathcal{L}\left(\mathcal{E}_{U}\right)$, is applied to the first histogram in list $L$ then the list is recovered, $N_{P}\left(L_{1}\right)=L$. The delta histogram expression list, $N_{P}$, is congruent with respect to $L_{1}$.

Given two histogram expression lists of deltas $N_{P}, N_{Q} \in \mathcal{L}\left(\mathcal{E}_{U}\right)$, where $P, Q \in$
$\mathcal{L}(\mathcal{A} \times \mathcal{A})$, which are such that the final histograms are equal, $N_{P}(A)_{p}=$ $N_{Q}(A)_{q}$, where $p=\left|N_{P}(A)\right|$ and $q=\left|N_{Q}(A)\right|$, then the longer list may be said to have smaller delta expressions. That is, if $q>p$ then $N_{Q}$ has smaller delta expressions than $N_{P}$, and vice-versa.

If a histogram expression list $M \in \mathcal{L}\left(\mathcal{E}_{U}\right)$ is size conserving but not congruent with respect to initial histogram $A \in \mathcal{A}_{U}$ then in some cases there may exist a corresponding list of one functional transforms $X \in \mathcal{L}\left(\mathcal{T}_{U, f, 1}\right)$ such that $\forall i \in\{1 \ldots|M|\}\left(A * X_{i}=M(A)_{i+1}\right)$. In addition, if the histogram expression list, $M$, consists of transform histogram expressions, $N_{T} \in \mathcal{E}_{U}$ which are such that $N_{T}(B)=B * T$, constructed from a list of one functional transforms $Y \in \mathcal{L}\left(\mathcal{T}_{U, f, 1}\right)$ such that $M=\left\{\left(i, N_{T}\right):(i, T) \in Y\right\}$, then the transforms of $Y$ may be viewed as the changes between the transforms of $X$, $\left(X_{i}, X_{i-1}\right) \cong Y_{i}$. Again, the longer the list, $M(A)$, the smaller the transform histogram expressions, $\operatorname{set}(M)$.

Given a histogram expression list $M \in \mathcal{L}\left(\mathcal{E}_{U}\right)$ and an initial histogram $A \in$ $\mathcal{A}_{U}$, an orbit is the pair of histogram expression list applications initialised by the histogram itself, $A$, and the independent histogram, $A^{\mathrm{X}}$. That is, $\left(M(A), M\left(A^{\mathrm{X}}\right)\right)$. The lengths of the orbit lists are equal, $|M(A)|=\left|M\left(A^{\mathrm{X}}\right)\right|$. If it is the case that the orbit map is such that $\forall i \in\{1 \ldots l\}\left(M(A)_{i}^{\mathrm{X}}=\right.$ $M\left(A^{\mathrm{X}}\right)_{i}$ ), where $l=|M(A)|$, then the histogram expression list, $M$, is independence conserving, $\forall B \in \operatorname{set}\left(M\left(A^{\mathrm{X}}\right)\right)\left(B=B^{\mathrm{X}}\right)$, and the orbit is said to be an independent function, map(independent, $M(A))=M\left(A^{\mathrm{X}}\right)$. If $M(A)$ is iso-independence conserving, $\operatorname{set}(M(A)) \subseteq Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, and the orbit is an independent function then the histogram expressions are identity functions when applied to the independent argument, $\operatorname{set}\left(M\left(A^{\mathrm{X}}\right)\right)=\left\{A^{\mathrm{X}}\right\}$.

Let $N_{R} \in \mathcal{E}_{U}$ be a histogram expression of roll $R \in$ rolls having variables $V$. The orbit of the non-empty value roll list $J \in \mathcal{J}_{U, V}$ is functionally independent. Let $M_{J}=\left\{\left(i, N_{(V, w, s, t)^{\mathbb{R}}}\right):(i,(V, w, s, t)) \in J\right\}$, then orbit $\left(M_{J}(A), M_{J}\left(A^{\mathrm{X}}\right)\right)$ is such that $\left\{\left(i, M_{J}(A)_{i}^{\mathrm{X}}\right): i \in\{1 \ldots l\}\right\}=M_{J}\left(A^{\mathrm{X}}\right)$ and hence is an independent function. The value roll histogram expression list, $M_{J}$, is not iso-independence conserving with respect to $A$ and hence $M_{J}\left(A^{\mathrm{X}}\right)$ is not singleton, $\left|M_{J}\left(A^{\mathrm{X}}\right)\right|>1$.

The transforms of a non-circular fud $F \in \mathcal{F}$ can be arranged in a list of layer fuds $L=\operatorname{inverse}(\{(T, \operatorname{layer}(F, \operatorname{der}(T))): T \in F\}) \in \mathcal{L}(\mathrm{P}(F))$. A linear fud is a non-circular fud such that the underlying variables of the transforms in each layer fud are the derived variables of the layer fud immediately below, $\forall i \in\{2 \ldots|L|\}\left(\operatorname{und}\left(L_{i}\right) \subseteq \operatorname{der}\left(L_{i-1}\right)\right)$. Each of the layer fuds,
$\operatorname{set}(L) \in \mathrm{B}(F)$, can be combined into a single transform. Thus a linear fud may be represented as a histogram expression list of transform expressions, $M_{F}=\left\{\left(i, N_{G^{\mathrm{T}}}\right):(i, G) \in L\right\} \in \mathcal{L}\left(\mathcal{E}_{U}\right)$, which is such that $M_{F}(A)_{l}=A * F^{\mathrm{T}}$ where $\operatorname{und}(F)=\operatorname{vars}(A)$ and $l=\left|M_{F}(A)\right|$. The transform expressions of $M_{F}$ may be viewed as changes between the cumulative fuds at each layer. Let $T_{\{1 \ldots i\}}=\operatorname{transform}(\bigcup \operatorname{set}(\operatorname{take}(i, L)))=\{T: T \in F, i \leq \operatorname{layer}(F, \operatorname{der}(T))\}^{\mathrm{T}}$. Then $M_{F}(A)_{i}=A * T_{\{1 \ldots i\}}$ and $M_{F}(i)\left(A * T_{\{1 \ldots i-1\}}\right)=A * T_{\{1 \ldots i\}}$. If the layer transforms, $\left\{\left(i, G^{\mathrm{T}}\right):(i, G) \in L\right\} \in \mathcal{L}\left(\mathcal{T}_{U, \mathrm{f}, 1}\right)$, are non-overlapping, $\forall i \in\{1 \ldots|L|\}\left(\neg \operatorname{overlap}\left(L_{i}^{\mathrm{T}}\right)\right)$, then the application of the linear fud histogram expression list, $M_{F}\left(A^{\mathrm{X}}\right)$, is independence conserving, $M_{F}\left(A^{\mathrm{X}}\right)_{i} * L_{i}^{\mathrm{T}}=$ $\left(M_{F}\left(A^{\mathrm{X}}\right)_{i} * L_{i}^{\mathrm{T}}\right)^{\mathrm{X}}$. However, the orbit, $\left(M_{F}(A), M_{F}\left(A^{\mathrm{X}}\right)\right)$, is not necessarily an independent function. This is because it is not always the case that $\left(M_{F}(A)_{i} * L_{i}^{\mathrm{T}}\right)^{\mathrm{X}}=M_{F}\left(A^{\mathrm{X}}\right)_{i} * L_{i}^{\mathrm{T}}$ even if $L_{i}^{\mathrm{T}}$ is non-overlapping.

A non-circular fud $H \in \mathcal{F}$ that is not necessarily a linear fud can be viewed as a histogram expression list of histogram expressions that multiply the argument by the product of the histograms of the layer fud transforms. Let $N_{G} \in \mathcal{E}_{U}$, where $G \in \mathcal{F}$, be such that $N_{G}(B)=B * \prod_{(X, \cdot) \in G} X$. Then $M_{H}=$ $\left\{\left(i, N_{G}\right):(i, G) \in L\right\} \in \mathcal{L}\left(\mathcal{E}_{U}\right)$, where $L=\operatorname{inverse}(\{(T, \operatorname{layer}(H, \operatorname{der}(T))):$ $T \in H\}) \in \mathcal{L}(\mathrm{P}(H))$. Then $M_{H}$ is such that $M_{H}(A)_{l} \% \operatorname{der}(H)=A * H^{\mathrm{T}}$ where $l=\left|M_{H}(A)\right|$. The cardinality of the variables of the histograms of the applied list, $M_{H}(A)$, increase as derived variables are added in each layer, $\forall i \in\{1 \ldots l\}\left(\left|\operatorname{vars}\left(M_{H}(A)_{i+1}\right)\right| \geq\left|\operatorname{vars}\left(M_{H}(A)_{i}\right)\right|\right)$. The histogram expression list, $M_{H}$, is size conserving. Also the underlying histogram is conserved, $\left\{B \% V: B \in M_{H}(A)\right\}=\{A\}$ where $V=\operatorname{vars}(A)$.

A distinct decomposition $X \in \mathcal{D}_{\mathrm{d}, U}$ having underlying variables $V$ has a components tree, components $(U)(X) \in \operatorname{trees}\left(\mathrm{P}\left(V^{\mathrm{CS}}\right)\right)$. Let $L \in \mathcal{L}\left(\mathrm{P}\left(V^{\mathrm{CS}}\right)\right)$ be one of the paths, $L \in$ paths $(\operatorname{components}(U)(X))$. Each successive component on the path is a subset of the previous component, $\forall i \in\{1 \ldots|L|-$ $1\}\left(L_{i+1} \subseteq L_{i}\right)$. Thus there exists a delta histogram expression list $N_{L}=$ $\left\{\left(i, N_{(D, I)}\right): i \in\{1 \ldots|L|-1\},(D, I)=\left(L_{i}^{\mathrm{U}}-L_{i+1}^{\mathrm{U}}, \emptyset\right)\right\} \in \mathcal{L}\left(\mathcal{E}_{U}\right)$ where $N_{(D, I)} \in \mathcal{E}_{U}$ is a histogram expression of delta $(D, I) \in \mathcal{A} \times \mathcal{A}$ having variables $\operatorname{vars}(D)=\operatorname{vars}(I)=V$. The application to the first component $L_{1}$ recovers the components path, $N_{L}\left(L_{1}^{\mathrm{U}}\right)=\left\{\left(i, C^{\mathrm{U}}\right):(i, C) \in L\right\}$. If the path's components are cartesian sub-volumes, $\forall C \in \operatorname{set}(L)\left(C^{\mathrm{UF}}=C^{\mathrm{UXF}}\right)$, then the expression list application is independence conserving.

### 3.16 Distinct geometry sized cardinal substrate histograms

Let the set of sized cardinal substrate histograms $\mathcal{A}_{z}$ be the set of complete integral cardinal substrate histograms of size $z$ and dimension less than or equal to the size such that the independent is completely effective

$$
\mathcal{A}_{z}=\left\{A: A \in \mathcal{A}_{\mathrm{c}} \cap \mathcal{A}_{\mathrm{i}}, \operatorname{size}(A)=z,\left|V_{A}\right| \leq z, A^{\mathrm{U}}=A^{\mathrm{XF}}=A^{\mathrm{C}}\right\}
$$

where $A^{\mathrm{CS}}=\operatorname{cartesian}\left(U_{A}\right)\left(V_{A}\right)$ and $U_{A}=\operatorname{implied}(\operatorname{implied}(A))$ and $V_{A}=$ $\operatorname{vars}(A)$. There is no single system that contains all the substrate histograms. The infinite implied system, $U_{A}$ where $A \in \mathcal{A}_{z}$, contains the substrate variables, $V_{A} \subset \operatorname{vars}\left(U_{A}\right)$, and all the partition variables in the power functional definition set on $V_{A}, \forall F \in \mathcal{F}_{U_{A}, V_{A}}\left(\operatorname{vars}(F) \subset \operatorname{vars}\left(U_{A}\right)\right)$.

The set of substrate histograms of zero size is empty, $\mathcal{A}_{0}=\emptyset$. The set of substrate histograms of size one is a singleton of the mono-variate, monovalent histogram, $\mathcal{A}_{1}=\left\{\{\{(1,1)\}\}^{\mathrm{U}}\right\}$. The set of substrate histograms of a given size is finite, $\left|\mathcal{A}_{z}\right|<\infty$. The cardinality of substrate histograms of a given non-zero size has a lower bound implied by the strong compositions of the reductions

$$
\left|\mathcal{A}_{z}\right| \geq\left(\sum_{d \in\{1 \ldots z\}}|\mathrm{C}(\{1 \ldots d\}, z)|\right)^{z}=\left(\sum_{d \in\{1 \ldots z\}} \frac{(z-1)!}{(d-1)!(z-d)!}\right)^{z}
$$

The finite set of sized cardinal substrate histograms may be constructed explicitly by constructing cardinal systems and cardinal histories in the systems,

$$
\begin{aligned}
\mathcal{A}_{z}=\{A: x \in & \{1 \ldots z\}, V=\{1 \ldots x\}, \\
& U \in \prod_{v \in V}\{v\} \times\{\{1 \ldots u\}: u \in\{1 \ldots z\}\}, \\
& H \in\{1 \ldots z\}: \rightarrow V^{\mathrm{CS}} \\
& \left.A=\operatorname{histogram}(H)+V^{\mathrm{CZ}}, A^{\mathrm{XF}}=A^{\mathrm{C}}\right\}
\end{aligned}
$$

Each substrate histogram $A \in \mathcal{A}_{z}$ has $\left|V_{A}\right|!\prod_{w \in V_{A}}\left|U_{A}(w)\right|$ ! cardinal substrate permutations. These frame mappings partition the substrate histograms into equivalence classes having the same geometry. Let $P_{z}$ be the partition, $P_{z} \in \mathrm{~B}\left(\mathcal{A}_{z}\right)$, such that the components of $P_{z}$ are the equivalence classes by cardinal substrate permutation, $\forall C \in P_{z} \forall A \in C\left(|C|=\left|V_{A}\right|!\prod_{w \in V_{A}}\left|U_{A}(w)\right|\right)$.

Each of the substrate histograms in a component of $P_{z}$, that are equivalent by cardinal substrate permutation, have the same entropy, $\forall C \in P_{z} \forall A, B \in$ $C(\operatorname{entropy}(A)=\operatorname{entropy}(B))$.

A subset $X_{z} \subset \mathcal{A}_{z}$ of the substrate histograms can be defined such that each element of $X_{z}$ is uniquely chosen from a component of $P_{z}$, so that $\left|X_{z}\right|=\left|P_{z}\right|$ and $\exists M \in X_{z} \leftrightarrow P_{z} \forall(A, C) \in M(A \in C)$. The set $X_{z}$ of substrate histograms, which are distinct by geometry, then forms a support of a uniform probability function, $\left\{\left(A, 1 /\left|P_{z}\right|\right): A \in X_{z}\right\} \in \mathcal{P}$, upon which the calculation of expectation and variance of derived substrate structures could be made.

Instead of choosing a distinct geometry subset, $X_{z} \subset \mathcal{A}_{z}$, as the support, consider weighting a support of $\mathcal{A}_{z}$. Let the geometry-weighted function $Q_{z} \in \mathcal{A}_{z} \rightarrow \mathbf{Q}_{>0}$ be defined

$$
Q_{z}=\left\{\left(A, \frac{1}{\left|V_{A}\right|!\prod_{w \in V_{A}}\left|U_{A}(w)\right|!}\right): A \in \mathcal{A}_{z}\right\}
$$

which is such that $\forall C \in P \forall A \in C\left(Q_{z}(A)=1 /|C|\right)$. The geometry-weighted probability function $\hat{Q}_{z} \in \mathcal{P}$ is the normalised geometry-weighted function, $\hat{Q}_{z}=$ normalise $\left(Q_{z}\right)$. The geometry-weighted probability function, $\hat{Q}_{z}$, can be calculated without explicitly calculating $P_{z}$ itself. Using the weightings of the support of substrate histograms, $\mathcal{A}_{z}$, avoids the need to specify the selection of distinct substrate histograms, $X_{z}$, from the permutation equivalence classes, $P_{z}$.

If the substrate histograms are partitioned, for example to analyse correlations grouped by low or high entropy, then the partition should be a parent partition of $P_{z}$. That is, the substrate histograms partition should be independent of cardinal substrate permutation.

Define the central moment functions of the geometry-weighted probability function, $\hat{Q}_{z}$, that operate on real-valued functions of the sized cardinal substrate histograms, $\mathcal{A}_{z} \rightarrow \mathbf{R}$. In the cases where the real-valued functions are not left total, the geometry-weighted probability function $\hat{Q}_{z} \in \mathcal{P}$ is renormalised for the subset of the substrate histograms. Define the function $\operatorname{ex}(z) \in\left(\mathcal{A}_{z} \rightarrow \mathbf{R}\right) \rightarrow \mathbf{R}$ as

$$
\operatorname{ex}(z)(F):=\operatorname{expected}\left(\hat{R}_{z}\right)(F)
$$

where

$$
\hat{R}_{z}=\operatorname{normalise}\left(\left\{\left(A, \frac{1}{\left|V_{A}\right|!\prod_{w \in V_{A}}\left|U_{A}(w)\right|!}\right): A \in \operatorname{dom}(F)\right\}\right) \in \mathcal{P}
$$

and $F \neq \emptyset$. Define the function $\operatorname{var}(z) \in\left(\mathcal{A}_{z} \rightarrow \mathbf{R}\right) \rightarrow \mathbf{R}$ as

$$
\operatorname{var}(z)(F):=\operatorname{variance}\left(\hat{R}_{z}\right)(F)
$$

Define the function $\operatorname{cov}(z) \in\left(\mathcal{A}_{z} \rightarrow \mathbf{R}\right) \times\left(\mathcal{A}_{z} \rightarrow \mathbf{R}\right) \rightarrow \mathbf{R}$ as

$$
\operatorname{cov}(z)(F, G):=\operatorname{covariance}\left(\hat{R}_{z}\right)(F, G)
$$

where $\operatorname{dom}(F) \cap \operatorname{dom}(G) \neq \emptyset$ and

$$
\hat{R}_{z}=\operatorname{normalise}\left(\left\{\left(A, \frac{1}{\left|V_{A}\right|!\prod_{w \in V_{A}}\left|U_{A}(w)\right|!}\right): A \in \operatorname{dom}(F) \cap \operatorname{dom}(G)\right\}\right) \in \mathcal{P}
$$

Define the function $\operatorname{corr}(z) \in\left(\mathcal{A}_{z} \rightarrow \mathbf{R}\right) \times\left(\mathcal{A}_{z} \rightarrow \mathbf{R}\right) \rightarrow \mathbf{R}$ as

$$
\operatorname{corr}(z)(F, G):=\operatorname{correlation}\left(\hat{R}_{z}\right)(F, G)
$$

The correlation is defined only if it is the case that both variances are nonzero, $\operatorname{var}(z)(\operatorname{filter}(\operatorname{dom}(G), F))>0$ and $\operatorname{var}(z)(\operatorname{filter}(\operatorname{dom}(F), G))>0$.

Also, let the arithmetic binary operators on reals, $(+),(-),(\times),(/) \in \mathbf{R}^{2} \rightarrow$ $\mathbf{R}$, be lifted to operators on real-valued functions. That is, the addition operator is lifted $F+G:=\left\{\left(x, F_{x}+G_{x}\right): x \in \operatorname{dom}(F) \cap \operatorname{dom}(G)\right\}$. The subtraction operator is lifted, $F-G:=\left\{\left(x, F_{x}-G_{x}\right): x \in \operatorname{dom}(F) \cap \operatorname{dom}(G)\right\}$. The multiplication operator is lifted, $F * G:=\left\{\left(x, F_{x} \times G_{x}\right): x \in \operatorname{dom}(F) \cap\right.$ $\operatorname{dom}(G)\}$. The divison operator is lifted $F / G:=\left\{\left(x, F_{x} / G_{x}\right): x \in \operatorname{dom}(F) \cap\right.$ $\left.\operatorname{dom}(G), G_{x} \neq 0\right\}$.

### 3.17 Distribution over histograms

The set of distributions $\mathcal{Q}$ is a set of positive rational valued finite functions of integral histograms that have common variables. That is, $\mathcal{Q} \subset \mathcal{A}_{\mathrm{i}} \rightarrow \mathbf{Q} \geq 0$ such that $\forall Q \in \mathcal{Q}(|Q|<\infty)$ and $\forall Q \in \mathcal{Q} \forall A \in \operatorname{dom}(Q)(\operatorname{vars}(A)=\operatorname{vars}(Q))$ where vars $\in \mathcal{Q} \rightarrow \mathrm{P}(\mathcal{V})$ is defined $\operatorname{as} \operatorname{vars}(Q):=\bigcup\{\operatorname{vars}(A): A \in \operatorname{dom}(Q)\}$.

The elements of the range of a distribution $Q \in \mathcal{Q}, \operatorname{ran}(Q)$, are called the frequencies. The domain of $Q, \operatorname{dom}(Q)$, is called the support. The elements of the support are called sample histograms if there is associated with $Q$ a distribution histogram $E$ having the same variables, $\operatorname{vars}(E)=\operatorname{vars}(Q)$, and some non-zero integral size $z_{E} \in \mathbf{N}_{>0}$. A draw is a pair of (i) the distribution histogram, $E$, and (ii) some non-zero integral size $z \in \mathbf{N}_{>0},(E, z) \in \mathcal{A}_{\mathbf{i}} \times \mathbf{N}_{>0}$.

Define the set of complete distributions $\mathcal{Q}_{U} \subset \mathcal{Q} \cap\left(\mathcal{A}_{U} \rightarrow \mathbf{Q}_{\geq 0}\right)$ such that all the sample histograms of the domain are complete in system $U$

$$
\forall Q \in \mathcal{Q}_{U} \forall A \in \operatorname{dom}(Q)\left(A^{\mathrm{U}}=A^{\mathrm{C}}\right)
$$

Define the set of congruent distributions of integral size $z \in \mathbf{N}, \mathcal{Q}_{z} \subset \mathcal{Q}$, such that all the sample histograms of the domain are congruent

$$
\forall Q \in \mathcal{Q}_{z} \forall A \in \operatorname{dom}(Q)(\operatorname{size}(A)=z)
$$

Define the set of constructible distributions which have integral frequencies, $\mathcal{Q}_{\mathrm{i}} \subset \mathcal{Q}$,

$$
\mathcal{Q}_{\mathrm{i}}=\{Q: Q \in \mathcal{Q}, \operatorname{ran}(Q) \subset \mathbf{N}\}
$$

The histograms of shuffles of a history $H$ that is congruent to the support of a congruent distribution $Q \in \mathcal{Q}_{z}, \operatorname{vars}(H)=\operatorname{vars}(Q)$ and $|H|=z$, may also be in the support because they are congruent and integral, $\{\operatorname{histogram}(G): G \in$ $\operatorname{shuffles}(H)\} \subset \mathcal{A}_{\mathrm{i}}$. The independent histograms of histograms in the support may be in the support where they are integral, $\left\{A^{\mathrm{X}}: A \in \operatorname{dom}(Q)\right\} \cap \mathcal{A}_{\mathrm{i}}$.

The integral congruent support $\mathcal{A}_{U, \mathrm{i}, V, z}$ of size $z$ and variables $V$ in system $U$ is the finite set of all complete congruent integral histograms

$$
\mathcal{A}_{U, \mathrm{i}, V, z}=\left\{A: A \in \mathcal{A}_{U, \mathrm{i}}, A^{\mathrm{U}}=V^{\mathrm{C}}, \operatorname{size}(A)=z\right\}
$$

The integral congruent support can be constructed recursively, $\mathcal{A}_{U, \mathrm{i}, V, z}=\{A+$ $\left.\{S\}^{\mathrm{U}}: A \in \mathcal{A}_{U, \mathrm{i}, V, z-1}, S \in V^{\mathrm{CS}}\right\}$ where $\mathcal{A}_{U, \mathrm{i}, V, 0}=\left\{V^{\mathrm{CZ}}\right\}$. The cardinality of the integral congruent support is the cardinality of weak compositions $\left|\mathrm{C}^{\prime}\left(V^{\mathrm{C}}, z\right)\right|$

$$
\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right|=\frac{(z+v-1)!}{z!(v-1)!}
$$

where $v=\left|V^{\mathrm{C}}\right|$.
A stuffed congruent distribution $Q$ has a domain of the integral congruent support, $Q \in\left(\mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathrm{Q}_{\geq 0}\right) \cap \mathcal{Q}_{U} \cap \mathcal{Q}_{z}$.

The multiple support $\mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}}$ of maximum count $z$ and variables $V$ in system $U$ is the finite set of all complete integral histograms

$$
\mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}}=\left\{A: A \in \mathcal{A}_{U, \mathrm{i}}, A^{\mathrm{U}}=V^{\mathrm{C}}, \operatorname{ran}(A) \subseteq\{0 \ldots z\}\right\}
$$

The minimum size of the multiple support histograms is zero and the maximum size is $v z$ where $v=\left|V^{\mathrm{C}}\right|$. That is, $\forall A \in \mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}}(0 \leq \operatorname{size}(A) \leq v z)$.

The maximum count is $\forall A \in \mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}}(\operatorname{maxr}(A) \leq z)$. The histograms of a multiple support are not all congruent, but the integral congruent supports of sizes less than or equal to $z$ are subsets, $\forall i \in\{0 \ldots z\}\left(\mathcal{A}_{U, \mathrm{i}, V, i} \subset\right.$ $\left.\mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}}\right)$. The multiple supports of maximum counts less than $z$ are subsets, $\forall i \in\{0 \ldots z-1\}\left(\mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots i\}} \subset \mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}}\right)$. The cardinality of the multiple support is $\left|\mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}}\right|=(z+1)^{v}$.

A distribution $Q \in \mathcal{Q}$ is a probability distribution if it is in the set of probability functions, $Q \in \mathcal{P}$. That is, the sum of the range is $1, \forall Q \in$ $\mathcal{Q} \cap \mathcal{P}(\operatorname{sum}(Q)=1)$.

The positive rational sum of a distribution $Q$ is $\operatorname{sum}(Q) \in \mathbf{Q}_{\geq 0}$.
Define the modal set of a distribution as modes $\in \mathcal{Q} \rightarrow \mathrm{P}(\mathcal{A})$ as

$$
\operatorname{modes}(Q):=\operatorname{maxd}(Q)
$$

Define the mean histogram of a distribution as mean $\in \mathcal{Q} \rightarrow \mathcal{A}$ as

$$
\operatorname{mean}(Q):=\sum(\operatorname{scalar}(f) * A:(A, f) \in Q) / \operatorname{scalar}(\operatorname{sum}(Q))
$$

The mean is undefined if the frequencies sum to zero, $\operatorname{sum}(Q)=0$. The mean of a complete distribution is a complete histogram, $M^{\mathrm{U}}=M^{\mathrm{C}}$ where $M=$ mean $(Q)$ and $Q \in \mathcal{Q}_{U}$. The mean of a congruent distribution $Q \in \mathcal{Q}_{z}$ has size equal to $z, \operatorname{size}(M)=z$, and so is congruent to the sample histograms in the support, $\forall Q \in \mathcal{Q}_{z} \forall A \in \operatorname{dom}(Q)$ (congruent $(A, M)$ ). The mean histogram is not necessarily integral and so is not necessarily in the support, $M \notin \mathcal{A}_{\mathrm{i}} \Longrightarrow$ $M \notin \operatorname{dom}(Q)$. If $Q$ is a complete probability distribution, $Q \in \mathcal{Q}_{U} \cap \mathcal{P}$, then the mean histogram is the histogram of expected counts

$$
\operatorname{mean}(Q)=\left\{\left(S, \operatorname{expected}(Q)\left(\left\{\left(A, A_{S}\right): A \in \operatorname{dom}(Q)\right\}\right)\right): S \in V^{\mathrm{CS}}\right\}
$$

where $V=\operatorname{vars}(Q)$.
Define the variance of the counts of a state in a complete distribution as $\operatorname{var}(U) \in \mathcal{Q}_{U} \rightarrow\left(\mathcal{S}_{U} \rightarrow \mathbf{Q}_{\geq 0}\right)$ as
$\operatorname{var}(U)(Q):=\left\{\left(S, \sum\left(f / \operatorname{sum}(Q) \times\left(A_{S}-M_{S}\right)^{2}:(A, f) \in Q\right)\right): S \in V^{\mathrm{CS}}\right\}$
where $V=\operatorname{vars}(Q)$ and $M=\operatorname{mean}(Q)$. The variance is undefined if the frequencies sum to zero, $\operatorname{sum}(Q)=0$. Note that in the case of uniform distribution, $|\operatorname{ran}(Q)|=1$, the variance of each state, $\operatorname{var}(U)(Q)(S)$, is the
population variance, not the sample variance. Although the range of the variance is a subset of the positive rationals, it is not treated here as a histogram, but grouped along with the higher central moments of the distribution which are not necessarily positive. If $Q$ is a probability distribution, $Q \in \mathcal{P}$, then the variance is the variance of the counts

$$
\operatorname{var}(U)(Q)=\left\{\left(S, \text { variance }(Q)\left(\left\{\left(A, A_{S}\right): A \in \operatorname{dom}(Q)\right\}\right)\right): S \in V^{\mathrm{CS}}\right\}
$$

Similarly the covariance of the counts of a pair of states in a complete probability distribution is $\operatorname{cov}(U) \in\left(\mathcal{Q}_{U} \cap \mathcal{P}\right) \rightarrow\left(\left(\mathcal{S}_{U} \times \mathcal{S}_{U}\right) \rightarrow \mathbf{Q}\right)$

$$
\begin{aligned}
& \operatorname{cov}(U)(Q):=\{((S, R), \\
& \left.\quad \operatorname{covariance}(Q)\left(\left\{\left(A, A_{S}\right): A \in \operatorname{dom}(Q)\right\}, \quad\left\{\left(A, A_{R}\right): A \in \operatorname{dom}(Q)\right\}\right)\right): \\
& \left.\quad S, R \in V^{\mathrm{CS}}\right\}
\end{aligned}
$$

The moment generating function of the counts of states having moment parameters $T \in \mathcal{S} \rightarrow \mathbf{R}$ in a probability distribution is mgf $\in(\mathcal{Q} \cap \mathcal{P}) \rightarrow((\mathcal{S} \rightarrow$ $\mathbf{R}) \rightarrow \mathbf{R}$ )

$$
\operatorname{mgf}(Q)(T):=\operatorname{expected}(Q)\left(\left\{\left(A, \exp \left(\sum_{S \in A^{\mathrm{S}}} T_{S} A_{S}\right)\right): A \in \operatorname{dom}(Q)\right\}\right)
$$

where $\operatorname{dom}(T)=\operatorname{dom}(\operatorname{mean}(Q))$ and $\exp$ is the exponential function.

### 3.17.1 Historical distributions

Consider the subsets of non-empty history $H_{E} \in \mathcal{H} \backslash\{\emptyset\}$ of cardinality $z,\left\{G: G \subseteq H_{E},|G|=z\right\} \subset \mathcal{H}$. The historical distribution drawn without replacement from $H_{E}$ is the distribution of these sample histories over the histograms,

$$
\operatorname{count}\left(\left\{(\operatorname{histogram}(G), G): G \subseteq H_{E},|G|=z\right\}\right) \in \mathcal{Q}_{z}
$$

where histogram $(G):=\left\{(S,|C|):(S, C) \in G^{-1}\right\}$, and $\operatorname{count}(X):=\{(a, \mid\{c:$ $(b, c) \in X, b=a\} \mid): a \in \operatorname{dom}(X)\}$.

The historical distribution can equally well be defined in terms of a subset of the histogram function. Let $I \subset$ histogram be the histogram valued function of all possible subsets of the history $H_{E}$ of cardinality $z$,

$$
I=\left\{(G, \text { histogram }(G)): G \subseteq H_{E},|G|=z\right\}
$$

Then the historical distribution is $\left\{(A,|D|):(A, D) \in I^{-1}\right\} \in \mathcal{Q}_{z}$.

The event identifiers, $\operatorname{dom}\left(H_{E}\right)$, serve merely to make the subsets unique so the distribution may be defined in terms of an arbitrarily constructed history of the distribution histogram $E=$ histogram $\left(H_{E}\right)$, count $(\{(\operatorname{histogram}(G), G)$ : $G \subseteq \operatorname{history}(E),|G|=z\})=\operatorname{count}\left(\left\{(\operatorname{histogram}(G), G): G \subseteq H_{E},|G|=\right.\right.$ $z\})$. The set of historical distributions $Q_{\mathrm{h}} \in \mathcal{A}_{\mathrm{i}} \times \mathbf{N} \rightarrow \mathcal{Q}_{\mathrm{i}}$ is the set of constructible distributions parameterised by the without replacement draw $(E, z) \in \mathcal{A}_{\mathbf{i}} \times \mathbf{N}$
$Q_{\mathrm{h}}(E, z)=\operatorname{count}(\{(\operatorname{histogram}(G), G): G \subseteq \operatorname{history}(E),|G|=z\}) \in \mathcal{Q}_{\mathrm{i}} \cap \mathcal{Q}_{z}$
The size of the distribution histogram is $z_{E}=\operatorname{size}(E)=\left|H_{E}\right|>0$. The draw size must be less than or equal to the distribution size, $z \leq z_{E}$. All of the sample histograms are less than or equal to the distribution histogram, $\forall A \in$ $\operatorname{dom}\left(Q_{\mathrm{h}}(E, z)\right)(A \leq E)$. The maximum count in the sample histograms is less than or equal to the draw size $\forall A \in \operatorname{dom}\left(Q_{\mathrm{h}}(E, z)\right)(\operatorname{maxr}(A) \leq z)$.

The without replacement character of the draw can be shown by a recursive definition that draws one event from the implied history at each step. Define drawnr $\in \mathcal{H} \times \mathbf{N} \times \mathcal{H} \rightarrow \mathrm{P}(\mathcal{H})$ as drawnr $(H, z, G):=\bigcup\{d r a w n r(H \backslash$ $\{e\}, z-1, G \cup\{e\}): e \in H\}$ where drawnr $(H, 0, G):=\{G\}$. Then $Q_{\mathrm{h}}(E, z)=$ count $(\{(\operatorname{histogram}(X), X): X \in \operatorname{drawnr}($ history $(E), z, \emptyset)\})$.

The sum of a historical distribution $Q_{\mathrm{h}}(E, z)$ is the combination of $z$ drawn from $z_{E}$

$$
\operatorname{sum}\left(Q_{\mathrm{h}}(E, z)\right)=\binom{z_{E}}{z}=\frac{z_{E}!}{z!\left(z_{E}-z\right)!} \in \mathbf{N}_{>0}
$$

Each frequency of a sample histogram $A \in \operatorname{dom}\left(Q_{\mathrm{h}}(E, z)\right)$ in a historical distribution is the product of the combinations in which the subset $A_{S}$ is drawn from $E_{S}$ for all of the states

$$
Q_{\mathrm{h}}(E, z)(A)=\prod_{S \in A^{\mathrm{S}}}\binom{E_{S}}{A_{S}}=\prod_{S \in A^{\mathrm{S}}} \frac{E_{S}!}{A_{S}!\left(E_{S}-A_{S}\right)!} \in \mathbf{N}_{>0}
$$

If the historical distribution histogram $E$ is incomplete, that is, it does not contain all of its cartesian states, $E^{\mathrm{U}} \neq E^{\mathrm{C}}$, for some system $U$, then all of the element histograms in the support must necessarily be incomplete in that system, $E^{\mathrm{U}} \neq E^{\mathrm{C}} \Longrightarrow \forall z \in\left\{1 \ldots z_{E}\right\} \forall A \in \operatorname{dom}\left(Q_{\mathrm{h}}(E, z)\right)\left(A^{\mathrm{U}} \neq A^{\mathrm{C}}\right)$. Even if the historical distribution histogram is complete, $E^{\mathrm{U}}=E^{\mathrm{C}}$, many of its element histograms would be incomplete because each must have non-zero counts, $\operatorname{minr}(A)>0$. In fact, only when the size $z$ is greater than or equal to the distribution histogram's volume, $z \geq\left|E^{\mathrm{C}}\right|$, can any of the element
histograms be complete, $z<\left|E^{\mathrm{C}}\right| \Longrightarrow \forall A \in \operatorname{dom}\left(Q_{\mathrm{h}}(E, z)\right)\left(A^{\mathrm{U}} \neq A^{\mathrm{C}}\right)$.
Furthermore, the support of a historical distribution cannot equal the integral congruent support, $\operatorname{dom}\left(Q_{\mathrm{h}}(E, z)\right) \neq \mathcal{A}_{U, \mathrm{i}, V, z}$ where $V=\operatorname{vars}(E)$, because the integral congruent support contains histograms with zero counts, $\exists A \in \mathcal{A}_{U, \mathrm{i}, V, z}(0 \in \operatorname{ran}(A))$. The stuffed historical distribution $Q_{\mathrm{h}, U}(E, z) \in$ $\left(\mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{Q}_{U} \cap \mathcal{Q}_{z}$ can be constructed from a historical distribution, $Q_{\mathrm{h}}(E, z)$, by completing the support histograms and stuffing with the disjoint subset of the integral congruent support with zero frequencies

$$
\begin{aligned}
Q_{\mathrm{h}, U}(E, z)= & \left\{\left(A+A^{\mathrm{CZ}}, f\right):(A, f) \in Q_{\mathrm{h}}(E, z)\right\} \cup \\
& \left(\mathcal{A}_{U \mathrm{i}, \mathrm{i},, z} \backslash\left\{A+A^{\mathrm{CZ}}: A \in \operatorname{dom}\left(Q_{\mathrm{h}}(E, z)\right)\right\}\right) \times\{0\}
\end{aligned}
$$

where $V=\operatorname{vars}(E)$. The stuffed historical distribution support equals the integral congruent support, $\operatorname{dom}\left(Q_{\mathrm{h}, U}(E, z)\right)=\mathcal{A}_{U, \mathrm{i}, V, z}$, so each of the histograms in the support is unique by histogram equivalence

$$
\forall A, B \in \operatorname{dom}\left(Q_{\mathrm{h}, U}(E, z)\right)(A \equiv B \Longrightarrow A=B)
$$

The sum of a stuffed historical distribution equals the sum of its corresponding historical distribution

$$
\operatorname{sum}\left(Q_{\mathrm{h}, U}(E, z)\right)=\operatorname{sum}\left(Q_{\mathrm{h}}(E, z)\right)=\frac{z_{E}!}{z!\left(z_{E}-z\right)!}
$$

The stuffed historical distribution can be defined explicitly

$$
Q_{\mathrm{h}, U}(E, z)=\left\{\left(A, \operatorname{if}\left(A \leq E, \prod_{S \in A^{\mathrm{FS}}} \frac{E_{S}!}{A_{S}!\left(E_{S}-A_{S}\right)!}, 0\right)\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
$$

The stuffed historical probability distribution $\hat{Q}_{\mathrm{h}, U}(E, z) \in\left(\mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow\right.$ $\left.\mathrm{Q}_{\geq 0}\right) \cap \mathcal{Q}_{U} \cap \mathcal{Q}_{z} \cap \mathcal{P}$ is defined

$$
\begin{aligned}
\hat{Q}_{\mathrm{h}, U}(E, z) & =\text { normalise }\left(Q_{\mathrm{h}, U}(E, z)\right) \\
& =\left\{\left(A, f / \operatorname{sum}\left(Q_{\mathrm{h}, U}(E, z)\right)\right):(A, f) \in Q_{\mathrm{h}, U}(E, z)\right\}
\end{aligned}
$$

where $z_{E}>0$ and $z>0$. The stuffed historical probability distribution is a multivariate hypergeometric distribution. The sum of the stuffed historical probability distribution is one

$$
\operatorname{sum}\left(\hat{Q}_{\mathrm{h}, U}(E, z)\right)=1
$$

The mean of the stuffed historical probability distribution is

$$
\operatorname{mean}\left(\hat{Q}_{\mathrm{h}, U}(E, z)\right)=\operatorname{scalar}(z) * P
$$

where $P=E / \operatorname{scalar}\left(z_{E}\right)+E^{\mathrm{CZ}}$. The mean is congruent to the histograms of the integral congruent support, $\forall A \in \mathcal{A}_{U, i, V, z}$ (congruent $(A, M)$ ), where $M=\operatorname{mean}\left(\hat{Q}_{\mathrm{h}, U}(E, z)\right)$. If the mean is integral then it is in the support, $M \in \mathcal{A}_{\mathbf{i}} \Longrightarrow M \in \mathcal{A}_{U, \mathrm{i}, V, z}$.

The variance of state $S$ in the stuffed historical probability distribution is

$$
\operatorname{var}(U)\left(\hat{Q}_{\mathrm{h}, U}(E, z)\right)(S)=z \frac{z_{E}-z}{z_{E}-1} P_{S}\left(1-P_{S}\right)
$$

The covariance of a pair of states $(S, R)$, where $R \neq S$, in the stuffed historical probability distribution is

$$
\operatorname{cov}(U)\left(\hat{Q}_{\mathrm{h}, U}(E, z)\right)((S, R))=-z \frac{z_{E}-z}{z_{E}-1} P_{S} P_{R}
$$

### 3.17.2 Multinomial distributions

Let the power of a set, $X^{n}$, be defined as the set of all n-tuples of the elements of the set, $X^{n}=\prod(\{1 \ldots n\} \times\{X\})=\{L: L \in \mathcal{L}(X),|L|=n\}$. The cardinality of the power is $\left|X^{n}\right|=|X|^{n}$.

Consider the set of lists of the events drawn with replacement from non-empty history $H_{E} \in \mathcal{H} \backslash\{\emptyset\}$ of cardinality $z, H_{E}^{z}=\left\{L: L \in \mathcal{L}\left(H_{E}\right),|L|=z\right\}$. Construct from this set, $H_{E}^{z}$, a set of sample histories of cardinality $z$ with new event identifiers modified to include the position, $X=\left\{G: L \in H_{E}^{z}, G=\right.$ $\{((i, x), S):(i,(x, S)) \in L\}\} \subset \mathcal{H}$. The set of sample histories, $X$, is bijective with the set of event lists, $|X|=\left|H_{E}^{z}\right|$. The multinomial distribution drawn with replacement from $H_{E}$ is the distribution of these sample histories over the histograms,

$$
\operatorname{count}(\{(\operatorname{histogram}(G), G): G \in X\}) \in \mathcal{Q}_{z}
$$

The distribution is the same for all histories for which $E=\operatorname{histogram}\left(H_{E}\right)$ is the distribution histogram, count $\left(\left\{(\operatorname{histogram}(G), G): L \in \operatorname{history}(E)^{z}, G=\right.\right.$ $\{((i, x), S):(i,(x, S)) \in L\}\})=\operatorname{count}(\{(\operatorname{histogram}(G), G): G \in X\})$. The set of multinomial distributions $Q_{\mathrm{m}} \in \mathcal{A}_{\mathrm{i}} \times \mathbf{N} \rightarrow \mathcal{Q}_{\mathrm{i}}$ is the set of constructible distributions parameterised by the with replacement draw $(E, z) \in \mathcal{A}_{\mathrm{i}} \times \mathbf{N}$

$$
\begin{aligned}
& Q_{\mathrm{m}}(E, z)=\operatorname{count}(\{(\operatorname{histogram}(G), G): \\
& \left.\left.\quad L \in \operatorname{history}(E)^{z}, G=\{((i, x), S):(i,(x, S)) \in L\}\right\}\right) \in \mathcal{Q}_{\mathrm{i}} \cap \mathcal{Q}_{z}
\end{aligned}
$$

The distribution can also be written, $Q_{\mathrm{m}}(E, z)=\operatorname{count}(\{(\operatorname{count}(\{(S, i)$ : $\left.\left.(i,(\cdot, S)) \in L\}), L): L \in \operatorname{history}(E)^{z}\right\}\right)$. The size of the distribution histogram is $z_{E}=\operatorname{size}(E)=\left|H_{E}\right|$. The draw size, $z$, is not constrained by the distribution size, $z_{E}, z \in \mathbf{N}$. The maximum count in the sample histograms is less than or equal to the draw size $\forall A \in \operatorname{dom}\left(Q_{\mathrm{m}}(E, z)\right)(\operatorname{maxr}(A) \leq z)$.

The multinomial distribution can be constructed in steps of with replacement draws of one event. This contrasts with the non replacement draw of the historical distribution. Define drawwr $\in \mathcal{H} \times \mathbf{N} \times \mathcal{H} \rightarrow \mathrm{P}(\mathcal{H})$ as drawwr $(H, z, G):=\bigcup\{\operatorname{drawwr}(H, z-1, G \cup\{((z, x), S)\}):(x, S) \in H\}$ where drawwr $(H, 0, G):=\{G\}$. Then the multinomial distribution is such that $Q_{\mathrm{m}}(E, z)=\operatorname{count}(\{(\operatorname{histogram}(X), X): X \in \operatorname{drawwr}($ history $(E), z, \emptyset)\})$. Here the event identifier is prefixed with a sequence position, so that

$$
\mid \operatorname{drawwr}(\text { history }(E), z, \emptyset)\left|=\left|H_{E}^{z}\right|\right.
$$

The sum of a multinomial distribution $Q_{\mathrm{m}}(E, z)$ is equal to $\left|H_{E}^{z}\right|=\left|H_{E}\right|^{z}$

$$
\operatorname{sum}\left(Q_{\mathrm{m}}(E, z)\right)=z_{E}^{z} \in \mathbf{N}
$$

Each frequency of a sample histogram $A \in \operatorname{dom}\left(Q_{\mathrm{m}}(E, z)\right)$ in a multinomial distribution is the product of (i) the multinomial coefficient which is the combination in which the subsets of cardinality $A_{S}$ are chosen from a set of cardinality $z$ for all states, and (ii) the cardinality of the lists drawn with replacement from $H_{E}$ equivalent to a permutation defined by some order on the states $D \in \operatorname{enums}\left(A^{S}\right)$, $\operatorname{concat}\left(\left\{\left(i,\left\{1 \ldots A_{S}\right\} \times\{S\}\right):(S, i) \in D\right\}\right) \in$ $\left\{G: L \in H_{E}^{z}, G=\{(i, S):(i,(\cdot, S)) \in L\}\right\}$

$$
Q_{\mathrm{m}}(E, z)(A)=\frac{z!}{\prod_{S \in A^{\mathrm{s}}} A_{S}!} \prod_{S \in A^{\mathrm{s}}} E_{S}^{A_{S}} \in \mathbf{N}_{>0}
$$

The generalised multinomial distribution $Q_{\mathrm{m}, U}(E, z) \in\left(\mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathrm{Q}_{\geq 0}\right) \subset$ $\mathcal{Q}_{U} \cap \mathcal{Q}_{z}$ is a stuffed congruent distribution that can be constructed from a multinomial distribution, $Q_{\mathrm{m}}(E, z)$, by completing the support histograms and stuffing with the disjoint subset of the integral congruent support with zero frequencies

$$
\begin{aligned}
Q_{\mathrm{m}, U}(E, z)= & \left\{\left(A+A^{\mathrm{CZ}}, f\right):(A, f) \in Q_{\mathrm{m}}(E, z)\right\} \cup \\
& \left(\mathcal{A}_{U \mathrm{i}, V, z} \backslash\left\{A+A^{\mathrm{CZ}}: A \in \operatorname{dom}\left(Q_{\mathrm{m}}(E, z)\right)\right\}\right) \times\{0\}
\end{aligned}
$$

where $V=\operatorname{vars}(E)$. The generalised multinomial distribution support equals the integral congruent support, $\operatorname{dom}\left(Q_{\mathrm{m}, U}(E, z)\right)=\mathcal{A}_{U, \mathrm{i}, V, z}$, so each of the histograms in the support is unique by histogram equivalence

$$
\forall A, B \in \operatorname{dom}\left(Q_{\mathrm{m}, U}(E, z)\right)(A \equiv B \Longrightarrow A=B)
$$

The sum of a generalised multinomial distribution equals the sum of its corresponding multinomial distribution

$$
\operatorname{sum}\left(Q_{\mathrm{m}, U}(E, z)\right)=\operatorname{sum}\left(Q_{\mathrm{m}}(E, z)\right)=z_{E}^{z}
$$

The definition of the set of generalised multinomial distributions is generalised to allow parameterisation by non-integral distribution histograms, $Q_{\mathrm{m}, U} \in \mathcal{A} \times \mathbf{N} \rightarrow \mathcal{Q}$. Contrast this to parameterisation by draw, $\mathcal{A}_{\mathrm{i}} \times \mathbf{N}$, which is defined only for integral distribution histograms. Define the generalised multinomial distribution, $Q_{\mathrm{m}, U}(E, z) \in\left(\mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathbf{Q}_{\geq 0}\right) \subset \mathcal{Q}_{U} \cap \mathcal{Q}_{z}$, explicitly as

$$
Q_{\mathrm{m}, U}(E, z):=\left\{\left(A, \frac{z!}{\prod_{S \in A^{\mathrm{s}}} A_{S}!} \prod_{S \in A^{\mathrm{s}}} E_{S}^{A_{S}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
$$

where $V=\operatorname{vars}(E)$ and $E$ is complete $E^{\mathrm{U}}=E^{\mathrm{C}}$. Define $0^{0}=0!=1!=1$ so that the multinomial coefficient is defined for zero $A_{S}$. Define $0^{x}=0$ where $x \neq 0$. The multinomial coefficient is integral and is greater than or equal to one

$$
\forall A \in \mathcal{A}_{U, \mathrm{i}, V, z}\left(\frac{z!}{\prod_{S \in A^{\mathrm{s}}} A_{S}!} \in \mathbf{N}_{>0}\right)
$$

The generalised multinomial probability distribution $\hat{Q}_{\mathrm{m}, U}(E, z) \in\left(\mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow\right.$ $\left.\mathrm{Q}_{\geq 0}\right) \cap \mathcal{Q}_{U} \cap \mathcal{Q}_{z} \cap \mathcal{P}$ is defined

$$
\begin{aligned}
\hat{Q}_{\mathrm{m}, U}(E, z) & =\text { normalise }\left(Q_{\mathrm{m}, U}(E, z)\right) \\
& =\left\{\left(A, f / \operatorname{sum}\left(Q_{\mathrm{m}, U}(E, z)\right)\right):(A, f) \in Q_{\mathrm{m}, U}(E, z)\right\} \\
& =\left\{\left(A, \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}}\left(\frac{E_{S}}{z_{E}}\right)^{A_{S}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
\end{aligned}
$$

where $\operatorname{sum}\left(Q_{\mathrm{m}, U}(E, z)\right)>0$ which implies that $z_{E}>0$ and $z>0$. The sum of the generalised multinomial probability distribution is one

$$
\operatorname{sum}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)=\sum_{A \in \mathcal{A}_{U, i, V, z}} \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}}\left(\frac{E_{S}}{z_{E}}\right)^{A_{S}}=1
$$

The generalised multinomial probability distribution may be expressed in terms of a probability distribution histogram $\hat{E}=E / \operatorname{scalar}\left(z_{E}\right) \in \mathcal{A} \cap \mathcal{P}$,

$$
\hat{Q}_{\mathrm{m}, U}(E, z)=\left\{\left(A, z!\prod_{S \in A^{\mathrm{S}}} \frac{\hat{E}_{S}^{A_{S}}}{A_{S}!}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
$$

The frequencies of the generalised multinomial probability distribution can be approximated by means of the Stirling approximation

$$
\hat{Q}_{\mathrm{m}, U}(E, z)(A)=z!\prod_{S \in A^{\mathrm{S}}} \frac{\hat{E}_{S}^{A_{S}}}{A_{S}!} \approx \prod_{S \in A^{\mathrm{FS}}}\left(\frac{\hat{E}_{S}}{\hat{A}_{S}}\right)^{A_{S}}
$$

where $\hat{A}=\operatorname{resize}(1, A)$. Compare this approximation to the same term for a scaled draw size $k z$ and scaled sample histogram $\operatorname{scalar}(k) * A$ where $k \in \mathbf{N}_{>0}$

$$
\begin{aligned}
\hat{Q}_{\mathrm{m}, U}(E, k z)(\operatorname{scalar}(k) * A) & =(k z)!\prod_{S \in A^{\mathrm{S}}} \frac{\hat{E}_{S}^{k A_{S}}}{\left(k A_{S}\right)!} \\
& \approx\left(\prod_{S \in A^{\mathrm{FS}}}\left(\frac{\hat{E}_{S}}{\hat{A}_{S}}\right)^{A_{S}}\right)^{k} \\
& =\left(\hat{Q}_{\mathrm{m}, U}(E, z)(A)\right)^{k}
\end{aligned}
$$

The probability of drawing $A$ in each of $k$ draws $(E, z)$ of sets of lists of the events drawn with replacement from history $H_{E} \in \mathcal{H}$ of cardinality $z$, having total cardinality $\left|H_{E}^{z}\right|^{k}$, is equal to the probability of drawing $A$ once from $(E, z)$ raised to the power $k,\left(\hat{Q}_{\mathrm{m}, U}(E, z)(A)\right)^{k}$. This is approximately equal to the probability of drawing $\operatorname{scalar}(k) * A$ from $(E, k z)$ in the set of lists of the events drawn with replacement from history $H_{E}$ of cardinality $k z$, having the same total cardinality $\left|H_{E}^{k z}\right|=\left|H_{E}^{z}\right|^{k}$. The approximation is best when the multinomial coefficient is minimised. This is the case when the entropy of $A$, entropy $(A)$, is low, for example when $A$ is diagonal.

Noting that the cardinality of the integral congruent support is less than or equal to the cardinality of the scaled integral congruent support, $\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right| \leq$ $\left|\mathcal{A}_{U, \mathrm{i}, V, k z}\right|$, the sum of the generalised multinomial probability distribution can be approximated in terms of the scaled generalised multinomial probability distribution

$$
\operatorname{sum}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right) \approx \sum_{A \in \mathcal{A}_{U, i, V, z}}\left(\hat{Q}_{\mathrm{m}, U}(E, k z)(\operatorname{scalar}(k) * A)\right)^{1 / k}
$$

The mean of the generalised multinomial probability distribution is

$$
\operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)=\operatorname{scalar}(z) * \hat{E}
$$

The integral mean multinomial probability distribution conjecture states that if the mean of the multinomial probability distribution is integral then it is also modal

$$
\operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right) \in \mathcal{A}_{i} \Longrightarrow \operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right) \in \operatorname{modes}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)
$$

See the discussion in 'Minimum Alignment', below, which generalises the multinomial probability distribution to be a probability density function (by using the gamma function), and then shows that non-integral means can have probability density less than the modes, in the case of negative alignment.

Consider the subset of the integral congruent support which consists of the histograms bracketing the mean $M=\operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)$ by floor and ceiling counts, $\left\{A: A \in \mathcal{A}_{U, \mathrm{i}, V, z}, \forall S \in A^{\mathrm{S}}\left(A_{S} \in\left\{\left\lfloor M_{S}\right\rfloor,\left\lceil M_{S}\right\rceil\right\}\right)\right\}$. It is the case that there exist multinomial probability distributions such that this bracketing subset is not a superset of the modes

$$
\begin{aligned}
& \exists(E, z) \in \mathcal{A}_{\mathrm{i}} \times \mathbf{N} \diamond M=\operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right) \\
& \quad \exists A \in \operatorname{modes}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right) \exists S \in A^{\mathrm{S}}\left(A_{S} \notin\left\{\left\lfloor M_{S}\right\rfloor,\left\lceil M_{S}\right\rceil\right\}\right)
\end{aligned}
$$

The variance of state $S$ in the generalised multinomial probability distribution is

$$
\operatorname{var}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)(S)=z \hat{E}_{S}\left(1-\hat{E}_{S}\right)
$$

The covariance of a pair of states $(S, R)$, where $R \neq S$, in the generalised multinomial probability distribution is

$$
\operatorname{cov}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)((S, R))=-z \hat{E}_{S} \hat{E}_{R}
$$

The moment generating function of the generalised multinomial probability distribution is

$$
\operatorname{mgf}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)(T)=\left(\sum_{S \in V^{\mathrm{CS}}} \hat{E}_{S} e^{T_{S}}\right)^{z}
$$

where $T \in V^{\mathrm{CS}} \rightarrow \mathbf{R}$.

Compare the historical and multinomial distributions. The multinomial coefficient can be separated from the permutorial part in both distributions showing that the historical distribution frequency, $Q_{\mathrm{h}}(E, z)(A)$, is less than or equal to the multinomial distribution frequency, $Q_{\mathrm{m}}(E, z)(A)$, of the histogram, $A$,

$$
\begin{aligned}
Q_{\mathrm{h}}(E, z)(A) & =\prod_{S \in A^{\mathrm{S}}} \frac{E_{S}!}{A_{S}!\left(E_{S}-A_{S}\right)!} \\
& =\frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \frac{1}{z!} \prod_{S \in A^{\mathrm{S}}} E^{A_{S}} \\
& \leq \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}} E_{S}^{A_{S}} \\
& =Q_{\mathrm{m}}(E, z)(A)
\end{aligned}
$$

where $A \leq E$ and $x^{\underline{n}}$ is the falling factorial.
In the multinomial distribution, drawn with replacement, the permutorial is the product of the counts of the states of the distribution histogram raised to the power of the count of the corresponding state of the sample histogram, $E_{S}^{A_{S}}$. The permutorial of the historical distribution, drawn without replacement, is the same except that the power is falling factorial, $E_{S}^{A_{S}}$.

The multinomial distribution frequency is also larger than the historical distribution frequency because of the factor of $z!$. This arises because in order to have integral frequencies, $Q_{\mathrm{m}}(E, z)(A) \in \mathbf{N}$, the multinomial distribution must modify the event identifiers with the position in the lists in $H_{E}^{z} \in \mathcal{L}\left(\mathcal{L}\left(H_{E}\right)\right)$. If the historical distribution was defined to be constructed from a list of modified histories $J=\left\{G: L \in \mathcal{L}\left(H_{E}\right),|\operatorname{set}(L)|=\right.$ $|L|=z, G=\{((i, x), S):(i,(x, S)) \in L\}\}$ rather than from subsets $K=\left\{G: G \subseteq H_{E},|G|=z\right\}$ then the same factor, $z!$, would also appear in the historical distribution, $|J|=z_{E}^{z}$ and $|K|=z_{E}^{z} / z!$, hence $|J|=z!|K|$.

Compare the stuffed historical and multinomial probability distributions

$$
\begin{aligned}
\hat{Q}_{\mathrm{m}, U}(E, z)(A) & =\frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}}\left(\frac{E_{S}}{z_{E}}\right)^{A_{S}} \\
& =\frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \frac{1}{z_{E}^{z}} \prod_{S \in A^{\mathrm{S}}} E_{S}^{A_{S}} \\
\hat{Q}_{\mathrm{h}, U}(E, z)(A) & =\frac{z!\left(z_{E}-z\right)!}{z_{E}!} \prod_{S \in A^{\mathrm{S}}} \frac{E_{S}!}{A_{S}!\left(E_{S}-A_{S}\right)!} \\
& =\frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \frac{1}{z_{E}^{z}} \prod_{S \in A^{\mathrm{S}}} E^{A_{S}}
\end{aligned}
$$

Here the scaling factor of $z!$ disappears.
As the ratio $z_{E} / z$ increases the generalised multinomial probability distribution increasingly approximates to the stuffed historical probability distribution, $\hat{Q}_{\mathrm{m}, U}(E, z) \approx \hat{Q}_{\mathrm{h}, U}(E, z)$. The ratio of multinomial frequency to the historical frequency for distribution histogram $E \in \mathcal{A}_{U, \mathrm{i}, V, z_{E}}$ and sample his-
togram $A \in \mathcal{A}_{U, \mathrm{i}, V, z}$ such that $A \leq E$ and $A \in \operatorname{dom}\left(Q_{\mathrm{h}, U}(E, z)\right)$ is

$$
\begin{aligned}
\frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\hat{Q}_{\mathrm{h}, U}(E, z)(A)} & =\frac{z_{E}!}{\left(z_{E}-z\right)!z_{E}^{z}} \prod_{S \in A^{\mathrm{S}}} \frac{\left(E_{S}-A_{S}\right)!}{E_{S}!} E_{S}^{A_{S}} \\
& =\prod_{i \in\{1 \ldots z\}}\left(\frac{z_{E}-z+i}{z_{E}}\right) \prod_{S \in A^{\mathrm{S}},} \prod_{j \in\left\{1 \ldots A_{S}\right\}}\left(\frac{E_{S}}{E_{S}-A_{S}+j}\right)
\end{aligned}
$$

Calculating the special case of the scaled cartesian distribution histogram $E=\operatorname{scalar}\left(z_{E} / v\right) * V^{\mathrm{C}}$ and sample histogram $A=\operatorname{scalar}(z / v) * V^{\mathrm{C}}$, where $v=\left|V^{\mathrm{C}}\right|, z / v \in \mathbf{N}_{>0}$ and $z_{E} / z \in \mathbf{N}_{>0}$, then

$$
\begin{aligned}
\frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\hat{Q}_{\mathrm{h}, U}(E, z)(A)} & =\prod_{i \in\{1 \ldots z\}}\left(\frac{z_{E}-z+i}{z_{E}}\right) \prod_{j \in\{1 \ldots z / v\}}\left(\frac{z_{E}}{z_{E}-z+v j}\right)^{v} \\
& \approx \prod_{i \in\{1 \ldots z\}}\left(\frac{z_{E}-z+i}{z_{E}}\right) \prod_{i \in\{1 \ldots z\}}\left(\frac{z_{E}}{z_{E}-z+i}\right) \\
& =1
\end{aligned}
$$

Taking the root is less of an approximation where $z$ is small, $z \ll z_{E} / v$.

A constraint exists on the induction of the multinomial distribution histogram $E \in \mathcal{A}_{\mathrm{i}, U}$, of size $z_{E}$, given a sample histogram $A \in \operatorname{dom}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)$ and draw size $z=\operatorname{size}(A)$. If $A$ is assumed to be modal, $A \in \operatorname{modes}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)$, and $A$ is not completely uniform, $A \neq \operatorname{resize}\left(z, A^{\mathrm{C}}\right)$, then $E$ cannot be completely uniform, $E \neq \operatorname{resize}\left(z_{E}, E^{\mathrm{C}}\right)$. That is

$$
A \in \operatorname{modes}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right) \wedge\left(A \neq Z_{z / v} * V^{\mathrm{C}}\right) \Longrightarrow\left(E \neq Z_{z_{E} / v} * V^{\mathrm{C}}\right)
$$

where $V=\operatorname{vars}(E), v=\left|V^{\mathrm{CS}}\right|$ and $Z_{x}=\operatorname{scalar}(x)$. The mean $M$ of the completely uniform distribution histogram $\hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)$ is also completely uniform, $M=\operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)\right)=Z_{z / v} * V^{\mathrm{C}}$. The probability of the mean histogram is the frequency

$$
\hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)(M)=\frac{z!}{\left(\frac{z}{v}!\right)^{v}}\left(\frac{1}{v}\right)^{z}
$$

Let perturb $\in \mathcal{A} \rightarrow \mathrm{P}(\mathcal{A})$ be the set of effective event perturbations of a histogram, excluding the given histogram,

$$
\begin{aligned}
& \text { perturb }(A):= \\
& \qquad\left\{A+\{S\}^{\mathrm{U}}-\{R\}^{\mathrm{U}}:(S, c) \in A, c>0,(R, d) \in A, S \neq R, d \geq 1\right\}
\end{aligned}
$$

All perturbations of the mean are less probable than the mean

$$
\forall A \in \operatorname{perturb}(M)\left(\hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)(A)<\hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)(M)\right)
$$

because

$$
\frac{1}{\left(\frac{z}{v}-1\right)!\left(\frac{z}{v}+1\right)!}<\frac{1}{\left(\frac{z}{v}!\right)^{2}}
$$

All sample histograms can be placed in a list $L \in \mathcal{L}\left(\operatorname{dom}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right)$ beginning with the mean and followed by perturbations of the previous item. That is, $L_{1}=M$ and $\forall i \in\{1 \ldots|L|-1\}\left(L_{i+1} \in \operatorname{perturb}\left(L_{i}\right)\right)$. Each step on paths constructed for a completely uniform distribution is subject to the inequality above, $\forall i \in\{1 \ldots|L|-1\}\left(\hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)\left(L_{i+1}\right)<\hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)\left(L_{i}\right)\right)$. Thus all sample histograms except for the mean are less probable than the mean in a completely uniform distribution. Furthermore, the mean is modal according to the conjecture above for integral means in the multinomial distribution, $M \in \operatorname{modes}\left(\hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)\right)$. Therefore the set of modes of a completely uniform distribution histogram is a singleton of the mean histogram, $\operatorname{modes}\left(\hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)\right)=\{M\}$. Hence the constraint on induction.

The entropy (defined in appendix 'Entropy and Gibbs' inequality') of the distribution histogram $E$ scaled by the draw size $z$ approximates to the sum variance of the generalised multinomial probability distribution

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname{var}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right) & =\sum_{S \in V^{\mathrm{CS}}} z \hat{E}_{S}\left(1-\hat{E}_{S}\right) \\
& \sim-z \sum_{S \in E^{\mathrm{FS}}} \hat{E}_{S} \ln \hat{E}_{S} \\
& =z \times \operatorname{entropy}(\hat{E}) \\
& =z \times \operatorname{entropy}(E)
\end{aligned}
$$

where $\hat{E}=\operatorname{resize}(1, E)$ and $V=\operatorname{vars}(E)$. The approximate proportionality depends on the first term of the Taylor series, $\ln x \approx(x-1)$, and so is a very coarse approximation. Increasing entropy tends to increase the sum variance. Conversely, increasing entropy tends to decrease the absolute sum covariance, $\operatorname{sum}\left(\operatorname{cov}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right)-\operatorname{sum}\left(\operatorname{var}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right)=\sum\left(-z \hat{E}_{S} \hat{E}_{R}\right.$ : $\left.S, R \in V^{\mathrm{CS}}, R \neq S\right)$, becoming less negative.

Conjecture that the cardinality of the modal set of the multinomial distribution tends to increase with increasing entropy for constant draw size

$$
\begin{aligned}
\left|\operatorname{modes}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right| & \sim \operatorname{sum}\left(\operatorname{var}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right) \\
& \sim z \times \operatorname{entropy}(E)
\end{aligned}
$$

Note that the entropy is of the distribution histogram, entropy $(E)$, not the distribution itself, entropy $\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)$.

Consider the special case of a draw of size $z$ from two uniform distribution histograms $E$ and $D$ having volumes $v$ and $k v$ respectively where $k \in \mathbf{N}_{>1}$. The ratio of the sum variance of the generalised multinomial probability distribution of these draws is

$$
\begin{aligned}
\frac{\operatorname{sum}\left(\operatorname{var}(U)\left(\hat{Q}_{\mathrm{m}, U}(D, z)\right)\right)}{\operatorname{sum}\left(\operatorname{var}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right)} & =\frac{\sum z \hat{D}_{R}\left(1-\hat{D}_{R}\right): R \in D^{\mathrm{S}}}{\sum z \hat{E}_{S}\left(1-\hat{E}_{S}\right): S \in E^{\mathrm{S}}} \\
& =\frac{k v z \frac{1}{k v}\left(1-\frac{1}{k v}\right)}{v z \frac{1}{v}\left(1-\frac{1}{v}\right)} \\
& =\frac{v-\frac{1}{k}}{v-1} \\
& >1
\end{aligned}
$$

where $\hat{D}=\operatorname{resize}(1, D)$ and $\hat{E}=\operatorname{resize}(1, E)$. Thus the sum variance increases with increasing volume, but the effect is not very large. Similarly, the ratios of the entropies is

$$
\begin{aligned}
\frac{\operatorname{entropy}(D)}{\operatorname{entropy}(E)} & =\frac{-\sum \hat{D}_{R} \ln \hat{D}_{R}: R \in D^{\mathrm{FS}}}{-\sum \hat{E}_{S} \ln \hat{E}_{S}: S \in E^{\mathrm{FS}}} \\
& =\frac{k v \frac{1}{k v} \ln \frac{1}{k v}}{v \frac{1}{v} \ln \frac{1}{v}} \\
& =1+\frac{\ln k}{\ln v} \\
& >1
\end{aligned}
$$

Consider a one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ having underlying variables equal to the variables $V$ of uniform distribution histogram $D, \operatorname{und}(T)=V=$ $\operatorname{vars}(D)$. The entropy of the application of $T$ to $D$ must be less than or equal to the entropy of $D$, entropy $\left(V^{\mathrm{C}} * T\right) \leq \operatorname{entropy}\left(V^{\mathrm{C}}\right)$, because the derived volume is less than or equal to the underlying volume, $\left|W^{\mathrm{C}}\right| \leq\left|V^{\mathrm{C}}\right|$ where $W=\operatorname{der}(T)$. The entropies are equal when $W$ is a frame of $V$ and thus $T$ is full functional.

The $\log$ of the generalised multinomial probability distribution, $\ln \circ \hat{Q}_{\mathrm{m}, U}(E, z) \in$ $\mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathbf{R}$, can be approximated by the sized negative relative entropy between the sample histogram and the distribution histogram by means of the

Stirling approximation

$$
\hat{Q}_{\mathrm{m}, U}(E, z)(A)=z!\prod_{S \in A^{\mathrm{S}}} \frac{\hat{E}_{S}^{A_{S}}}{A_{S}!} \approx \prod_{S \in A^{\mathrm{FS}}}\left(\frac{\hat{E}_{S}}{\hat{A}_{S}}\right)^{A_{S}}
$$

where $\hat{E}=\operatorname{resize}(1, E)$ and $\hat{A}=\operatorname{resize}(1, A)$. So

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{m}, U}(E, z)(A) & \approx \sum_{S \in A^{\mathrm{FS}}} A_{S} \ln \frac{\hat{E}_{S}}{\hat{A}_{S}} \\
& =-z \sum_{S \in A^{\mathrm{FS}}} \hat{A}_{S} \ln \frac{\hat{A}_{S}}{\hat{E}_{S}} \\
& =-z \times \operatorname{entropy} \operatorname{Relative}(\hat{A}, \hat{E})
\end{aligned}
$$

where $A^{\mathrm{F}} \leq E^{\mathrm{F}}$. By Gibbs' inequality, the logarithm is maximised when the sample histogram is the mean, $A=\operatorname{scalar}\left(z / z_{E}\right) * E$. Thus the mean is modal within the approximation. The sized negative relative entropy can be thought of as the similarity of the sample histogram to the distribution histogram. This can be seen by comparing the sized negative relative entropy,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{m}, U}(E, z)(A) & \approx-z \sum_{S \in A^{\mathrm{FS}}} \hat{A}_{S} \ln \frac{\hat{A}_{S}}{\hat{E}_{S}} \\
& \approx z \sum_{S \in A^{\mathrm{FS}}} \hat{A}_{S}\left(1-\frac{\hat{A}_{S}}{\hat{E}_{S}}\right)
\end{aligned}
$$

where $\hat{A}_{S} \approx \hat{E}_{S}$, to the sum variance,

$$
\operatorname{sum}\left(\operatorname{var}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right)=z \sum_{S \in V^{\mathrm{CS}}} \hat{E}_{S}\left(1-\hat{E}_{S}\right)
$$

In any case, it can be seen that the log of the generalised multinomial probability distribution varies with the sized entropy of the sample histogram as well as the sized negative relative entropy,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{m}, U}(E, z)(A) & \approx-z \sum_{S \in A^{\mathrm{FS}}} \hat{A}_{S} \ln \frac{\hat{A}_{S}}{\hat{E}_{S}} \\
& =z \times \operatorname{entropy}(A)+z \sum_{S \in A^{\mathrm{FS}}} \hat{A}_{S} \ln \hat{E}_{S}
\end{aligned}
$$

In the case where the states are uniformly probable, the distribution histogram is the cartesian, $V^{\mathrm{C}}$. In this case the generalised multinomial probability distribution is proportional to the multinomial coefficient,

$$
\hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)(A)=\frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \frac{1}{v^{z}}
$$

and the logarithm of the multinomial probability distribution varies with the sized entropy,

$$
\ln \hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)(A) \sim z \times \operatorname{entropy}(A)
$$

This case is equivalent to the case discussed in 'Histogram entropy', above. Let $I \subset$ histogram be the histogram valued function of all possible histories of size $z$ in variables $V$,

$$
I=\left\{(H, \operatorname{histogram}(H)): H \in\{1 \ldots z\}: \rightarrow V^{\mathrm{CS}}\right\}
$$

Let $W$ be the cardinality of histories for each histogram,

$$
W=\left\{(A,|D|):(A, D) \in I^{-1}\right\}
$$

The histogram probability function, $\hat{W} \in \mathcal{P}$, equals the cartesian-distributed multinomial probability distribution,

$$
\hat{W}(A)=\frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \frac{1}{v^{z}}=\hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)(A)
$$

That is, the case where the histogram is drawn from the uniform cartesian distribution histogram is equivalent to uniformly probable state.

Consider functions of the sample histograms. Conjecture that the expected independent histogram of a generalised multinomial probability distribution equals the scaled independent distribution histogram

$$
\begin{array}{r}
\left\{\left(S, \operatorname{expected}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\left(\left\{\left(A, A_{S}^{\mathrm{X}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right)\right): S \in V^{\mathrm{CS}}\right\}= \\
\operatorname{scalar}(z) * \hat{E}^{\mathrm{X}}=\operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)\right)
\end{array}
$$

where $\hat{E}=E / \operatorname{scalar}\left(z_{E}\right)$. Conjecture that the counts of the states of the sample histograms are positively correlated with the counts of the states of the independent of the sample histograms, but that the correlation is less than one

$$
\forall S \in V^{\mathrm{CS}}(0 \leq X(E, z, S)<1)
$$

where independent correlation function $X(E, z, S)$ is defined for effective volumes greater than one, $\left|E^{\mathrm{F}}\right|>1$

$$
\begin{aligned}
& X(E, z, S):= \\
& \quad \text { correlation }\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\left(\left\{\left(A, A_{S}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\},\left\{\left(A, A_{S}^{\mathrm{X}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right)
\end{aligned}
$$

Compare the positive correlation between a state of the sample histograms and the corresponding state of the independent sample histograms to the negative correlation between different states of the sample histograms,

$$
\operatorname{cov}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)((S, R))=-z \hat{E}_{S} \hat{E}_{R}
$$

Conjecture that the covariance between different states of the independent of sample histograms is less negative

$$
\forall S, R \in V^{\mathrm{CS}}\left(R \neq S \Longrightarrow|Y(E, z, S, R)| \leq\left|\operatorname{cov}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)((S, R))\right|\right)
$$

where independent covariance function $Y(E, z, S, R)$ is defined for $R \neq S$

$$
\begin{aligned}
& Y(E, z, S, R):= \\
& \quad \text { covariance }\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\left(\left\{\left(A, A_{R}^{\mathrm{X}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\},\left\{\left(A, A_{S}^{\mathrm{X}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right)
\end{aligned}
$$

Consider the logarithm of the factorial function when interpolated by means of the unit-translated gamma function. The unit-translated gamma function is defined $\left(\Gamma_{!}\right) \in \mathbf{R} \rightarrow \mathbf{R}$ as $\Gamma_{!} x=\Gamma(x+1)$ which is such that $\forall x \in \mathbf{N}(\ln \Gamma!x=\ln \Gamma(x+1)=\ln x!)$. The gamma function is log convex and hence the expected logarithm of the factorial of the counts of the states of the sample histograms is greater than or equal to the logarithm of the factorial of the counts of the states of the mean histogram by Jensen's inequality

$$
\forall S \in V^{\mathrm{CS}}\left(\operatorname{expected}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\left(\left\{\left(A, \ln A_{S}!\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right) \geq \ln \Gamma_{!} M_{S}\right)
$$

where the mean histogram is $M=\operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)$. Conjecture that the expected logarithm of the factorial of the counts of the states of the sample histograms is greater than or equal to the expected logarithm of the factorial of the counts of the states of the independent sample histograms

$$
\begin{aligned}
\forall S \in V^{\mathrm{CS}} & \left(\operatorname{expected}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\left(\left\{\left(A, \ln A_{S}!\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right) \geq\right. \\
& \left.\quad \operatorname{expected}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\left(\left\{\left(A, \ln \Gamma!A_{S}^{\mathrm{X}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right)\right)
\end{aligned}
$$

### 3.17.3 Multiple binomial distributions

Consider the set of lists of the events drawn with replacement from history $H_{E} \in \mathcal{H}$ of cardinality $z, H_{E}^{z}=\left\{L: L \in \mathcal{L}\left(H_{E}\right),|L|=z\right\} \subset \mathcal{L}\left(H_{E}\right)$. Whereas above the lists where modified to construct multinomial sample histories drawn with replacement, here they are modified to form binomial sample histories drawn with replacement of some given state $S \in V^{\mathrm{CS}}$ where $V=\operatorname{vars}\left(H_{E}\right)$. Replace all states not equal to $S$ with a dummy empty state $\emptyset \in \mathcal{S}$ to define a set of sample histories, $X=\left\{G: L \in H_{E}^{z}, G=\{((i, x), R):\right.$ $(i,(x, R)) \in L, R=S\} \cup\{((i, x), \emptyset):(i,(x, R)) \in L, R \neq S\}\} \subset \mathcal{X} \rightarrow \mathcal{S}$. Strictly speaking the set $X$ is not a set of histories because vars $(\emptyset) \neq V$ (except in the case where the history $H_{E}$ is scalar, $V=\emptyset$ ), but the construction serves to show how the draw is binomial.

Now consider $H_{E}^{z}$ raised to the power of the volume $v=\left|V^{\mathrm{C}}\right|,\left(H_{E}^{z}\right)^{v}=$ $\left\{L: L \in \mathcal{L}\left(H_{E}^{z}\right),|L|=v\right\} \subset \mathcal{L}\left(\mathcal{L}\left(H_{E}\right)\right)$. Each of the lists of this set represents an independent binomial draw for each of the states in the volume. Let $D \in \operatorname{enums}\left(V^{\mathrm{CS}}\right)$ be some map between the states of $V$ and the elements of this set, $\forall L \in\left(H_{E}^{z}\right)^{v}\left(D \in V^{\mathrm{CS}} \leftrightarrow \operatorname{dom}(L)\right)$. Construct from this set, $\left(H_{E}^{z}\right)^{v}$, a set of sample histories of cardinality less than or equal to $z^{v}, Y=\{G$ : $\left.L \in\left(H_{E}^{z}\right)^{v}, G=\left\{((i, j, x), S):(S, i) \in D,(j,(x, R)) \in L_{i}, R=S\right\}\right\} \subset \mathcal{H}$. Here $Y$ is a set of multiple binomial sample histories drawn with replacement. The events of the states corresponding to the dummy empty state are not included in this construction.

The set of multiple binomial distributions $Q_{\mathrm{b}, U} \in \mathcal{A}_{\mathrm{i}, U} \times \mathbf{N} \rightarrow \mathcal{Q}_{U} \cap \mathcal{Q}_{\mathrm{i}}$ is the set of constructible distributions parameterised by the with replacement draw $(E, z) \in \mathcal{A}_{\mathrm{i}, U} \times \mathbf{N}$

$$
\begin{aligned}
& Q_{\mathrm{b}, U}(E, z)=\operatorname{count}\left(\left\{\left(\operatorname{histogram}(G)+V^{\mathrm{CZ}}, G\right): L \in\left(H_{E}^{z}\right)^{v},\right.\right. \\
& \left.\left.\quad G=\left\{((i, j, x), S):(S, i) \in D,(j,(x, R)) \in L_{i}, R=S\right\}\right\}\right) \in \mathcal{Q}_{U} \cap \mathcal{Q}_{\mathrm{i}}
\end{aligned}
$$

where $V=\operatorname{vars}(A)$ and $D \in \operatorname{enums}\left(V^{\mathrm{CS}}\right)$. The support of the multiple binomial distribution is the multiple support, $\operatorname{dom}\left(Q_{\mathrm{b}, U}(E, z)\right)=\mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}}$. Hence the sample size is not constrained to be equal to the draw size. The minimum size of the sample histograms is zero and the maximum size is $v z, \forall A \in \operatorname{dom}\left(Q_{\mathrm{b}, U}(E, z)\right)(0 \leq \operatorname{size}(A) \leq v z)$. The maximum count in the sample histograms is less than or equal to the draw size

$$
\forall A \in \operatorname{dom}\left(Q_{\mathrm{m}}(E, z)\right)(\operatorname{maxr}(A) \leq z)
$$

The sum of a multiple binomial distribution is

$$
\operatorname{sum}\left(Q_{\mathrm{b}, U}(E, z)\right)=z_{E}^{z v}
$$

The set of generalised multiple binomial distributions $Q_{b, U} \in \mathcal{A}_{U} \times \mathbf{N} \rightarrow \mathcal{Q}_{U}$ is the set of distributions parameterised by non-integral distribution histograms as well as integral draw distribution histograms. They are defined explicitly, $Q_{\mathrm{b}, U}(E, z) \in\left(\mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}} \rightarrow \mathrm{Q}_{\geq 0}\right) \subset \mathcal{Q}_{U}$, as
$Q_{\mathrm{b}, U}(E, z):=\left\{\left(A, \prod_{S \in V^{\mathrm{CS}}} \frac{z!}{A_{S}!\left(z-A_{S}\right)!} E_{S}^{A_{S}}\left(z_{E}-E_{S}\right)^{z-A_{S}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}}\right\}$
where $V=\operatorname{vars}(E)$.
The generalised multiple binomial probability distribution is $\hat{Q}_{\mathrm{b}, U}(E, z) \in$ $\left(\mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}} \rightarrow \mathrm{Q}_{\geq 0}\right) \cap \mathcal{Q}_{U} \cap \mathcal{P}$

$$
\begin{aligned}
\hat{Q}_{\mathrm{b}, U}(E, z) & =\text { normalise }\left(Q_{\mathrm{b}, U}(E, z)\right) \\
& =\left\{\left(A, \prod_{S \in V^{\mathrm{CS}}} \frac{z!}{A_{S}!\left(z-A_{S}\right)!} \hat{E}_{S}^{A_{S}}\left(1-\hat{E}_{S}\right)^{z-A_{S}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}}\right\}
\end{aligned}
$$

where $\hat{E}=E / \operatorname{scalar}\left(z_{E}\right)$.
The mean of the generalised multiple binomial probability distribution is

$$
\operatorname{mean}\left(\hat{Q}_{\mathrm{b}, U}(E, z)\right)=\operatorname{scalar}(z) * \hat{E}
$$

If the mean of the generalised multiple binomial probability distribution is integral then it is the element of the singleton modal set

$$
M \in \mathcal{A}_{i} \Longrightarrow \operatorname{modes}\left(\hat{Q}_{\mathrm{b}, U}(E, z)\right)=\{M\}
$$

where $M=\operatorname{mean}\left(\hat{Q}_{\mathrm{b}, U}(E, z)\right)$. If the mean is not integral then the modal set is a singleton consisting of the floor of the mean

$$
\operatorname{modes}\left(\hat{Q}_{\mathrm{b}, U}(E, z)\right)=\{\operatorname{floor}(A)\}
$$

The variance of state $S$ in the generalised multiple binomial probability distribution is

$$
\operatorname{var}(U)\left(\hat{Q}_{\mathrm{b}, U}(E, z)\right)(S)=z \hat{E}_{S}\left(1-\hat{E}_{S}\right)
$$

The covariance of a pair of states $(S, R)$, where $R \neq S$, is zero because the states are independently drawn,

$$
\operatorname{cov}(U)\left(\hat{Q}_{\mathrm{b}, U}(E, z)\right)((S, R))=0
$$

The moment generating function of the generalised multiple binomial probability distribution is

$$
\operatorname{mgf}(U)\left(\hat{Q}_{\mathrm{b}, U}(E, z)\right)(T)=\prod_{S \in V^{\mathrm{CS}}}\left(1-\hat{E}_{S}+\hat{E}_{S} e^{T_{S}}\right)
$$

where $\hat{E}=E / \operatorname{scalar}\left(z_{E}\right)$ and $T \in V^{\mathrm{CS}} \rightarrow \mathbf{R}$.
The mean and variance of the generalised multiple binomial probability distribution equals the mean and variance of the generalised multinomial probability distribution

$$
\operatorname{mean}\left(\hat{Q}_{\mathrm{b}, U}(E, z)\right)=\operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)
$$

and

$$
\operatorname{var}(U)\left(\hat{Q}_{\mathrm{b}, U}(E, z)\right)=\operatorname{var}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)
$$

However the covariance is not equal, $\operatorname{cov}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)((S, R)) \neq 0$ where $E_{S}, E_{R}>0$. Increasing entropy of the distribution histogram, entropy $(E)$, tends to decrease the absolute sum covariance of joint states, $R \neq S$, of the generalised multinomial probability distribution

$$
\left|\operatorname{sum}\left(\operatorname{cov}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right)-\operatorname{sum}\left(\operatorname{var}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right)\right|
$$

So as entropy increases the moments converge and the generalised multiple binomial probability distribution increasingly approximates to the generalised multinomial probability distribution where the supports intersect

$$
\left\{(A, f):(A, f) \in \hat{Q}_{\mathrm{b}, U}(E, z), \operatorname{size}(A)=z\right\} \approx \hat{Q}_{\mathrm{m}, U}(E, z)
$$

Similarly, the conjecture above that the covariance between different states of the independent of sample histograms in the generalised multinomial probability distribution is less negative than between different states of the sample histograms suggests that the generalised multiple binomial probability distribution approximates to the generalised multinomial probability distribution better for the independent sample histograms

$$
\begin{aligned}
\{(A, f):(A, f) & \left.\in \hat{Q}_{\mathrm{b}, U}(E, z), \operatorname{size}(A)=z, A=A^{\mathrm{x}}\right\} \approx \\
& \left\{(A, f):(A, f) \in \hat{Q}_{\mathrm{m}, U}(E, z), A=A^{\mathrm{x}}\right\}
\end{aligned}
$$

The multiple Poisson probability function is $\hat{Q}_{\mathrm{p}, U}(E, z) \in\left(\mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}} \rightarrow\right.$ $\left.\mathbf{R}_{\geq 0}\right) \cap \mathcal{P}$ is defined

$$
\hat{Q}_{\mathrm{p}, U}(E, z)=\left\{\left(A, \prod_{S \in V^{\mathrm{CS}}} \frac{e^{-z \hat{E}_{S}}\left(z \hat{E}_{S}\right)^{A_{S}}}{A_{S}!}\right): A \in \mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}}\right\}
$$

where $\hat{E}=E / \operatorname{scalar}\left(z_{E}\right)$. Here the Poisson distribution parameter is $z \hat{E}_{S}$. This function is not a distribution because it is real-valued. Hence it cannot be constructed from finite $H_{E}$. However at large $z$ and $v$ it approximates to the generalised multiple binomial probability distribution. Using Stirling's approximation,

$$
\begin{aligned}
\hat{Q}_{\mathrm{p}, U}(E, z) & =\left\{\left(A, \prod_{S \in V^{\mathrm{CS}}} \frac{e^{-z \hat{E}_{S}}\left(z \hat{E}_{S}\right)^{A_{S}}}{A_{S}!}\right): A \in \mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}}\right\} \\
& =\left\{\left(A, e^{-z} z^{z} \prod_{S \in V^{\mathrm{CS}}} \frac{\hat{E}_{S}^{A_{S}}}{A_{S}!}\right): A \in \mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}}\right\} \\
& \approx\left\{\left(A, z!\prod_{S \in V^{\mathrm{CS}}} \frac{\hat{E}_{S}^{A_{S}}}{A_{S}!}\right): A \in \mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}}\right\} \\
& \approx\left\{\left(A, \prod_{S \in V^{\mathrm{CS}}} \frac{z!}{A_{S}!\left(z-A_{S}\right)!} \hat{E}_{S}^{A_{S}}\left(1-\hat{E}_{S}\right)^{z-A_{S}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V,\{00 . z\}}\right\} \\
& =\hat{Q}_{\mathrm{b}, U}(E, z)
\end{aligned}
$$

The multiple Poisson probability function also approximates to the generalised multinomial probability distribution at large $z$ and $v$

$$
\begin{aligned}
\left\{\left(A, z!\prod_{S \in V^{\mathrm{CS}}} \frac{\hat{E}_{S}^{A_{S}}}{A_{S}!}\right): A \in \mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}}\right\} & \supset\left\{\left(A, z!\prod_{S \in V^{\mathrm{CS}}} \frac{\hat{E}_{S}^{A_{S}}}{A_{S}!}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\} \\
& =\hat{Q}_{\mathrm{m}, U}(E, z)
\end{aligned}
$$

### 3.17.4 Uniform distributions

The uniform distributions in system $U$ are parameterised by a pair of (i) a set of draw variables $V \subset \mathcal{V}_{U}$ and (ii) a non-zero integral draw size $z \in$ $\mathbf{N}_{>0}$. In terms of sets of histories, the uniform distribution is a constructible distribution $Q_{\mathrm{u}, U} \in \mathcal{V}_{U} \times \mathbf{N}_{>0} \rightarrow \mathcal{Q}_{\mathrm{i}}$ is defined

$$
\begin{aligned}
Q_{\mathrm{u}, U}(V, z) & =\operatorname{count}\left(\left\{(\operatorname{histogram}(G), G): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, G=\operatorname{history}(A)\right\}\right) \\
& =\mathcal{A}_{U, \mathrm{i}, V, z} \times\{1\}
\end{aligned}
$$

The support of uniform distributions is the integral congruent support. That is, $\operatorname{dom}\left(Q_{\mathrm{u}, U}(V, z)\right)=\mathcal{A}_{U, \mathrm{i}, V, z}$.

The uniform probability distribution $\hat{Q}_{\mathbf{u}, U}(V, z) \in\left(\mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{Q}_{U} \cap$ $\mathcal{Q}_{z} \cap \mathcal{P}$ is defined

$$
\begin{aligned}
\hat{Q}_{\mathrm{u}, U}(V, z) & =\mathcal{A}_{U, \mathrm{i}, V, z} \times\left\{1 /\left|\mathcal{A}_{U \mathrm{i}, V, z}\right|\right\} \\
& =\mathcal{A}_{U, \mathrm{i}, V, z} \times\left\{\frac{z!(v-1)!}{(z+v-1)!}\right\}
\end{aligned}
$$

where $v=\left|V^{\mathrm{CS}}\right|$. The modal set of a uniform probability distribution is the entire support, $\operatorname{modes}\left(\hat{Q}_{\mathrm{u}, U}(V, z)\right)=\mathcal{A}_{U, \mathrm{i}, V, z, z}$. The mean histogram is the uniform histogram, mean $\left(\hat{Q}_{\mathrm{u}, U}(V, z)\right)=\operatorname{scalar}(z / v) * V^{\mathrm{C}}$ where $v=\left|V^{\mathrm{C}}\right|$. Compare this to the mean histogram of the multiple support, mean $\left(\mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}} \times\right.$ $\{1\})=\operatorname{scalar}(z / 2) * V^{\mathrm{C}}$.

The supports of the uniform probability distribution $\hat{Q}_{\mathrm{u}, U}(V, z)$ and the generalised multinomial probability distribution of the uniform distribution histogram $\hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)$ are equal

$$
\operatorname{dom}\left(\hat{Q}_{\mathrm{u}, U}(V, z)\right)=\operatorname{dom}\left(\hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)\right)=\mathcal{A}_{U, \mathrm{i}, V, z}
$$

but the distributions are not equal, $\hat{Q}_{\mathrm{u}, U}(V, z) \neq \hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)$, except in the trivial case of mono-variate, mono-valent $V$.

### 3.17.5 Iso-independent conditional multinomial distributions

The discussion 'Historical distributions', above, shows how the historical distribution, $Q_{\mathrm{h}}(E, z)$, is derived from subsets of the events drawn without replacement from history $H_{E} \in \mathcal{H}$ of cardinality $z,\left\{G: G \subseteq H_{E},|G|=z\right\}$. The set of historical distributions $Q_{\mathrm{h}} \in \mathcal{A}_{\mathrm{i}} \times \mathbf{N} \rightarrow \mathcal{Q}_{\mathrm{i}}$ is the set of constructible distributions parameterised by a without replacement draw $(E, z) \in \mathcal{A}_{\mathrm{i}} \times \mathbf{N}$
$Q_{\mathrm{h}}(E, z)=\operatorname{count}(\{(\operatorname{histogram}(G), G): G \subseteq \operatorname{history}(E),|G|=z\}) \in \mathcal{Q}_{\mathrm{i}} \cap \mathcal{Q}_{z}$
Similarly, the discussion 'Multinomial distributions', above, shows how the multinomial distribution, $Q_{\mathrm{m}}(E, z)$, is derived from the set of lists of the events drawn with replacement from history $H_{E} \in \mathcal{H}$ of cardinality $z, H_{E}^{z}=$ $\left\{L: L \in \mathcal{L}\left(H_{E}\right),|L|=z\right\}$. The set of multinomial distributions $Q_{\mathrm{m}} \in$ $\mathcal{A}_{\mathrm{i}} \times \mathbf{N} \rightarrow \mathcal{Q}_{\mathrm{i}}$ is the set of constructible distributions parameterised by a with replacement draw $(E, z) \in \mathcal{A}_{\mathrm{i}} \times \mathbf{N}$

$$
\begin{aligned}
& Q_{\mathrm{m}}(E, z)=\operatorname{count}(\{(\operatorname{histogram}(G), G): \\
& \left.\left.\quad L \in \operatorname{history}(E)^{z}, G=\{((i, x), S):(i,(x, S)) \in L\}\right\}\right) \in \mathcal{Q}_{\mathrm{i}} \cap \mathcal{Q}_{z}
\end{aligned}
$$

Both cases construct an intermediate set of histories $I \subset \mathcal{H}$. In the historical case the intermediate histories are simply subsets of the given history, $I=\left\{G: G \subseteq H_{E},|G|=z\right\} \in \mathrm{P}(\mathcal{H})$. In the multinomial case the intermediate histories are constructed by prefixing by list position the event identifiers of lists of events of the given history, $I=\left\{G: L \in H_{E}^{z}, G=\{((i, x), S)\right.$ : $(i,(x, S)) \in L\}\} \in \mathrm{P}(\mathcal{H})$. The cardinalities of the components of the partition of $I$ implied by the inverse of the histogram function, histogram $\in$ $\mathcal{H} \rightarrow \mathcal{A}$, form the frequencies of the constructible distribution, $\{(A,|C|)$ : $(A, C) \in \operatorname{inverse}($ filter $(I$, his $))\}=\operatorname{count}(\{(\operatorname{his}(G), G): G \in I\}) \in \mathrm{Q}_{\mathrm{i}}$, where his $=$ histogram. So the count partition is $\operatorname{ran}($ inverse(filter $(I$, his $)))=$ $\operatorname{ran}($ inverse $(\{(G, \operatorname{his}(G)): G \in I\})) \in \mathrm{B}(I)$.

Given some partition $P \in \mathrm{~B}(I)$ of the intermediate set of drawn histories $I \in \mathrm{P}(\mathcal{H})$, a second intermediate set $J \in \mathrm{P}(\mathcal{H})$ having a corresponding partition $R \in \mathrm{~B}(J)$ may be constructed such that (i) there exists a bijection $M \in P \cdot R$ between the partitions, and (ii) the cardinalities of the components of $R$ are uniform, $\left|\left\{\left|C^{\prime}\right|: C^{\prime} \in R\right\}\right|=1$. Each component $C^{\prime} \in R$ corresponding to a component $C \in P$, that is, $\left(C, C^{\prime}\right) \in M$, may be constructed by prefixing each of the event identifiers of each of the histories in $C$ with the sets of histories in the product of the remaining components, $\prod_{D \in P \backslash\{C\}} D \subset \mathrm{P}(\mathcal{H})$. Define hiso $\in \mathrm{P}(\mathrm{P}(\mathcal{H})) \rightarrow \mathrm{P}(\mathrm{P}(\mathcal{H}))$ as
hiso $(P):=$

$$
\left\{C^{\prime}: C \in P, C^{\prime}=\left\{\{((N, x), S):(x, S) \in G\}: G \in C, N \in \prod_{D \in P \backslash\{C\}} D\right\}\right\}
$$

Then $R=\operatorname{hiso}(P)$ and $J=\bigcup R$. If the argument $P$ to the history iso function is a partition, $P \in \mathrm{~B}(\bigcup P)$, then the cardinality of each of the components of the resultant partition is $\prod_{C \in P}|C|$. The sum of the cardinalities is $|J|=\sum_{C^{\prime} \in R}\left|C^{\prime}\right|=|P| \prod_{C \in P}|C|$. The resultant second intermediate set of histories $J$ forms a new distribution, $\operatorname{count}\left(\{(\operatorname{his}(G), G): G \in J\} \in \mathcal{Q}_{\mathrm{i}}\right.$.

Now consider a with replacement draw parameterised by (i) a distribution histogram $E$ in variables $V$ and system $U$, and (ii) an independent histogram $A^{\mathrm{X}}$ in variables $V$ having integral size $z=\operatorname{size}\left(A^{\mathrm{X}}\right) \in \mathbf{N}$. That is, draw parameters $\left(E, A^{\mathrm{X}}\right) \in \mathcal{A}_{U, \mathrm{i}} \times \mathcal{A}_{U}$. The independent histogram size, $z$, defines the draw size. The independent histogram is also constrained such that the integral iso-independent set defined by it is non-empty, $\left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|>0$, where $Y_{U, \mathrm{i}, V, z}=\left\{\left(B, B^{\mathrm{X}}\right): B \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\} \subset$ independent is the integral congruent independent function.

Define the iso-independent conditional multinomial distribution $Q_{\mathrm{m}, \mathrm{y}}\left(E, A^{\mathrm{X}}\right)$ as the distribution derived from the subset of the lists of the events drawn with replacement, $H_{E}^{z}$, that are constrained to the set of integral iso-independents defined by the draw parameter $A^{\mathrm{X}}$,

$$
\begin{aligned}
& \left\{L: L \in \mathcal{L}\left(H_{E}\right),\right. \\
& \left.\quad G=\{((i, x), S):(i,(x, S)) \in L\}, B=\operatorname{histogram}(G), B^{\mathrm{x}} \equiv A^{\mathrm{x}}\right\} \subseteq H_{E}^{z}
\end{aligned}
$$

That is

$$
\begin{aligned}
& Q_{\mathrm{m}, \mathrm{y}}\left(E, A^{\mathrm{X}}\right)=\operatorname{count}(\{(B, G): \\
& \quad L \in \operatorname{history}(E)^{z}, G=\{((i, x), S):(i,(x, S)) \in L\}, \\
& \left.\left.\quad B=\operatorname{histogram}(G), B^{\mathrm{X}} \equiv A^{\mathrm{X}}\right\}\right) \in \mathcal{Q}_{z}
\end{aligned}
$$

The iso-independent conditional multinomial distribution, $Q_{\mathrm{m}, \mathrm{y}}\left(E, A^{\mathrm{X}}\right)$, is a subset of the corresponding multinomial distribution of the same size, $Q_{\mathrm{m}}(E, z)$. That is, $Q_{\mathrm{m}, \mathrm{y}}\left(E, A^{\mathrm{X}}\right)=\left\{(B, f):(B, f) \in Q_{\mathrm{m}}(E, z), B^{\mathrm{X}} \equiv A^{\mathrm{X}}\right\}$. Thus $\operatorname{sum}\left(Q_{\mathrm{m}, \mathrm{y}}\left(E, A^{\mathrm{X}}\right)\right) \leq \operatorname{sum}\left(Q_{\mathrm{m}}(E, z)\right)$. The iso-independent conditional multinomial distribution can be defined explicitly for $B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$ as

$$
Q_{\mathrm{m}, \mathrm{y}}\left(E, A^{\mathrm{X}}\right)(B)=Q_{\mathrm{m}}(E, z)(B)=\frac{z!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!} \prod_{S \in B^{\mathrm{S}}} E_{S}^{B_{S}} \in \mathbf{N}_{>0}
$$

The stuffed iso-independent conditional multinomial distribution

$$
Q_{\mathrm{m}, \mathrm{y}, U}\left(E, A^{\mathrm{X}}\right) \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right) \rightarrow \mathbf{Q}_{\geq 0} \subset \mathcal{Q}_{U} \cap \mathcal{Q}_{z}
$$

can be constructed from an iso-independent conditional multinomial distribution, $Q_{\mathrm{m}, \mathrm{y}}\left(E, A^{\mathrm{X}}\right)$, by completing the support histograms and stuffing with the disjoint subset of the integral congruent support that are iso-independent histograms with zero frequencies

$$
\begin{aligned}
Q_{\mathrm{m}, \mathrm{y}, U}\left(E, A^{\mathrm{X}}\right)= & \left\{\left(B+B^{\mathrm{CZ}}, f\right):(B, f) \in Q_{\mathrm{m}, \mathrm{y}}\left(E, A^{\mathrm{X}}\right)\right\} \cup \\
& \left(Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right) \backslash\left\{B+B^{\mathrm{CZ}}: B \in \operatorname{dom}\left(Q_{\mathrm{m}, \mathrm{y}}\left(E, A^{\mathrm{X}}\right)\right)\right\}\right) \times\{0\}
\end{aligned}
$$

The stuffed iso-independent conditional multinomial probability distribution $\hat{Q}_{\mathrm{m}, \mathrm{y}, U}\left(E, A^{\mathrm{X}}\right) \in\left(Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right) \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{Q}_{U} \cap \mathcal{Q}_{z} \cap \mathcal{P}$ is defined

$$
\begin{aligned}
\hat{Q}_{\mathrm{m}, \mathrm{y}, U}\left(E, A^{\mathrm{X}}\right) & =\operatorname{normalise}\left(Q_{\mathrm{m}, \mathrm{y}, U}\left(E, A^{\mathrm{X}}\right)\right) \\
& =\left\{\left(B, f / \operatorname{sum}\left(Q_{\mathrm{m}, \mathrm{y}, U}\left(E, A^{\mathrm{X}}\right)\right)\right):(B, f) \in Q_{\mathrm{m}, \mathrm{y}, U}\left(E, A^{\mathrm{X}}\right)\right\}
\end{aligned}
$$

where $z_{E}>0$ and $z>0$.

Finally the generalised iso-independent conditional multinomial probability distribution over the entire integral congruent support, $\mathcal{A}_{U, \mathrm{i}, V, z}$, can be constructed by treating each of the iso-independent components of the partition implied by the integral congruent independent function, $\operatorname{ran}\left(Y_{U, i, V, z}^{-1}\right) \in$ $\mathrm{B}\left(\mathcal{A}_{U, \mathrm{i}, V, z}\right)$, as equally probable. Define the generalised iso-independent conditional multinomial probability distributions parameterised by both integral and non-integral distribution histograms, $\hat{Q}_{\mathrm{m}, \mathrm{y}, U} \in \mathcal{A}_{U} \times \mathbf{N} \rightarrow \mathcal{Q}_{U}$, explicitly $\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z) \in\left(\mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P} \subset \mathcal{Q}_{U} \cap \mathcal{Q}_{z}$ as
$\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z):=\operatorname{normalise}\left(\left\{\left(A, \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} Q_{\mathrm{m}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right)$
which is such that

$$
\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z)=\operatorname{normalise}\left(\bigcup\left(\hat{Q}_{\mathrm{m}, \mathrm{y}, U}\left(E, A^{\mathrm{x}}\right): A^{\mathrm{X}} \in \operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)\right)\right)
$$

In the case of integral distribution histogram, $E \in \mathcal{A}_{\mathrm{i}}$, this definition of the generalised iso-independent conditional multinomial probability distribution, $\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z)$, implies a corresponding constructible distribution $Q_{\mathrm{m}, \mathrm{y}, U}(E, z) \in$ $\left(\mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathbf{N}\right) \subset \mathcal{Q}_{\mathrm{i}}$, by scaling the frequencies of $\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z)$ by a factor,

$$
\begin{aligned}
& Q_{\mathrm{m}, \mathrm{y}, U}(E, z)(A):= \\
& \quad\left(\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)\right| \prod_{A^{\mathrm{x}} \in \operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)} \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} Q_{\mathrm{m}, U}(E, z)(B)\right) \times \hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z)(A)
\end{aligned}
$$

The iso-independent function, $Y_{U, \mathrm{i}, V, z} \in \mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathcal{A}_{U, V, z} \subset$ independent, implies a function of histories, $\left\{\left(G, Y_{U, i, V, z}\left(A+A^{\mathrm{CZ}}\right)\right): G \in I, A=\operatorname{his}(G)\right\}=$ $\left\{\left(G, A^{\mathrm{X}}+A^{\mathrm{CZ}}\right): G \in I, A=\operatorname{his}(G)\right\} \in \mathcal{H} \rightarrow \mathcal{A}_{U, V, z}$, where the multinomial intermediate set of histories is $I=\left\{G: L \in H_{E}^{z}, G=\{((i, x), S)\right.$ : $(i,(x, S)) \in L\}\} \in \mathrm{P}(\mathcal{H})$ and his = histogram. This in turn implies a partition of histories $P=\operatorname{ran}\left(\right.$ inverse $\left.\left(\left\{\left(G, A^{\mathrm{X}}+A^{\mathrm{CZ}}\right): G \in I, A=\operatorname{his}(G)\right\}\right)\right) \in$ $\mathrm{B}(I)$. This partition of histories is a parent partition of the partition of histories implied by the histogram function, parent $(P, \operatorname{ran}($ inverse $(f i l t e r(I$, his $))))$. The scaling factor is equal to the sum of the cardinalities of the resultant partition of the history iso function
$\sum_{C^{\prime} \in \mathrm{hiso}(P)}\left|C^{\prime}\right|=|P| \prod_{C \in P}|C|=\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)\right| \prod_{A^{\mathrm{x}} \in \operatorname{ran}\left(Y_{U, i, V, z}\right)} \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} Q_{\mathrm{m}, U}(E, z)(B)$
That is, the frequencies of the multinomial distribution, $Q_{\mathrm{m}, U}(E, z)$, are partitioned by the iso-independent function, $Y_{U, \mathrm{i}, V, z}$. The sum of the frequencies of each component of this partition is scaled. The scaling of the
frequencies of histograms corresponds to the repetition of histories in the components of partition $R=\operatorname{hiso}(P) \in \mathrm{B}(J)$, of the second intermediate set of histories $J=\bigcup R \subset \mathcal{H}$, having uniform component cardinalities, $\left|\left\{\left|C^{\prime}\right|: C^{\prime} \in R\right\}\right|=1$. The resultant second intermediate set of histories, $J$, forms the generalised iso-independent conditional multinomial distribution, $Q_{\mathrm{m}, \mathrm{y}, U}(E, z)=\operatorname{count}\left(\{(\operatorname{his}(G), G): G \in J\} \in \mathcal{Q}_{\mathrm{i}}\right.$.

The upper bound to the cardinality of the second intermediate history set, $|J|$, which is the sum of the generalised iso-independent conditional multinomial distribution, is

$$
\operatorname{sum}\left(Q_{\mathrm{m}, \mathrm{y}, U}(E, z)\right) \leq r\left(\frac{z_{E}^{z}}{r}\right)^{r}
$$

where $z_{E}^{z} \geq r$ and

$$
r=\left|\operatorname{ran}\left(Y_{U, i, V, z}\right)\right|=\prod_{w \in V} \frac{\left(z+\left|U_{w}\right|-1\right)!}{z!\left(\left|U_{w}\right|-1\right)!}
$$

The probability of an integral congruent support histogram $A \in \mathcal{A}_{U, \mathrm{i}, V, z}$ may be compared between the generalised iso-independent conditional multinomial probability distribution, $\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z)$, and the generalised multinomial probability distribution, $\hat{Q}_{\mathrm{m}, U}(E, z)$. The cardinality of the range of the integral congruent independent function is

$$
\left|\operatorname{ran}\left(Y_{U, i, V, z}\right)\right|=\prod_{w \in V} \frac{\left(z+\left|U_{w}\right|-1\right)!}{z!\left(\left|U_{w}\right|-1\right)!}
$$

If the sum of the iso-independent probabilities of $A$ is greater than the fraction implied by this cardinality

$$
\sum_{B \in Y_{U, i, V, z}^{1},\left(A^{\mathrm{X}}\right)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)>\frac{1}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)\right|}
$$

then the generalised iso-independent conditional multinomial probability is less than the generalised multinomial probability, $\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z)(A)<\hat{Q}_{\mathrm{m}, U}(E, z)(A)$, and vice-versa. In the case where the independent histogram is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$ and therefore an iso-independent, $A^{\mathrm{X}} \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, and such that

$$
\hat{Q}_{\mathrm{m}, U}(E, z)\left(A^{\mathrm{x}}\right)>\frac{1}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)\right|}
$$

then $\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z)(A)<\hat{Q}_{\mathrm{m}, U}(E, z)(A)$. Furthermore, it is conjectured above that the logarithm of the cardinality of the integral iso-independents corresponding to $A^{\mathrm{X}}$ varies with the size scaled independent entropy,

$$
\ln \left|Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right| \sim z \times \operatorname{entropy}\left(A^{\mathrm{X}}\right)
$$

Therefore conjecture that the generalised iso-independent conditional multinomial probability tends to be less than the generalised multinomial probability, $\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z)(A)<\hat{Q}_{\mathrm{m}, U}(E, z)(A)$, when the entropy of the independent histogram, entropy $\left(A^{\mathrm{X}}\right)$, is high, and vice-versa

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z)(A)-\ln \hat{Q}_{\mathrm{m}, U}(E, z)(A) \sim-\operatorname{entropy}\left(A^{\mathrm{X}}\right)
$$

The generalised iso-independent conditional multinomial probability distribution is constructed by normalising each of the components of the isoindependent partition of the integral congruent support, $\operatorname{ran}\left(Y_{U, i, V, z}^{-1}\right) \in \mathrm{B}\left(\mathcal{A}_{U, \mathrm{i}, V, z}\right)$. The same method can be applied to construct a conditional multinomial probability distribution given any partition. Consider the integral iso-transformindependent partition, $\operatorname{ran}\left(Y_{U, i, T, z}^{-1}\right) \in \mathrm{B}\left(\mathcal{A}_{U, \mathrm{i}, V, z}\right)$, given one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ where $\operatorname{und}(T)=V$ and $W=\operatorname{der}(T)$. The integral iso-transform-independent function is defined $Y_{U, \mathbf{i}, T, z} \in \mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow\left(\mathcal{A}_{U, W, z} \times\right.$ $\left.\mathcal{A}_{U, W, z}\right)$ as $Y_{U, \mathbf{i}, T, z}=\left\{\left(A,\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}$. Now the subset of the lists of the events drawn with replacement, $H_{E}^{z}$, that are constrained to the set of integral iso-transform-independents defined by the draw parameter $\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)$ is

$$
\begin{aligned}
& \left\{L: L \in \mathcal{L}\left(H_{E}\right),\right. \\
& \quad G=\{((i, x), S):(i,(x, S)) \in L\}, B=\operatorname{histogram}(G), \\
& \\
& \left.\quad B^{\mathrm{x}} * T \equiv A^{\mathrm{x}} * T,(B * T)^{\mathrm{x}} \equiv(A * T)^{\mathrm{x}}\right\} \subseteq H_{E}^{z}
\end{aligned}
$$

The generalised iso-transform-independent conditional multinomial probability distribution over the integral congruent support, $\mathcal{A}_{U, \mathrm{i}, V, z}$, is defined $\hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}(E, z) \in\left(\mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P} \subset \mathcal{Q}_{U} \cap \mathcal{Q}_{z}$ as

$$
\hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}(E, z)=
$$

$$
\text { normalise }\left(\left\{\left(A, \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{x}}\right)\right)} Q_{\mathrm{m}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right)
$$

In the case of integral distribution histogram, $E \in \mathcal{A}_{\mathrm{i}}$, this definition of the generalised iso-transform-independent conditional multinomial probability distribution, $\hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}(E, z)$, implies a corresponding constructible distribution $Q_{\mathrm{m}, \mathrm{y}, T, U}(E, z) \in\left(\mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathbf{N}\right) \subset \mathcal{Q}_{\mathrm{i}}$, by scaling the frequencies of
$\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z)$ by a factor,

$$
\begin{aligned}
& Q_{\mathrm{m}, \mathrm{y}, T, U}(E, z)(A):= \\
& \quad\left(\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, T, z}\right)\right| \prod_{X \in \operatorname{ran}\left(Y_{U, i, T, z}\right)} \sum_{B \in Y_{U, i, T, z}^{-1}(X)} Q_{\mathrm{m}, U}(E, z)(B)\right) \times \hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}(E, z)(A)
\end{aligned}
$$

### 3.17.6 Likely histograms

Let $A \in \mathcal{A}_{U, \mathrm{i}, V, z}$ be an integral substrate histogram in system $U$ having nonempty variables $V=\operatorname{vars}(A) \neq \emptyset$ and non-zero size $z=\operatorname{size}(A)>0$. The maximum likelihood estimate for the distribution histogram of the generalised multinomial probability of the histogram, $A$, is the mean or histogram itself,

$$
\{A\}=\operatorname{maxd}\left(\left\{\left(D, Q_{\mathrm{m}, U}(D, z)(A)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

The maximum likelihood estimate $A_{\mathrm{x}} \in \mathcal{A}_{U, V, z}$ for the distribution histogram of the sum of the generalised multinomial probabilities of the integral isoindependents of the histogram, $A$, is defined

$$
\left\{A_{\mathrm{x}}\right\}=\operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

where the integral iso-independents is

$$
Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{X}}=A^{\mathrm{x}}\right\}
$$

Conjecture that the maximum likelihood estimate for the multinomial probability of the membership of a histogram in the iso-independents is simply the independent, $A_{\mathrm{x}}=A^{\mathrm{X}}$.

The independent is in the iso-independents, $A^{\mathrm{X}} \in Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)$. If the independent is integral, it is in the integral iso-independents, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}} \Longrightarrow$ $A^{\mathrm{X}} \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$.

The histogram independent, $A^{\mathrm{X}}$, is the maximum likelihood estimate of the distribution histogram of the total multinomial probability of the subset of the integral substrate histograms which are such that the independent equals the histogram independent,

$$
\left\{A^{\mathrm{X}}\right\}=\operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

Now consider the case where the membership of the iso-independents is a given. Define the dependent histogram $A^{\mathrm{Y}} \in \mathcal{A}_{U, V, z}$ as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, A, conditional that it is an iso-independent,

$$
\left\{A^{\mathrm{Y}}\right\}=\operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

The dependent histogram, $A^{\mathrm{Y}}$, is only defined if there is a unique maximum,

$$
\left|\max \left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)\right|=1
$$

The dependent histogram equals the histogram if the histogram is independent, $A=A^{\mathrm{X}} \Longrightarrow A^{\mathrm{Y}}=A=A^{\mathrm{X}}$.

In the case where the histogram is not independent, $A \neq A^{\mathrm{X}}$, and the $i n$ dependent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, then the independent term appears in the denominator,

$$
\begin{aligned}
A^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}} & \Longrightarrow A^{\mathrm{x}} \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right) \Longrightarrow \\
& 0<Q_{\mathrm{m}, U}(D, z)\left(A^{\mathrm{x}}\right)<\sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right)
\end{aligned}
$$

The histogram term, $Q_{\mathrm{m}, U}(D, z)(A)$, appears in both the numerator and the denominator, so while (a) the maximum likelihood estimate for the numerator alone is just the mean, $A$, and (b) the maximum likelihood estimate for the denominator alone is the independent, $A^{\mathrm{X}}$, optimisation overall in the isoindependent case tends to minimise the independent term, $Q_{\mathrm{m}, U}(D, z)\left(A^{\mathrm{X}}\right)$, in the denominator, while maximising the histogram term, $Q_{\mathrm{m}, U}(D, z)(A)$, in the numerator. That is, in the denominator,

$$
\begin{aligned}
0 & <\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{Y}}, z\right)\left(A^{\mathrm{X}}\right) \\
& \leq \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{Y}}, z\right)(A) \\
& <\sum_{1}\left(\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{Y}}, z\right)(B): B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right) \\
& \leq 1
\end{aligned}
$$

So the overall maximum likelihood estimate, which is the dependent, is near the histogram, $A^{\mathrm{Y}} \sim A$, only in as much as it is far from the independent, $A^{\mathrm{Y}} \nsim A^{\mathrm{X}}$.

The dependent, $A^{\mathrm{Y}}$, is sometimes not computable. Although the substrate
histograms are countably infinite, $\mathcal{A}_{U, V, z} \leftrightarrow \mathbf{N}$, the maximisation never terminates. An approximation to the continuous case may be made by using a scaling factor. The scaled complete integral congruent histograms equals the complete congruent histograms in the limit

$$
\lim _{k \rightarrow \infty}\left\{A / Z_{k}: A \in \mathcal{A}_{U, \mathrm{i}, V, k z}\right\}=\mathcal{A}_{U, V, z}
$$

where $k \in \mathbf{N}_{>0}$ and $Z_{k}=\operatorname{scalar}(k)$. The finite approximation to the dependent is

$$
\begin{aligned}
& \left\{A_{k}^{\mathrm{Y}}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D / Z_{k}, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)}\right): D \in \mathcal{A}_{U, \mathrm{i}, V, k z}\right\}\right)
\end{aligned}
$$

which is defined if the maximisation is a singleton. The approximation, $A_{k}^{\mathrm{Y}} \approx A^{\mathrm{Y}}$, improves as $k$ tends to infinity.

Given a one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ having underlying variables equal to the variables $V$ of the substrate histogram, the transform-independent $A^{\mathrm{X}(T)} \in \mathcal{A}_{U, V, z}$ is defined as the maximum likelihood estimate for the distribution histogram of the sum of the generalised multinomial probabilities of the integral iso-transform-independents of the histogram, $A$,

$$
\left\{A^{\mathrm{X}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

where the integral iso-transform-independents is abbreviated

$$
\begin{aligned}
\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A) & =Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \\
& =\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{x}} * T=A^{\mathrm{x}} * T,(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}\right\}
\end{aligned}
$$

In the case where the integral iso-transform-independents equals the integral substrate histograms, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)=\mathcal{A}_{U, \mathrm{i}, V, z, z}$, there is no unique maximum, and the transform-independent is defined as the scaled normalised cartesian,

$$
\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)=\mathcal{A}_{U, \mathrm{i}, V, z} \Longrightarrow A^{\mathrm{X}(T)}:=Z_{A} * \hat{V}^{\mathrm{C}}
$$

where $Z_{A}=\operatorname{scalar}(\operatorname{size}(A))$ and $\hat{X}:=\operatorname{normalise}(X)$. Otherwise, this definition assumes that there is always a unique maximum,

$$
\begin{aligned}
& \forall A \in \mathcal{A}_{U, \mathrm{i}, V, z} \forall T \in \mathcal{T}_{U, V}\left(\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A) \neq \mathcal{A}_{U, \mathrm{i}, V, z} \Longrightarrow\right. \\
& \left.\quad\left(\left|\max \left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)\right|=1\right)\right)
\end{aligned}
$$

The transform-independent, $A^{\mathrm{X}(T)}$, is called the independent analogue of the iso-transform-independents.

The transform-independent is sometimes not computable. The likelihood function of the sum of the multinomial probabilities is a polynomial, so the roots of the derivative are algebraic rather than rational. The finite approximation to the algebraic case for the transform-independent for some $k \in \mathbf{N}_{>0}$ is

$$
\begin{aligned}
& \left\{A_{k}^{\mathrm{X}(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D / Z_{k}, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right)\right): D \in \mathcal{A}_{U, \mathrm{i}, V, k z}\right\}\right)
\end{aligned}
$$

In the case where the transform is full functional, $T=T_{\mathrm{f}}$, where $T_{\mathrm{f}}=$ $\left\{\{w\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: w \in V\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V}$, the iso-transform-independents equals the iso-independents, $Y_{U, i, T_{\mathrm{f}}, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T_{\mathrm{f}}\right),\left(A * T_{\mathrm{f}}\right)^{\mathrm{X}}\right)\right)=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, and the transform independent equals the independent, $A^{\mathrm{X}\left(T_{\mathrm{f}}\right)}=A^{\mathrm{X}}$.

At the other extreme where the transform is unary, $T=T_{\mathrm{u}}$, where $T_{\mathrm{u}}=$ $\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V}$, the iso-transform-independents equals the substrate histograms, $Y_{U, \mathrm{i}, T_{\mathrm{u}}, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T_{\mathrm{u}}\right),\left(A * T_{\mathrm{u}}\right)^{\mathrm{X}}\right)\right)=\mathcal{A}_{U, \mathrm{i}, V, z}$, and the transform independent equals the scaled normalised cartesian, $A^{\mathrm{X}\left(T_{\mathrm{u}}\right)}=Z_{A} * \hat{V}^{\mathrm{C}}$.

It is only in the case where the formal of the transform-independent equals the formal, $A^{\mathrm{X}(T) \mathrm{X}} * T=A^{\mathrm{X}} * T$ and the abstract of the transform-independent equals the abstract, $\left(A^{\mathrm{X}(T)} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$ that the transform-independent is in the iso-transform-independents,

$$
\begin{aligned}
\left(A^{\mathrm{X}(T) \mathrm{x}} * T=A^{\mathrm{x}} * T\right) \wedge\left(\left(A^{\mathrm{X}(T)} * T\right)^{\mathrm{x}}\right. & \left.=(A * T)^{\mathrm{X}}\right) \\
\Longleftrightarrow A^{\mathrm{X}(T)} & \in Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{x}}\right)\right)
\end{aligned}
$$

This is the case if the transform is full functional, $A^{\mathrm{X}\left(T_{\mathrm{f}}\right)}=A^{\mathrm{X}}$, or unary, $A^{\mathrm{X}\left(T_{\mathrm{u}}\right)}=Z_{A} * \hat{V}^{\mathrm{C}}$.

The integral iso-transform-independents have the same transform-independent,

$$
\forall B \in Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\left(B^{\mathrm{X}(T)}=A^{\mathrm{X}(T)}\right)
$$

so the relation is functional

$$
\left\{\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{x}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, T \in \mathcal{T}_{U, V}\right\}: \rightarrow\left\{A^{\mathrm{X}(T)}: A \in \mathcal{A}_{U, \mathrm{i}, V, z}, T \in \mathcal{T}_{U, V}\right\}
$$

Conjecture that, in the case where the independent is not cartesian, the relation is strictly iso-morphic,

$$
\begin{aligned}
&\left\{\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, \hat{A}^{\mathrm{X}} \neq \hat{V}^{\mathrm{C}}, T \in \mathcal{T}_{U, V}\right\}: \leftrightarrow: \\
&\left\{A^{\mathrm{X}(T)}: A \in \mathcal{A}_{U, \mathrm{i}, V, z}, \hat{A}^{\mathrm{X}} \neq \hat{V}^{\mathrm{C}}, T \in \mathcal{T}_{U, V}\right\}
\end{aligned}
$$

While the independent is in the iso-independents, $A^{\mathrm{X}} \in Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, it is only in the iso-transform-independents if the formal independent equals the abstract,

$$
\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}}=(A * T)^{\mathrm{x}} \Longrightarrow A^{\mathrm{X}} \in Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)
$$

The transform-independent is only in the iso-independents if its independent equals the independent,

$$
A^{\mathrm{X}(T) \mathrm{x}}=A^{\mathrm{X}} \Longrightarrow A^{\mathrm{X}(T)} \in Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)
$$

The degree to which the iso-transform-independents is said to be aligned-like is the iso-independence,

$$
\frac{\left|\mathcal{A}_{U \mathrm{i}, \mathrm{i}, T, z}(A) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|}{\left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A) \cup Y_{U U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|}=\frac{\left|Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left.\mid Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{x}}\right)\right) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right) \mid}
$$

As the iso-independence increases, the transform-independent, $A^{\mathrm{X}(T)}$, depends less on the transform, $T$, and tends to the independent, $A^{\mathrm{X}}$.

The lifted transform-independent $A^{\mathrm{X}(T)^{\prime}} \in \mathcal{A}_{U, W, z}$ is defined

$$
\begin{aligned}
& \left\{A^{\mathrm{X}(T)^{\prime}}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)\left(B^{\prime}\right): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right)\right): D \in \mathcal{A}_{U, W, z}\right\}\right)
\end{aligned}
$$

where the lifted integral iso-transform-independents is abbreviated

$$
\begin{aligned}
\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime} & (A) \\
& =\left\{B * T: B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right\} \\
& =\left\{B * T: B \in Y_{U \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right\} \\
& =\left\{B * T: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{X}} * T=A^{\mathrm{X}} * T,(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{X}}\right\}
\end{aligned}
$$

The derived iso-independence of the integral lifted iso-transform-independents is

$$
\frac{\left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right|}{\left|Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
$$

As the derived iso-independence increases, the lifted transform-independent, $A^{\mathrm{X}(T)^{\prime}}$, tends to the abstract, $(A * T)^{\mathrm{X}}$.

Conjecture that the maximum likelihood estimate for the integral isoformals is the naturalised formal, $A^{\mathrm{X}} * T * T^{\dagger}$,

$$
\begin{aligned}
& \left\{A^{\mathrm{X}} * T * T^{\dagger}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{x}} * T\right)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

where the integral iso-set does not equal the integral substrate histograms, $Y_{U \mathrm{i}, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \neq \mathcal{A}_{U, \mathrm{i}, V, z}$.

The naturalised formal, $A^{\mathrm{X}} * T * T^{\dagger}$, is the independent analogue of the iso-formals.

In the case where the transform is full functional, $T=T_{\mathrm{f}}$, the iso-formals equals the iso-independents, $Y_{U, i, T_{\mathrm{f}}, \mathrm{V}, z}^{-1}\left(A^{\mathrm{X}} * T_{\mathrm{f}}\right)=Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, and the naturalised formal equals the independent, $A^{\mathrm{X}} * T_{\mathrm{f}} * T_{\mathrm{f}}^{\dagger}=A^{\mathrm{X}}$. In the case where the transform is unary, $T=T_{\mathrm{u}}$, the iso-formals equals the substrate histograms, $Y_{U, i, T_{\mathrm{u}}, \mathrm{V}, z}^{-1}\left(A^{\mathrm{X}} * T_{\mathrm{u}}\right)=\mathcal{A}_{U, \mathrm{i}, V, z}$, and the naturalised formal equals the scaled normalised cartesian, $A^{\mathrm{X}} * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger}=Z_{A} * \hat{V}^{\mathrm{C}}$.

The naturalised formal is not necessarily in the iso-formals,

$$
\left(A^{\mathrm{x}} * T * T^{\dagger}\right)^{\mathrm{x}} * T=A^{\mathrm{x}} * T \Longleftrightarrow A^{\mathrm{x}} * T * T^{\dagger} \in Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{x}} * T\right)
$$

The naturalised formal is an iso-formal if the transform is full functional, $A^{\mathrm{X}} * T_{\mathrm{f}} * T_{\mathrm{f}}^{\dagger}=A^{\mathrm{X}}$, or unary, $A^{\mathrm{X}} * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger}=Z_{A} * \hat{V}^{\mathrm{C}}$.

Similarly, conjecture that the maximum likelihood estimate for the integral iso-abstracts is the naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$,

$$
\begin{aligned}
& \left\{(A * T)^{\mathrm{x}} * T^{\dagger}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

where the integral iso-set does not equal the integral substrate histograms, $Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \neq \mathcal{A}_{U, \mathrm{i}, V, z}$.

The naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$, is the independent analogue of the iso-abstracts.

In the case where the transform is full functional, $T=T_{\mathrm{f}}$, the iso-abstracts equals the iso-independents, $Y_{U, i, T, T_{\mathrm{f}}, \mathrm{W}, z}^{-1}\left(\left(A * T_{\mathrm{f}}\right)^{\mathrm{X}}\right)=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, and the naturalised abstract equals the independent, $\left(A * T_{\mathrm{f}}\right)^{\mathrm{X}} * T_{\mathrm{f}}^{\dagger}=A^{\mathrm{X}}$. In the case where
the transform is unary, $T=T_{\mathrm{u}}$, the iso-abstracts equals the substrate histograms, $Y_{U, \mathrm{i}, T_{\mathrm{u}}, \mathrm{W}, z}^{-1}\left(\left(A * T_{\mathrm{u}}\right)^{\mathrm{X}}\right)=\mathcal{A}_{U, \mathrm{i}, V, z}$, and the naturalised abstract equals the scaled normalised cartesian, $\left(A * T_{\mathrm{u}}\right)^{\mathrm{X}} * T_{\mathrm{u}}^{\dagger}=Z_{A} * \hat{V}^{\mathrm{C}}$.

The naturalised abstract is in the iso-abstracts, $(A * T)^{\mathrm{X}} * T^{\dagger} \in Y_{U, T, \mathrm{~W}, z}^{-1}((A *$ $T)^{\mathrm{X}}$ ), because $\left(\left((A * T)^{\mathrm{X}} * T^{\dagger}\right) * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$.

In the case where the formal equals the abstract, independent analogue of the iso-formals equals the independent analogue of the iso-abstracts,

$$
A^{\mathrm{x}} * T=(A * T)^{\mathrm{x}} \Longrightarrow A^{\mathrm{x}} * T * T^{\dagger}=(A * T)^{\mathrm{x}} * T^{\dagger}
$$

The iso-transform-independents is the intersection of the iso-formals and the iso-abstracts, so conjecture that, in this case, the independent analogue of the iso-transform-independents equals that of the iso-formals and the isoabstracts,

$$
A^{\mathrm{x}} * T=(A * T)^{\mathrm{X}} \Longrightarrow A^{\mathrm{x}(T)}=A^{\mathrm{x}} * T * T^{\dagger}=(A * T)^{\mathrm{x}} * T^{\dagger}
$$

In this case the transform-independent is formal, formal $\left(A^{\mathrm{X}(T)}, T\right)$,

$$
A^{\mathrm{x}} * T=(A * T)^{\mathrm{x}} \Longrightarrow A^{\mathrm{X}(T)} * T=A^{\mathrm{X}} * T
$$

and abstract, $\operatorname{abstract}\left(A^{\mathrm{X}(T)}, T\right)$,

$$
A^{\mathrm{x}} * T=(A * T)^{\mathrm{x}} \Longrightarrow A^{\mathrm{X}(T)} * T=(A * T)^{\mathrm{x}}=\left(A^{\mathrm{X}(T)} * T\right)^{\mathrm{x}}
$$

The transform-independent, $A^{\mathrm{X}(T)}$, is the maximum likelihood estimate of the distribution histogram of the multinomial probability of the subset of the substrate histograms which are such that the formal equals the histogram formal and the abstract equals the histogram abstract,

$$
\left\{A^{\mathrm{X}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

Now consider the case where the membership of the iso-transform-independents is a given. Define the transform-dependent $A^{\mathrm{Y}(T)} \in \mathcal{A}_{U, V, z}$ as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, $A$, conditional that it is an iso-transform-independent,

$$
\left\{A^{\mathrm{Y}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

The transform-dependent, $A^{\mathrm{Y}(T)}$, is the dependent analogue of the iso-transformindependents.

The transform-dependent histogram, $A^{\mathrm{Y}(T)}$, is only defined if there is a unique maximum,

$$
\left|\max \left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)\right|=1
$$

The transform-dependent histogram equals the histogram if the histogram equals the transform-independent histogram, $A=A^{\mathrm{X}(T)} \Longrightarrow A^{\mathrm{Y}(T)}=A=$ $A^{\mathrm{X}(T)}$.

The transform-dependent, $A^{\mathrm{Y}(T)}$, is sometimes not computable. The finite approximation to the transform-dependent is

$$
\begin{aligned}
& \left\{A_{k}^{\mathrm{Y}(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D / Z_{k}, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)}\right): D \in \mathcal{A}_{U, \mathrm{i}, V, k z}\right\}\right)
\end{aligned}
$$

In the case where the transform is full functional, $T=T_{\mathrm{f}}$, the iso-transformindependents equals the iso-independents, $Y_{U,, 1, T_{\mathrm{f}}, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T_{\mathrm{f}}\right),\left(A * T_{\mathrm{f}}\right)^{\mathrm{X}}\right)\right)=$ $Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, and the transform-dependent equals the dependent, $A^{\mathrm{Y}\left(T_{\mathrm{f}}\right)}=$ $A^{\mathrm{Y}}$. In the case where the transform is unary, $T=T_{\mathrm{u}}$, the iso-transformindependents equals the substrate histograms, $Y_{U, \mathbf{i}, T_{\mathrm{u}}, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T_{\mathrm{u}}\right),\left(A * T_{\mathrm{u}}\right)^{\mathrm{X}}\right)\right)=$ $\mathcal{A}_{U, \mathrm{i}, V, z}$, and the transform-dependent equals the histogram, $A^{\mathrm{Y}\left(T_{\mathrm{u}}\right)}=A$.

The maximum likelihood estimate for the numerator alone is the histogram, $A$, and the maximum likelihood estimate for the denominator alone is the transform-independent, $A^{\mathrm{X}(T)}$, so the overall maximum likelihood estimate, which is the transform-dependent, is near the histogram, $A^{\mathrm{Y}(T)} \sim A$, only in as much as it is far from the transform-independent, $A^{\mathrm{Y}(T)} \nsim A^{\mathrm{X}(T)}$.

As the iso-independence,
$\frac{\left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}=\frac{\left|Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cap Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}$
increases, the transform-dependent, $A^{\mathrm{Y}(T)}$, depends less on the transform, $T$, and tends to the dependent, $A^{\mathrm{Y}}$.

The maximum likelihood estimate for the integral iso-abstracts is conjectured above to be the naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$,

$$
\begin{aligned}
& \left\{(A * T)^{\mathrm{x}} * T^{\dagger}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$, is the independent analogue of the iso-abstracts.

The lifted abstract-independent $A^{\mathrm{U}(T)^{\prime}} \in \mathcal{A}_{U, W, z}$ is defined

$$
\begin{aligned}
& \left\{A^{\mathrm{U}(T)^{\prime}}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)\left(B^{\prime}\right): B^{\prime} \in \operatorname{isowl}(U)(T, A)\right)\right): D \in \mathcal{A}_{U, W, z}\right\}\right)
\end{aligned}
$$

where the lifted integral iso-abstracts is abbreviated

$$
\text { isowl }(U)(T, A):=\left\{B * T: B \in Y_{U, 1, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right\}
$$

The lifted iso-abstracts is a subset of the derived iso-independents, $\{B * T$ : $\left.B \in Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right\} \subseteq Y_{U, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$, so the derived iso-independence of the integral lifted iso-abstracts is

$$
\frac{\left|\left\{B * T: B \in Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right\}\right|}{\left|Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
$$

As the derived iso-independence increases, the lifted abstract-independent, $A^{\mathrm{U}(T)^{\prime}}$, tends to the abstract, $(A * T)^{\mathrm{X}}$.

Now consider the case where the membership of the iso-abstracts is a given. Define the abstract-dependent $A^{\mathrm{W}(T)} \in \mathcal{A}_{U, V, z}$ as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, A, conditional that it is an iso-abstract,

$$
\begin{aligned}
& \left\{A^{\mathrm{W}(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The abstract-dependent, $A^{\mathrm{W}(T)}$, is the dependent analogue of the iso-abstracts.
The abstract-dependent histogram, $A^{\mathrm{W}(T)}$, is only defined if there is a unique maximum,

$$
\left|\max \left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)\right|=1
$$

The abstract-dependent histogram equals the histogram if the histogram equals the naturalised abstract, $A=(A * T)^{\mathrm{x}} * T^{\dagger} \Longrightarrow A^{\mathrm{W}(T)}=A=(A * T)^{\mathrm{x}} * T^{\dagger}$.

The abstract-dependent, $A^{\mathrm{W}(T)}$, is sometimes not computable. The finite approximation to the abstract-dependent is

$$
\begin{aligned}
& \left\{A_{k}^{\mathrm{W}(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D / Z_{k}, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)}\right): D \in \mathcal{A}_{U, \mathrm{i}, V, k z}\right\}\right)
\end{aligned}
$$

In the case where the transform is full functional, $T=T_{\mathrm{f}}$, the iso-abstracts equals the iso-independents, $Y_{U, \mathrm{i}, T_{\mathrm{f}}, \mathrm{W}, z}^{-1}\left(\left(A * T_{\mathrm{f}}\right)^{\mathrm{X}}\right)=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, and the abstract-dependent equals the dependent, $A^{\mathrm{W}\left(T_{\mathrm{f}}\right)}=A^{\mathrm{Y}}$. In the case where the transform is unary, $T=T_{\mathrm{u}}$, the iso-abstracts equals the substrate histograms, $Y_{U, \mathrm{i}, T_{\mathrm{u}}, \mathrm{W}, z}^{-1}\left(\left(A * T_{\mathrm{u}}\right)^{\mathrm{X}}\right)=\mathcal{A}_{U, \mathrm{i}, V, z}$, and the abstract-dependent equals the histogram, $A^{\mathrm{W}\left(T_{\mathrm{u}}\right)}=A$.

The maximum likelihood estimate for the numerator alone is the histogram, $A$, and the maximum likelihood estimate for the denominator alone is the naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$, so the overall maximum likelihood estimate, which is the abstract-dependent, is near the histogram, $A^{\mathrm{W}(T)} \sim A$, only in as much as it is far from the naturalised abstract, $A^{\mathrm{W}(T)} \nsim(A * T)^{\mathrm{X}} * T^{\dagger}$.

Similar to the case of the iso-transform-independents, above, consider the case of the iso-partition-independents. Given a one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ having underlying variables equal to the variables $V$ of the substrate histogram, the partition-independent $A^{\mathrm{P}(T)} \in \mathcal{A}_{U, V, z}$ is defined as the maximum likelihood estimate for the distribution histogram of the sum of the generalised multinomial probabilities of the integral iso-partition-independents of the histogram, A,

$$
\left\{A^{\mathrm{P}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isop}(U)(T, A)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

where the integral iso-partition-independents is abbreviated

$$
\operatorname{isop}(U)(T, A):=Y_{U, \mathbf{i}, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \cap Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)
$$

and the iso-partition-independents is such that

$$
\begin{aligned}
& Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \\
& \quad=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z},\left(B^{\mathrm{X}} * T\right)^{\mathrm{x}}=\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}},(B * T)^{\mathrm{X}}=(A * T)^{\mathrm{x}}\right\}
\end{aligned}
$$

In the case where the transform is a substrate transform, $T \in \mathcal{T}_{U, V}$,

$$
\begin{aligned}
& Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}}\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \\
& \quad=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{~V}, z}, \forall P \in W\left(B^{\mathrm{x}} * P^{\mathrm{T}}=A^{\mathrm{x}} * P^{\mathrm{T}} \wedge B * P^{\mathrm{T}}=A * P^{\mathrm{T}}\right)\right\}
\end{aligned}
$$

In the case where the integral iso-partition-independents equals the integral substrate histograms, $\operatorname{isop}(U)(T, A)=\mathcal{A}_{U, \mathrm{i}, V, z}$, there is no unique maximum, and the partition-independent is defined as the scaled normalised cartesian,

$$
\operatorname{isop}(U)(T, A)=\mathcal{A}_{U, i, V, z} \Longrightarrow A^{\mathrm{P}(T)}:=Z_{A} * \hat{V}^{\mathrm{C}}
$$

where $Z_{A}=\operatorname{scalar}(\operatorname{size}(A))$ and $\hat{X}:=\operatorname{normalise}(X)$. Otherwise, this definition assumes that there is always a unique maximum,

$$
\begin{aligned}
& \forall A \in \mathcal{A}_{U, \mathrm{i}, V, z} \forall T \in \mathcal{T}_{U, V}\left(\operatorname{isop}(U)(T, A) \neq \mathcal{A}_{U, \mathrm{i}, V, z} \Longrightarrow\right. \\
& \left.\quad\left(\left|\max \left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isop}(U)(T, A)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)\right|=1\right)\right)
\end{aligned}
$$

The partition-independent, $A^{\mathrm{P}(T)}$, is called the independent analogue of the iso-partition-independents.

The partition-independent is sometimes not computable. The finite approximation for the partition-independent for some $k \in \mathbf{N}_{>0}$ is

$$
\begin{aligned}
& \left\{A_{k}^{\mathrm{P}(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D / Z_{k}, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isop}(U)(T, A)\right)\right): D \in \mathcal{A}_{U, \mathrm{i}, V, k z}\right\}\right)
\end{aligned}
$$

In the case where the transform is full functional, $T=T_{\mathrm{f}}$, where $T_{\mathrm{f}}=$ $\left\{\{w\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: w \in V\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V}$, the iso-partition-independents equals the isoindependents, $\operatorname{isop}(U)\left(T_{\mathrm{f}}, A\right)=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, and the partition-independent equals the independent, $A^{\mathrm{P}\left(T_{\mathrm{f}}\right)}=A^{\mathrm{X}}$.

At the other extreme where the transform is unary, $T=T_{\mathrm{u}}$, where $T_{\mathrm{u}}=$ $\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V}$, the iso-partition-independents equals the substrate histograms, $\operatorname{isop}(U)\left(T_{\mathrm{u}}, A\right)=\mathcal{A}_{U, \mathrm{i}, V, z}$, and the partition-independent equals the scaled normalised cartesian, $A^{\mathrm{P}\left(T_{\mathrm{u}}\right)}=Z_{A} * \hat{V}^{\mathrm{C}}$.

It is only in the case where the formal independent of the partition-independent equals the formal independent, $\left(A^{\mathrm{P}(T) \mathrm{X}} * T\right)^{\mathrm{X}}=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$ and the abstract of the partition-independent equals the abstract, $\left(A^{\mathrm{P}(T)} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$ that the partition-independent is in the iso-partition-independents,

$$
\begin{aligned}
& \left(\left(A^{\mathrm{P}(T) \mathrm{x}} * T\right)^{\mathrm{x}}=\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}}\right) \wedge\left(\left(A^{\mathrm{P}(T)} * T\right)^{\mathrm{x}}=(A * T)^{\mathrm{X}}\right) \\
& \quad \Longleftrightarrow A^{\mathrm{X}(T)} \in Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)
\end{aligned}
$$

This is the case if the transform is full functional, $A^{\mathrm{P}\left(T_{\mathrm{f}}\right)}=A^{\mathrm{X}}$, or unary, $A^{\mathrm{P}\left(T_{\mathrm{u}}\right)}=Z_{A} * \hat{V}^{\mathrm{C}}$.

The integral iso-partition-independents have the same partition-independent,

$$
\forall B \in \operatorname{isop}(U)(T, A)\left(B^{\mathrm{P}(T)}=A^{\mathrm{P}(T)}\right)
$$

so the relation is functional

$$
\left\{\left(\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}},(A * T)^{\mathrm{x}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, T \in \mathcal{T}_{U, V}\right\}: \rightarrow\left\{A^{\mathrm{P}(T)}: A \in \mathcal{A}_{U, \mathrm{i}, V, z}, T \in \mathcal{T}_{U, V}\right\}
$$

Conjecture that, in the case where the independent is not cartesian, the relation is strictly iso-morphic,

$$
\begin{aligned}
\left\{\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}},(A * T)^{\mathrm{x}}\right): A\right. & \left.\in \mathcal{A}_{U, \mathrm{i}, V, z}, \hat{A}^{\mathrm{X}} \neq \hat{V}^{\mathrm{C}}, T \in \mathcal{T}_{U, V}\right\}: \leftrightarrow: \\
& \left\{A^{\mathrm{P}(T)}: A \in \mathcal{A}_{U, \mathrm{i}, V, z}, \hat{A}^{\mathrm{X}} \neq \hat{V}^{\mathrm{C}}, T \in \mathcal{T}_{U, V}\right\}
\end{aligned}
$$

While the independent is in the iso-independents, $A^{\mathrm{X}} \in Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, it is only in the iso-partition-independents if the formal independent equals the abstract,
$\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}} \Longrightarrow A^{\mathrm{X}} \in Y_{U, T, \mathrm{~V}, \mathrm{x}, \mathrm{z}}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)$
The partition-independent is only in the iso-independents if its independent equals the independent,

$$
A^{\mathrm{P}(T) \mathrm{X}}=A^{\mathrm{X}} \Longrightarrow A^{\mathrm{P}(T)} \in Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)
$$

Conjecture that the maximum likelihood estimate for the integral iso-formal-independents is the naturalised formal independent, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}} * T^{\dagger}$,

$$
\begin{aligned}
& \left\{\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}} * T^{\dagger}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}\right)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

where the integral iso-set does not equal the integral substrate histograms, $Y_{U, i, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \neq \mathcal{A}_{U, \mathrm{i}, V, z}$.

The naturalised formal independent, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}} * T^{\dagger}$, is the independent analogue of the iso-formal-independents.

In the case where the transform is full functional, $T=T_{\mathrm{f}}$, the iso-formalindependents equals the iso-independents, $Y_{U, i, T, T, V, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T_{\mathrm{f}}\right)^{\mathrm{X}}\right)=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, and the naturalised formal independent equals the independent, $\left(A^{\mathrm{X}} * T_{\mathrm{f}}\right)^{\mathrm{X}} *$ $T_{\mathrm{f}}^{\dagger}=A^{\mathrm{X}}$. In the case where the transform is unary, $T=T_{\mathrm{u}}$, the iso-formalindependents equals the substrate histograms, $Y_{U, i, T, T, V, \mathbf{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T_{\mathrm{u}}\right)^{\mathrm{X}}\right)=\mathcal{A}_{U, \mathrm{i}, V, z}$,
and the naturalised formal independent equals the scaled normalised cartesian, $\left(A^{\mathrm{X}} * T_{\mathrm{u}}\right)^{\mathrm{X}} * T_{\mathrm{u}}^{\dagger}=Z_{A} * \hat{V}^{\mathrm{C}}$.

The naturalised formal independent is not necessarily in the iso-formals,

$$
\left(\left(\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}} * T^{\dagger}\right)^{\mathrm{x}} * T\right)^{\mathrm{x}}=\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}} \Longleftrightarrow\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}} * T^{\dagger} \in Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}\right)
$$

The naturalised formal independent is an iso-formal-independent if the transform is full functional, $\left(A^{\mathrm{X}} * T_{\mathrm{f}}\right)^{\mathrm{X}} * T_{\mathrm{f}}^{\dagger}=A^{\mathrm{X}}$, or unary, $\left(A^{\mathrm{X}} * T_{\mathrm{u}}\right)^{\mathrm{X}} * T_{\mathrm{u}}^{\dagger}=$ $Z_{A} * \hat{V}^{\mathrm{C}}$.

In the case where the formal independent equals the abstract, independent analogue of the iso-formal-independents equals the independent analogue of the iso-abstracts,

$$
\left(A^{\mathrm{x}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{x}} \Longrightarrow\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}} * T^{\dagger}=(A * T)^{\mathrm{x}} * T^{\dagger}
$$

The iso-partition-independents is the intersection of the iso-formal independents and the iso-abstracts, so conjecture that, in this case, the independent analogue of the iso-partition-independents equals that of the iso-formal independents and the iso-abstracts,

$$
\left(A^{\mathrm{x}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}} \Longrightarrow A^{\mathrm{P}(T)}=\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}} * T^{\dagger}=(A * T)^{\mathrm{X}} * T^{\dagger}
$$

The partition-independent, $A^{\mathrm{P}(T)}$, is the maximum likelihood estimate of the distribution histogram of the multinomial probability of the subset of the substrate histograms which are such that the formal independent equals the histogram formal independent and the abstract equals the histogram abstract,
$\left\{A^{\mathrm{P}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isop}(U)(T, A)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)$
Now consider the case where the membership of the iso-partition-independents is a given. Define the partition-dependent $A^{\mathrm{R}(T)} \in \mathcal{A}_{U, V, z}$ as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, $A$, conditional that it is an iso-partition-independent,

$$
\left\{A^{\mathrm{R}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isop}(U)(T, A)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

The partition-dependent, $A^{\mathrm{R}(T)}$, is the dependent analogue of the iso-partitionindependents.

The partition-dependent histogram, $A^{\mathrm{R}(T)}$, is only defined if there is a unique maximum,

$$
\left|\max \left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isop}(U)(T, A)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)\right|=1
$$

The partition-dependent histogram equals the histogram if the histogram equals the partition-independent histogram, $A=A^{\mathrm{P}(T)} \Longrightarrow A^{\mathrm{R}(T)}=A=$ $A^{\mathrm{P}(T)}$.

The partition-dependent, $A^{\mathrm{R}(T)}$, is sometimes not computable. The finite approximation to the partition-dependent is

$$
\begin{aligned}
& \left\{A_{k}^{\mathrm{R}(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D / Z_{k}, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isop}(U)(T, A)}\right): D \in \mathcal{A}_{U, i, V, k z}\right\}\right)
\end{aligned}
$$

In the case where the transform is full functional, $T=T_{\mathrm{f}}$, the iso-partitionindependents equals the iso-independents, $\operatorname{isop}(U)\left(T_{\mathrm{f}}, A\right)=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, and the partition-dependent equals the dependent, $A^{\mathrm{R}\left(T_{\mathrm{f}}\right)}=A^{\mathrm{Y}}$. In the case where the transform is unary, $T=T_{\mathrm{u}}$, the iso-partition-independents equals the substrate histograms, $\operatorname{isop}(U)\left(T_{\mathrm{u}}, A\right)=\mathcal{A}_{U, \mathrm{i}, V, z}$, and the partition-dependent equals the histogram, $A^{\mathrm{R}\left(T_{\mathrm{u}}\right)}=A$.

The maximum likelihood estimate for the numerator alone is the histogram, $A$, and the maximum likelihood estimate for the denominator alone is the partition-independent, $A^{\mathrm{P}(T)}$, so the overall maximum likelihood estimate, which is the partition-dependent, is near the histogram, $A^{\mathrm{R}(T)} \sim A$, only in as much as it is far from the partition-independent, $A^{\mathrm{R}(T)} \nsim A^{\mathrm{P}(T)}$.

The maximum likelihood estimate for the integral iso-independents of histogram $A$ is conjectured above to be the independent, $A^{\mathrm{X}}$,

$$
\left\{A^{\mathrm{x}}\right\}=\operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

Similarly, conjecture that, given one functional transform $T \in \mathcal{T}_{U, f, 1}$, the maximum likelihood estimate for the integral iso-deriveds is the naturalisation, $A * T * T^{\dagger}$,

$$
\begin{aligned}
& \left\{A * T * T^{\dagger}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

where the integral iso-set does not equal the integral substrate histograms, $D_{U, i, T, z}^{-1}(A * T) \neq \mathcal{A}_{U, i, V, z}$.

The naturalisation, $A * T * T^{\dagger}$, is the independent analogue of the iso-deriveds.
The derived of the naturalisation equals the derived, $\left(A * T * T^{\dagger}\right) * T=A * T$, and the components of the naturalisation are uniform, $\forall C \in T^{\mathrm{P}}(((A * T *$ $\left.\left.\left.T^{\dagger}\right) * C^{\mathrm{U}}\right)^{\wedge}=\left(V^{\mathrm{C}} * C^{\mathrm{U}}\right)^{\wedge}\right)$. The naturalisation is a member of the iso-deriveds, $A * T * T^{\dagger} \in D_{U, T, z}^{-1}(A * T)$. If the naturalisation is integral it is a member of the integral iso-deriveds,

$$
A * T * T^{\dagger} \in \mathcal{A}_{\mathbf{i}} \Longrightarrow A * T * T^{\dagger} \in D_{U, i, T, z}^{-1}(A * T)
$$

In the case where the transform is full functional, $T=T_{\mathrm{f}}$, the integral isoderiveds is a singleton, $D_{U, i, T_{\mathrm{f}}, z}^{-1}\left(A * T_{\mathrm{f}}\right)=\{A\}$, and the naturalisation equals the histogram, $A * T_{\mathrm{f}} * T_{\mathrm{f}}^{\dagger}=A$. In the case where the transform is unary, $T=T_{\mathbf{u}}$, the integral iso-deriveds equals the substrate histograms, $D_{U, i, T, z}^{-1}(A *$ $\left.T_{\mathrm{u}}\right)=\mathcal{A}_{U, \mathrm{i}, V, z}$, and the naturalisation equals the scaled normalised cartesian, $A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger}=Z_{A} * \hat{V}^{\mathrm{C}}$.

Now consider the case where the membership of the iso-deriveds is a given. Define the derived-dependent $A^{\mathrm{D}(T)} \in \mathcal{A}_{U, V, z}$ as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, $A$, conditional that it is an iso-derived,

$$
\left\{A^{\mathrm{D}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

The derived-dependent, $A^{\mathrm{D}(T)}$, is the dependent analogue of the iso-deriveds.
The derived-dependent histogram, $A^{\mathrm{D}(T)}$, is only defined if there is a unique maximum,

$$
\left|\max \left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)\right|=1
$$

The derived-dependent histogram equals the histogram if the histogram equals the naturalisation histogram, $A=A * T * T^{\dagger} \Longrightarrow A^{\mathrm{D}(T)}=A=A * T * T^{\dagger}$.

The derived-dependent, $A^{\mathrm{D}(T)}$, is sometimes not computable. The finite ap-
proximation to the derived-dependent is

$$
\begin{aligned}
& \left\{A_{k}^{\mathrm{D}(T)}\right\}= \\
& \quad \quad \operatorname{maxd}\left(\left\{\left(D / Z_{k}, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in D_{U, \mathbf{i}, T, z}^{-1}(A * T)}\right): D \in \mathcal{A}_{U, \mathrm{i}, V, k z}\right\}\right)
\end{aligned}
$$

In the case where the transform is full functional, $T=T_{\mathrm{f}}$, the integral isoderiveds is a singleton, $D_{U, \mathbf{i}, T_{\mathrm{f}}, z}^{-1}\left(A * T_{\mathrm{f}}\right)=\{A\}$, and the derived-dependent is undefined. In the case where the transform is unary, $T=T_{\mathrm{u}}$, the integral iso-deriveds equals the substrate histograms, $D_{U, i, T_{\mathbf{u}}, z}^{-1}\left(A * T_{\mathbf{u}}\right)=\mathcal{A}_{U, \mathrm{i}, V, z}$, and the derived-dependent equals the histogram, $A^{\mathrm{D}\left(T_{\mathrm{u}}\right)}=A$.

The maximum likelihood estimate for the numerator alone is the histogram, $A$, and the maximum likelihood estimate for the denominator alone is the naturalisation, $A * T * T^{\dagger}$, so the overall maximum likelihood estimate, which is the derived-dependent, is near the histogram, $A^{\mathrm{D}(T)} \sim A$, only in as much as it is far from the naturalisation, $A^{\mathrm{D}(T)} \nsim A * T * T^{\dagger}$.

Now consider the case where the model is extended from transforms to (i) fuds, (ii) decompositions and (iii) fud decompositions.

Let $F$ be a one functional definition set, $F \in \mathcal{F}_{U, 1}$, such that the underlying are a subset of the histogram variables, und $(F) \subseteq V$, and there exists a top transform, $\exists T \in F(\operatorname{der}(T)=\operatorname{der}(F))$. The derived set valued function of the substrate histograms is

$$
D_{U, F, z}=\left\{\left(A,\left\{A * T_{F}: T \in F\right\}\right): A \in \mathcal{A}_{U, V, z}\right\}
$$

where $T_{F}:=\operatorname{depends}(F, \operatorname{der}(T))^{\mathrm{T}}$. In this case the top transform exists so the set of iso-fuds is a subset of the iso-deriveds,

$$
D_{U, F, z}^{-1}\left(\left\{A * T_{F}: T \in F\right\}\right) \subseteq D_{U, F^{\mathrm{T}}, z}^{-1}\left(A * F^{\mathrm{T}}\right)
$$

Define the fud-independent $A^{\mathrm{E}_{\mathbf{F}}(F)} \in \mathcal{A}_{U, V, z}$, as the maximum likelihood estimate for the distribution histogram of the sum of the generalised multinomial probabilities of the integral iso-fuds of the histogram, A,

$$
\begin{aligned}
& \left\{A^{\mathrm{E}_{\mathrm{F}}(F)}\right\}= \\
& \quad \quad \operatorname{maxd}\left(\left\{\left(E, \sum\left(Q_{\mathrm{m}, U}(E, z)(B): B \in D_{U, \mathbf{i}, F, z}^{-1}\left(D_{U, F, z}(A)\right)\right)\right): E \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The fud-independent, $A^{\mathrm{E}_{\mathrm{F}}(F)}$, is the independent analogue of the iso-fuds.

Like the transform-independent, $A^{\mathrm{X}(T)}$, the fud-independent, $A^{\mathrm{E}_{\mathrm{F}}(F)}$, is sometimes not computable. It approximates, however, to the arithmetic average of the naturalisations,

$$
A^{\mathrm{E}_{\mathrm{F}}(F)} \approx Z_{1 /|F|} * \sum_{T \in F} A * T_{F} * T_{F}^{\dagger}
$$

Define the fud-dependent $A^{\mathrm{D}_{\mathrm{F}}(F)} \in \mathcal{A}_{U, V, z}$ as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, $A$, conditional that it is an iso-fud,

$$
\begin{aligned}
& \left\{A^{\mathrm{D}_{\mathrm{F}}(F)}\right\}= \\
& \quad \quad \operatorname{maxd}\left(\left\{\left(E, \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum Q_{\mathrm{m}, U}(E, z)(B): B \in D_{U, \mathrm{i}, F, z}^{-1}\left(D_{U, F, z}(A)\right)}\right): E \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The fud-dependent, $A^{\mathrm{D}_{\mathrm{F}}(F)}$, is the dependent analogue of the set of the isofuds.

The fud-dependent equals the histogram only if the histogram equals the fud-independent,

$$
A=A^{\mathrm{E}_{\mathrm{F}}(F)} \Longrightarrow A^{\mathrm{D}_{\mathrm{F}}(F)}=A
$$

The maximum likelihood estimate is near the histogram, $A^{\mathrm{D}_{\mathrm{F}}(F)} \sim A$, only in as much as it is far from the fud-independent, $A^{\mathrm{D}_{\mathrm{F}}(F)} \nsim A^{\mathrm{E}_{\mathrm{F}}(F)}$.

Let $D$ be a decomposition of one functional transforms, $D \in \mathcal{D}_{U}=\mathcal{D} \cap$ $\operatorname{trees}\left(\mathcal{S}_{U} \times \mathcal{T}_{U, \mathrm{f}, 1}\right)$, such that the underlying are a subset of the histogram variables, $\operatorname{und}(D) \subseteq V$. The component-derived relation valued function of the substrate histograms is

$$
D_{U, D, z}=\left\{(A,\{(C, A * C * T):(C, T) \in \operatorname{cont}(D)\}): A \in \mathcal{A}_{U, V, z}\right\}
$$

where $\operatorname{cont}(D)=$ elements $($ contingents $(D))$.
The set of iso-decompositions is a subset of the iso-deriveds of the transform of the decomposition,

$$
D_{U, D, z}^{-1}\left(D_{U, D, z}(A)\right) \subseteq D_{U, D^{\mathrm{T}}, z}^{-1}\left(A * D^{\mathrm{T}}\right)
$$

Define the decomposition-independent $A^{\mathrm{E}_{\mathrm{D}}(D)} \in \mathcal{A}_{U, V, z}$, as the maximum likelihood estimate for the distribution histogram of the sum of the generalised
multinomial probabilities of the integral iso-decompositions of the histogram, A,

$$
\begin{aligned}
& \left\{A^{\mathrm{E}_{\mathrm{D}}(D)}\right\}= \\
& \quad \quad \operatorname{maxd}\left(\left\{\left(E, \sum\left(Q_{\mathrm{m}, U}(E, z)(B): B \in D_{U, \mathrm{i}, D, z}^{-1}\left(D_{U, D, z}(A)\right)\right)\right): E \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The decomposition-independent, $A^{\mathrm{E}_{\mathrm{D}}(D)}$, is the independent analogue of the iso-decompositions.

The decomposition-independent, $A^{\mathrm{E}_{\mathrm{D}}(D)}$, is sometimes not computable. It approximates, however, to the scaled sum of the slice naturalisations,

$$
A^{\mathrm{E}_{\mathrm{D}}(D)} \approx Z_{z} *\left(\sum_{(C, T) \in \operatorname{cont}(D)} A * C * T * T^{\dagger}\right)^{\wedge}
$$

where ()$^{\wedge}=$ normalise.
Define the decomposition-dependent $A^{\mathrm{D}_{\mathrm{D}}(D)} \in \mathcal{A}_{U, V, z}$ as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, $A$, conditional that it is an iso-decomposition,

$$
\begin{aligned}
& \left\{A^{\mathrm{D}_{\mathrm{D}}(D)}\right\}= \\
& \quad \quad \operatorname{maxd}\left(\left\{\left(E, \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum Q_{\mathrm{m}, U}(E, z)(B): B \in D_{U, \mathrm{i}, D, z}^{-1}\left(D_{U, D, z}(A)\right)}\right): E \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The decomposition-dependent, $A^{\mathrm{D}_{\mathrm{D}}(D)}$, is the dependent analogue of the set of the iso-decompositions.

The decomposition-dependent equals the histogram only if the histogram equals the decomposition-independent,

$$
A=A^{\mathrm{E}_{\mathrm{D}}(D)} \Longrightarrow A^{\mathrm{D}_{\mathrm{D}}(D)}=A
$$

The maximum likelihood estimate is near the histogram, $A^{\mathrm{D}_{\mathrm{D}}(D)} \sim A$, only in as much as it is far from the decomposition-independent, $A^{\mathrm{D}_{\mathrm{D}}(D)} \nsim A^{\mathrm{E}_{\mathrm{D}}(D)}$.

Let $D$ be a fud decomposition of one functional definition sets, $D \in \mathcal{D}_{\mathrm{F}, U}=$ $\mathcal{D}_{\mathrm{F}} \cap \operatorname{trees}\left(\mathcal{S}_{U} \times \mathcal{F}_{U, 1}\right)$, such that the underlying are a subset of the histogram variables, und $(D) \subseteq V$, and the top transform exists for all of the fuds, $\forall F \in \operatorname{fuds}(D) \exists T \in F(\operatorname{der}(T)=\operatorname{der}(F))$. The component-derived-set relation valued function of the substrate histograms is

$$
D_{U, D, F, z}=\left\{\left(A,\left\{\left(C,\left\{A * C * T_{F}: T \in F\right\}\right):(C, F) \in \operatorname{cont}(D)\right\}\right): A \in \mathcal{A}_{U, V, z}\right\}
$$

In this case the top transforms exist, so the set of iso-fud-decompositions is a subset of the iso-deriveds of the transform of the decomposition,

$$
D_{U, D, \mathrm{~F}, z}^{-1}\left(D_{U, D, \mathrm{~F}, z}(A)\right) \subseteq D_{U, D^{\mathrm{T}}, z}^{-1}\left(A * D^{\mathrm{T}}\right)
$$

Define the fud-decomposition-independent $A^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}(D)} \in \mathcal{A}_{U, V, z}$, as the maximum likelihood estimate for the distribution histogram of the sum of the generalised multinomial probabilities of the integral iso-fuds of the histogram, $A$,
$\left\{A^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}(D)}\right\}=$

$$
\operatorname{maxd}\left(\left\{\left(E, \sum\left(Q_{\mathrm{m}, U}(E, z)(B): B \in D_{U, \mathrm{i}, D, \mathrm{~F}, z}^{-1}\left(D_{U, D, \mathrm{~F}, z}(A)\right)\right)\right): E \in \mathcal{A}_{U, V, z}\right\}\right)
$$

The fud-decomposition-independent, $A^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}(F)}$, is the independent analogue of the iso-fuds.

The fud-decomposition-independent, $A^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}(D)}$, is sometimes not computable. It approximates, however, to the scaled sum of the slice arithmetic average of the naturalisations,

$$
A^{\mathrm{E}_{\mathrm{D}, \mathrm{~F}}(D)} \approx Z_{z} *\left(\sum_{(C, F) \in \operatorname{cont}(D)}\left(Z_{1 /|F|} * \sum_{T \in F} A * C * T_{F} * T_{F}^{\dagger}\right)\right)^{\wedge}
$$

Define the fud-decomposition-dependent $A^{\mathrm{D}_{\mathrm{D}, \mathrm{F}}(D)} \in \mathcal{A}_{U, V, z}$ as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, $A$, conditional that it is an iso-fud-decomposition,

$$
\begin{aligned}
& \left\{A^{\mathrm{D}_{\mathrm{D}, \mathrm{~F}(D)}}\right\}= \\
& \quad \quad \operatorname{maxd}\left(\left\{\left(E, \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum Q_{\mathrm{m}, U}(E, z)(B): B \in D_{U, i, D, \mathrm{~F}, z}^{-1}\left(D_{U, D, \mathrm{~F}, z}(A)\right)}\right): E \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The fud-decomposition-dependent, $A^{\mathrm{D}_{\mathrm{D}, \mathrm{F}}(D)}$, is the dependent analogue of the set of the iso-fud-decompositions.

The fud-decomposition-dependent equals the histogram only if the histogram equals the fud-decomposition-independent,

$$
A=A^{\mathrm{E}_{\mathrm{D}, \mathrm{~F}}(D)} \Longrightarrow A^{\mathrm{D}_{\mathrm{D}, \mathrm{~F}}(D)}=A
$$

The maximum likelihood estimate is near the histogram, $A^{\mathrm{D}_{\mathrm{D}, \mathrm{F}}(D)} \sim A$, only in as much as it is far from the decomposition-independent, $A^{\mathrm{D}_{\mathrm{D}, \mathrm{F}}(D)} \nsim A^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}(D)}$.

Conjecture that the maximum likelihood estimate for the integral isocomponents is the unnaturalisation, $V_{z}^{\mathrm{C}} * T * T^{\odot A}$,

$$
\begin{aligned}
& \left\{V_{z}^{\mathrm{C}} * T * T^{\odot A}\right\}= \\
& \quad \quad \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in C_{U, \mathrm{i}, T, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right)\right)\right)\right.\right.
\end{aligned}
$$

$$
\left.\left.: D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

where the integral iso-set does not equal the integral substrate histograms, $C_{U, i, T, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right) \neq \mathcal{A}_{U, \mathrm{i}, V, z}$.

The unnaturalisation, $V_{z}^{\mathrm{C}} * T * T^{\odot A}$, is the independent analogue of the isocomponents.

Now consider the case where the membership of the iso-components is a given. Define the components-dependent $A^{\mathrm{C}(T)} \in \mathcal{A}_{U, V, z}$ as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, $A$, conditional that it is an iso-components,

$$
\begin{aligned}
& \left\{A^{\mathrm{C}(T)}\right\}= \\
& \qquad \begin{array}{l}
\operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in C_{U, \mathrm{i}, T, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right)}\right)\right.\right. \\
\\
\left.\left.: D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{array}
\end{aligned}
$$

The components-dependent, $A^{\mathrm{C}(T)}$, is the dependent analogue of the isocomponents.

The maximum likelihood estimate is near the histogram, $A^{\mathrm{C}(T)} \sim A$, only in as much as it is far from the unnaturalisation, $A^{\mathrm{C}(T)} \nsim V_{z}^{\mathrm{C}} * T * T^{\odot A}$.

The set of iso-liftisations is defined (in section 'Iso-sets', above) as the intersection of the iso-formals and iso-deriveds

$$
Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap D_{U, T, z}^{-1}(A * T)
$$

Define the liftisation, $A^{\mathrm{K}(T)} \in \mathcal{A}_{U, V, z}$, as the maximum likelihood estimate for the distribution histogram of the sum of the generalised multinomial probabilities of the integral iso-liftisations of the histogram, $A$,
$\left\{A^{\mathrm{K}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isol}(U)(T, A)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)$
where $\operatorname{isol}(U)(T, A):=Y_{U, i, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap D_{U, \mathrm{i}, T, z}^{-1}(A * T)$, and the integral isoset does not equal the integral substrate histograms, $\operatorname{isol}(U)(T, A) \neq \mathcal{A}_{U, \mathrm{i}, V, z}$.

The liftisation, $A^{\mathrm{K}(T)}$, is the independent analogue of the iso-liftisations.
Like the transform-independent, $A^{\mathrm{X}(T)}$, the liftisation, $A^{\mathrm{K}(T)}$, is sometimes not computable.

As for the set of iso-deriveds and the corresponding independent analogue, the naturalisation, $A * T * T^{\dagger}$, in the case where the transform is full functional, $T=T_{\mathrm{f}}$, the liftisation equals the histogram, $A^{\mathrm{K}\left(T_{\mathrm{f}}\right)}=A$, and in the case where the transform is unary, $T=T_{\mathrm{u}}$, the liftisation equals the scaled normalised cartesian, $A^{\mathrm{K}\left(T_{\mathrm{u}}\right)}=Z_{A} * \hat{V}^{\mathrm{C}}$. In the case where the formal of the naturalisation equals the formal, the liftisation equals the naturalisation, $\left(A * T * T^{\dagger}\right)^{\mathrm{X}} * T=A^{\mathrm{X}} * T \Longrightarrow A^{\mathrm{K}(T)}=A * T * T^{\dagger}$, otherwise the liftisation varies between the naturalised formal, $A^{\mathrm{K}(T)} \sim A^{\mathrm{X}} * T * T^{\dagger}$, and the naturalisation, $A^{\mathrm{K}(T)} \sim A * T * T^{\dagger}$.

It is only in the case where the formal of the liftisation equals the formal, $A^{\mathrm{K}(T) \mathrm{X}} * T=A^{\mathrm{X}} * T$ and the derived of the liftisation equals the derived, $A^{\mathrm{K}(T)} * T=A * T$, that the liftisation is in the iso-liftisations,

$$
\begin{aligned}
\left(A^{\mathrm{K}(T) \mathrm{X}} * T=A^{\mathrm{X}} * T\right) \wedge & \left(A^{\mathrm{K}(T)} * T=A * T\right) \\
& \Longleftrightarrow A^{\mathrm{K}(T)} \in Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap D_{U, T, z}^{-1}(A * T)
\end{aligned}
$$

Consider the case where the membership of the iso-liftisations is a given. Define the liftisation-dependent $A^{\mathrm{L}(T)} \in \mathcal{A}_{U, V, z}$ as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, $A$, conditional that it is an iso-liftisation,

$$
\begin{aligned}
& \left\{A^{\mathrm{L}(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isol}(U)(T, A)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The liftisation-dependent, $A^{\mathrm{L}(T)}$, is the dependent analogue of the set of the iso-liftisations.

The maximum likelihood estimate is near the histogram, $A^{\mathrm{L}(T)} \sim A$, only in as much as it is far from the liftisation, $A^{\mathrm{L}(T)} \nsim A^{\mathrm{K}(T)}$.

The set of iso-idealisations is (i) the intersection of the iso-componentindependents and the iso-derived which is (ii) a subset of the intersection
of the iso-independents and iso-deriveds which is (iii) a subset of the isoliftisations which is (iv) a subset of the iso-transform-independents which is (v) a subset of the iso-partition-independents which is (vi) a subset of the iso-abstracts,

$$
\begin{aligned}
Y_{U, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right) & =C_{U T, \mathrm{x}, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\mathrm{X} \wedge}: C \in T^{\mathrm{P}}\right\}\right) \cap D_{U, T, z}^{-1}(A * T) \\
& \subseteq Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right) \cap D_{U, T, z}^{-1}(A * T) \\
& \subseteq Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap D_{U, T, z}^{-1}(A * T) \\
& \subseteq Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \\
& \subseteq Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \\
& \subseteq Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)
\end{aligned}
$$

Conjecture that, given one functional transform $T \in \mathcal{T}_{U, f, 1}$, the maximum likelihood estimate for the integral iso-idealisations is the idealisation, $A * T *$ $T^{\dagger A}$,

$$
\begin{aligned}
& \left\{A * T * T^{\dagger A}\right\}= \\
& \quad \quad \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isoi}(U)(T, A)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

where isoi $(U)(T, A):=Y_{U, \mathrm{i}, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)$ and the integral iso-set does not equal the integral substrate histograms, isoi $(U)(T, A) \neq \mathcal{A}_{U, \mathrm{i}, V, z}$.

The idealisation, $A * T * T^{\dagger A}$, is the independent analogue of the iso-idealisations.
The derived of the idealisation equals the derived, $\left(A * T * T^{\dagger} A\right) * T=A * T$, the independent of the idealisation equals the independent, $\left(A * T * T^{\dagger A}\right)^{\mathrm{X}}=A^{\mathrm{X}}$, and the components of the idealisation are independent, $\forall C \in T^{\mathrm{P}}((A * T *$ $\left.\left.T^{\dagger A}\right) * C^{\mathrm{U}}=\left(\left(A * T * T^{\dagger A}\right) * C^{\mathrm{U}}\right)^{\mathrm{X}}\right)$. If the idealisation is integral it is a member of the integral iso-idealisations,

$$
A * T * T^{\dagger A} \in \mathcal{A}_{\mathrm{i}} \Longrightarrow A * T * T^{\dagger A} \in Y_{U,, i, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)
$$

In addition, it is a member of the integral iso-independents, integral isoderiveds, and the integral iso-transform-independents,

$$
\begin{aligned}
A * T * T^{\dagger A} \in \mathcal{A}_{\mathbf{i}} & \Longrightarrow \\
A * T * T^{\dagger A} \in & Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right) \cap D_{U, \mathrm{i}, T, z}^{-1}(A * T) \cap \\
& Y_{U, \mathrm{i}, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)
\end{aligned}
$$

In the case where the transform is full functional, $T=T_{\mathrm{f}}$, the integral isoidealisations is a singleton, $Y_{U, \mathrm{i}, T_{\mathrm{f}}, \mathrm{f}, z}^{-1}\left(A * T_{\mathrm{f}} * T_{\mathrm{f}}^{\dagger A}\right)=\{A\}$, and the idealisation
equals the histogram, $A * T_{\mathrm{f}} * T_{\mathrm{f}}^{\dagger A}=A$. In the case where the transform is unary, $T=T_{\mathrm{u}}$, the integral iso-idealisations equals the iso-independents, $Y_{U, i, T \mathrm{u}, \uparrow, z}^{-1}\left(A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger A}\right)=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, and the idealisation equals the independent, $A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger A}=A^{\mathrm{X}}$.

Consider the case where the membership of the iso-idealisations is a given. Define the idealisation-dependent $A^{\dagger(T)} \in \mathcal{A}_{U, V, z}$ as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, $A$, conditional that it is an iso-idealisation,

$$
\begin{aligned}
& \left\{A^{\dagger(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isoi}(U)(T, A)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The idealisation-dependent, $A^{\dagger(T)}$, is the dependent analogue of the set of the iso-idealisations.

The idealisation-dependent equals the histogram if the histogram is ideal, $\operatorname{ideal}(A, T) \Longrightarrow A^{\dagger(T)}=A=A * T * T^{\dagger A}$.

The maximum likelihood estimate is near the histogram, $A^{\dagger(T)} \sim A$, only in as much as it is far from the idealisation, $A^{\dagger(T)} \nsim A * T * T^{\dagger A}$.

The derived-dependent is intermediate between the idealisation-dependent and the transform-dependent, $A^{\dagger(T)} \sim A^{\mathrm{D}(T)} \sim A^{\mathrm{Y}(T)}$.

The set of iso-surrealisations is the intersection of the iso-abstracts and iso-components

$$
Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \cap C_{U, T, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right)
$$

Conjecture that the maximum likelihood estimate for the integral iso surrealisations is the surrealisation, $(A * T)^{\mathrm{X}} * T^{\odot A}$,

$$
\begin{aligned}
& \left\{(A * T)^{\mathrm{X}} * T^{\odot A}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isor}(U)(T, A)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

where isor $(U)(T, A):=Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \cap C_{U, \mathrm{i}, T, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right)$ and the integral iso-set does not equal the integral substrate histograms, $\operatorname{isor}(U)(T, A) \neq \mathcal{A}_{U, \mathrm{i}, V, z}$.

The surrealisation, $(A * T)^{\mathrm{X}} * T^{\odot A}$, is the independent analogue of the isosurrealisations.

The surrealisation is an iso-surrealisation, $(A * T)^{\mathrm{X}} * T^{\odot A} \in Y_{U, T, \mathrm{~W}, z}^{-1}((A *$ $\left.T)^{\mathrm{X}}\right) \cap C_{U, T, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right)$.

The surrealisation varies as the naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\odot A} \sim$ $(A * T)^{\mathrm{X}} * T^{\dagger}$, and the unnaturalisation, $(A * T)^{\mathrm{X}} * T^{\odot A} \sim V_{z}^{\mathrm{C}} * T * T^{\odot A}$.

Consider the case where the membership of the iso-surrealisations is a given. Define the surrealisation-dependent $A^{\odot(T)} \in \mathcal{A}_{U, V, z}$ as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, $A$, conditional that it is an iso-surrealisation,

$$
\begin{aligned}
& \left\{A^{\odot(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isor}(U)(T, A)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The surrealisation-dependent, $A^{\odot(T)}$, is the dependent analogue of the set of the iso-surrealisations.

The surrealisation-dependent equals the histogram if the histogram is surreal,

$$
\operatorname{abstract}(A, T) \Longrightarrow A^{\odot(T)}=A=(A * T)^{\mathrm{x}} * T^{\odot A}
$$

The maximum likelihood estimate is near the histogram, $A^{\odot}(T) \sim A$, only in as much as it is far from the surrealisation, $A^{\odot(T)} \nsim(A * T)^{\mathrm{X}} * T^{\odot A}$.

The surrealisation-dependent varies with the components-dependent, $A^{\odot(T)} \sim$ $A^{\mathrm{C}(T)}$.

The set of iso-extremes is defined in section 'Iso-sets', above, as the union of the iso-liftisations and the iso-surrealisations,

$$
\begin{aligned}
\left(Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)\right. & \left.\cap D_{U, T, z}^{-1}(A * T)\right) \cup \\
\left(Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right. & \left.\cap C_{U, T, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\wedge}: C \in T^{\mathrm{P}}\right\}\right)\right)
\end{aligned}
$$

The set of iso-extremes is not, strictly speaking, an iso-set, because there is no independent analogue valued function for which it is the component of the implied partition. A dependent analogue can be defined, however. Define the midisation, $A^{\mathrm{M}(T)} \in \mathcal{A}_{U, V, z}$, as the maximum likelihood estimate for the
distribution histogram of the (i) the multinomial probability of the histogram relative to (ii) the sum of the multinomial probabilities of the union of (a) the integral iso-liftisations and (b) the integral iso-surrealisations,

$$
\left\{A^{\mathrm{M}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isolr}(U)(T, A)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

where isolr $(U)(T, A):=\operatorname{isol}(U)(T, A) \cup \operatorname{isor}(U)(T, A)$.
The midisation is sometimes not computable. The finite approximation to the continuous case for the midisation for some $k \in \mathbf{N}_{>0}$ is

$$
\begin{aligned}
& \left\{A_{k}^{\mathrm{M}(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D / Z_{k}, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isolr}(U)(T, A)}\right): D \in \mathcal{A}_{U, \mathrm{i}, V, k z}\right\}\right)
\end{aligned}
$$

In the case where the transform is full functional, $T=T_{\mathrm{f}}$, the union of the iso-liftisations and the iso-surrealisations equals the iso-independents, and so the midisation equals the dependent, $A^{\mathrm{M}\left(T_{\mathrm{f}}\right)}=A^{\mathrm{Y}}$. In the case where the transform is unary, $T=T_{\mathrm{u}}$, the union of the iso-liftisations and the iso-surrealisations also equals the iso-independents, and so the midisation equals the dependent, $A^{\mathrm{M}\left(T_{\mathrm{u}}\right)}=A^{\mathrm{Y}}$.

The maximum likelihood estimate is near the histogram, $A^{\mathrm{M}(T)} \sim A$, only in as much as it is far from the liftisation, $A^{\mathrm{M}(T)} \nsim A^{\mathrm{K}(T)}$ and the surrealisation, $A^{\mathrm{M}(T)} \nsim(A * T)^{\mathrm{X}} * T^{\odot A}$. The midisation varies as the liftisation-dependent, $A^{\mathrm{M}(T)} \sim A^{\mathrm{L}(T)}$ and the surrealisation-dependent, $A^{\mathrm{M}(T)} \sim A^{\odot(T)}$. In as much as the idealisation-dependent varies with the liftisation-dependent, $A^{\dagger(T)} \sim$ $A^{\mathrm{L}(T)}$, the midisation varies as the idealisation-dependent, $A^{\mathrm{M}(T)} \sim A^{\dagger(T)}$.

Conjecture that the entropies of the likely histograms are subject to the following inequalities. First via the independent,

```
    \(\operatorname{entropy}\left(V_{z}^{\mathrm{C}} * T * T^{\dagger}\right)=\operatorname{entropy}\left(V_{z}^{\mathrm{C}}\right)\)
\(\geq \operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)\)
\(\geq \operatorname{entropy}\left(A^{\mathrm{P}(T)}\right)\)
\(\geq \operatorname{entropy}\left(A^{\mathrm{X}(T)}\right)\)
\(\geq\) entropy \(\left(A^{\mathrm{X}}\right)\)
\(\geq \operatorname{entropy}(A)\)
\(\geq \operatorname{entropy}\left(A^{\mathrm{Y}}\right)\)
\(\geq \operatorname{entropy}\left(A^{\mathrm{Y}(T)}\right)\)
\(\geq \operatorname{entropy}\left(A^{\mathrm{R}(T)}\right)\)
\(\geq \operatorname{entropy}\left(A^{\mathrm{W}(T)}\right)\)
\(\geq \operatorname{entropy}\left(Z_{A}\right)=0\)
```

Now via the idealisation,

$$
\begin{aligned}
& \operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\dagger}\right) \\
\geq & \operatorname{entropy}\left(A * T * T^{\dagger}\right) \\
\geq & \operatorname{entropy}\left(A^{\mathrm{K}(T)}\right) \\
\geq & \operatorname{entropy}\left(A * T * T^{\odot A^{\mathrm{X}}}\right) \\
\geq & \operatorname{entropy}\left(A * T * T^{\dagger A}\right) \\
\geq & \operatorname{entropy}(A) \\
\geq & \operatorname{entropy}\left(A^{\dagger(T)}\right) \\
\geq & \operatorname{entropy}\left(A^{\mathrm{L}(T)}\right) \\
\geq & \operatorname{entropy}\left(A^{\mathrm{D}(T)}\right) \\
\geq & \operatorname{entropy}\left(A^{\mathrm{Y}(T)}\right)
\end{aligned}
$$

Now via the surrealisation,

```
    \(\operatorname{entropy}\left(V_{z}^{\mathrm{C}} * T * T^{\dagger}\right)=\operatorname{entropy}\left(V_{z}^{\mathrm{C}}\right)\)
\(\geq \operatorname{entropy}\left(V_{z}^{\mathrm{C}} * T * T^{\odot A}\right)\)
\(\geq \operatorname{entropy}\left(A^{\mathrm{X}} * T * T^{\odot A}\right)\)
\(\geq\) entropy \((A)\)
\(\geq \operatorname{entropy}\left(A^{\odot(T)}\right)\)
\(\geq \operatorname{entropy}\left(A^{\mathrm{C}(T)}\right)\)
```

Finally via the midisation,

$$
\begin{aligned}
& \operatorname{entropy}\left(A^{\mathrm{K}(T)}\right) \\
\geq & \operatorname{entropy}(A) \\
\geq & \operatorname{entropy}\left(A^{\mathrm{M}(T)}\right)
\end{aligned}
$$

and

$$
\begin{aligned}
& \operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right) \\
\geq & \operatorname{entropy}(A) \\
\geq & \operatorname{entropy}\left(A^{\mathrm{M}(T)}\right)
\end{aligned}
$$

The entropy of the dependent analogue is conjectured to be less than or equal to entropy of the histogram. For example,

$$
\begin{aligned}
& \operatorname{entropy}(A) \\
\geq & \operatorname{entropy}\left(A^{\dagger(T)}\right) \\
\geq & \operatorname{entropy}\left(A^{\mathrm{L}(T)}\right) \\
\geq & \operatorname{entropy}\left(A^{\mathrm{D}(T)}\right) \\
\geq & \operatorname{entropy}\left(A^{\mathrm{Y}(T)}\right) \\
\geq & \operatorname{entropy}\left(A^{\mathrm{R}(T)}\right) \\
\geq & \operatorname{entropy}\left(A^{\mathrm{W}(T)}\right)
\end{aligned}
$$

The entropy of entity-like dependents varies against the cardinality of the iso-set,

$$
\operatorname{entropy}\left(A^{\mathrm{I}(T)}\right) \sim-|I|
$$

where $A \in I$ and $I \subseteq Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$.
In the case where the dependent analogue is in the iso-set and the iso-set is law-like, the difference in entropy must be in the entropy of the components. In the case of derived-dependent,

$$
\begin{aligned}
A^{\mathrm{D}(T)} \in D_{U, T, z}^{-1}(A * T) & \Longrightarrow \\
A^{\mathrm{D}(T)} * T=A * T & \Longrightarrow \operatorname{entropy}\left(A^{\mathrm{D}(T)} * T\right)=\operatorname{entropy}(A * T)
\end{aligned}
$$

So

$$
\begin{aligned}
& A^{\mathrm{D}(T)} \in D_{U, T, z}^{-1}(A * T) \Longrightarrow \\
& \sum\left(\operatorname{entropy}\left(A^{\mathrm{D}(T)} * C\right):(R, C) \in T^{-1},\left(A^{\mathrm{D}(T)} * T\right)_{R}>0\right) \\
& \leq \sum\left(\operatorname{entropy}(A * C):(R, C) \in T^{-1},(A * T)_{R}>0\right)
\end{aligned}
$$

Similarly for the idealisation-dependent,

$$
\begin{aligned}
& A^{\dagger(T)} \in D_{U, T, z}^{-1}(A * T) \Longrightarrow \\
& \sum\left(\operatorname{entropy}\left(A^{\dagger(T)} * C\right):(R, C) \in T^{-1},\left(A^{\dagger(T)} * T\right)_{R}>0\right) \\
& \leq \sum\left(\operatorname{entropy}(A * C):(R, C) \in T^{-1},(A * T)_{R}>0\right)
\end{aligned}
$$

The midisation varies with the histogram, $A^{\mathrm{M}(T)} \sim A$, in as much as it varies against the liftisation, $A^{\mathrm{M}(T)} \nsim A^{\mathrm{K}(T)}$ and the surrealisation, $A^{\mathrm{M}(T)} \nsim$ $(A * T)^{\mathrm{X}} * T^{\odot A}$. The multinomial probability with respect to the midisation is maximised at the mean, so conjecture that, in the case where the midisation is integral, $A^{\mathrm{M}(T)} \in \mathcal{A}_{\mathrm{i}}$, the multinomial probability of the midisation with respect to the midisation varies as the multinomial probability of the histogram divided by the sum of the multinomial probabilities of the liftisation and the surrealisation,

$$
\begin{aligned}
& Q_{\mathrm{m}, U}\left(A^{\mathrm{M}(T)}, z\right)\left(A^{\mathrm{M}(T)}\right) \\
& \quad \sim \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{M}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{M}(T)}, z\right)(B): B \in \operatorname{isolr}(U)(T, A)} \\
& \quad \sim \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{M}(T)}, z\right)(A)}{Q_{\mathrm{m}, U}\left(A^{\mathrm{M}(T)}, z\right)\left(A^{\mathrm{K}(T)}\right)+Q_{\mathrm{m}, U}\left(A^{\mathrm{M}(T)}, z\right)\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)}
\end{aligned}
$$

Dividing out the permutorial leaves the multinomial coefficient, so, after taking the logarithm, conjecture that the entropy of the midisation varies very approximately as the entropy of the histogram less the entropies of the liftisation and the surrealisation,

$$
\begin{aligned}
\operatorname{entropy}\left(A^{\mathrm{M}(T)}\right) \sim \operatorname{entropy}(A) & -\operatorname{entropy}\left(A^{\mathrm{K}(T)}\right) \\
& -\operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)
\end{aligned}
$$

The idealisation is in the iso-liftisations, $A * T * T^{\dagger A} \in Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap$ $D_{U, T, z}^{-1}(A * T)$, so, insofar as the entropy of the idealisation approximates to the entropy of the liftisation, entropy $\left(A * T * T^{\dagger A}\right) \approx \operatorname{entropy}\left(A^{\mathrm{K}(T)}\right)$, the entropy of the midisation varies computably as the entropy of the histogram less the entropies of the idealisation and the surrealisation,

$$
\begin{aligned}
\operatorname{entropy}\left(A^{\mathrm{M}(T)}\right) \sim \operatorname{entropy}(A) & -\operatorname{entropy}\left(A * T * T^{\dagger A}\right) \\
& -\operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)
\end{aligned}
$$

In section 'Converse action entropy', above, it is conjectured that the sum of the entropies of the contentisation and the neutralisation varies as the sum
of the entropies of the histogram and the independent
$\operatorname{entropy}\left(A^{\mathrm{X}} * T * T^{\odot A}\right)+\operatorname{entropy}\left(A * T * T^{\odot} A^{\mathrm{X}}\right) \sim \operatorname{entropy}(A)+\operatorname{entropy}\left(A^{\mathrm{X}}\right)$
So, insofar as the neutralisation entropy approximates to the idealisation entropy, entropy $\left(A * T * T^{\odot A^{\mathrm{x}}}\right) \approx \operatorname{entropy}\left(A * T * T^{\dagger A}\right)$, the entropy of the midisation varies as the computable difference between the entropies of the contentisation and the surrealisation less the entropy of the independent,

$$
\begin{aligned}
\operatorname{entropy}\left(A^{\mathrm{M}(T)}\right) \sim \operatorname{entropy}\left(A^{\mathrm{X}} * T * T^{\odot A}\right) & -\operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right) \\
& -\operatorname{entropy}\left(A^{\mathrm{X}}\right)
\end{aligned}
$$

If the histogram, $A$, is a given, then the entropy of the independent, entropy $\left(A^{\mathrm{X}}\right)$, is a constant with respect to varying transform. If, in addition, the formal is constrained to be independent, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, then the entropy of the midisation varies as the difference between the entropies of the formal independent and the abstract,

$$
\operatorname{entropy}\left(A^{\mathrm{M}(T)}\right) \sim \operatorname{entropy}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right)-\operatorname{entropy}\left((A * T)^{\mathrm{X}}\right)
$$

Since the entropy of the doubly-independent formal independent is greater than or equal to that of the singly-independent abstract, entropy $\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \geq$ entropy $\left((A * T)^{\mathrm{X}}\right)$, the minimisation of the midisation entropy, entropy $\left(A^{\mathrm{M}(T)}\right)$, tends to minimise the positive difference between the entropies of the formal independent and the abstract, entropy $\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right)-\operatorname{entropy}\left((A * T)^{\mathrm{X}}\right) \geq 0$, and so the abstract tends to equal the formal independent, which equals the formal, $(A * T)^{\mathrm{X}}=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=A^{\mathrm{X}} * T$. That is, in the case where the formal is constrained to be independent, for example when non-overlapping, $\neg \operatorname{overlap}(T) \Longrightarrow A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, then the minimisation of the midisation entropy, entropy $\left(A^{\mathrm{M}(T)}\right)$, tends to formal-abstract equivalence, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$.

This is consistent with the difference between the partition contentisation entropy and the partition surrealisation entropy in the case where the transform is a substrate transform $T \in \mathcal{T}_{U, V}$, having derived variables $W=\operatorname{der}(T)$. Given a partition variable $P \in W$, the difference is

$$
\begin{aligned}
& \operatorname{entropy}\left(A^{\mathrm{X}} * P^{\mathrm{T}} * P^{\mathrm{T} \odot A}\right)-\operatorname{entropy}\left(\left(A * P^{\mathrm{T}}\right)^{\mathrm{X}} * P^{\mathrm{T} \odot A}\right) \\
= & \operatorname{entropy}\left(A^{\mathrm{X}} * P^{\mathrm{T}} * P^{\mathrm{T} \odot A}\right)-\operatorname{entropy}(A)
\end{aligned}
$$

where the partition contentisation entropy is between the independent entropy and the histogram entropy, entropy $\left(A^{\mathrm{X}}\right) \geq \operatorname{entropy}\left(A^{\mathrm{X}} * P^{\mathrm{T}} * P^{\mathrm{T} \odot A}\right) \geq$
entropy $(A)$. When the formal independent equals the abstract, the partition transform is formal and the partition contentisation equals the histogram, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}} \Longrightarrow A * P^{\mathrm{T}}=A^{\mathrm{X}} * P^{\mathrm{T}} \Longrightarrow A^{\mathrm{X}} * P^{\mathrm{T}} * P^{\mathrm{T} \odot A}=A$, and so the difference between the partition contentisation entropy and the partition surrealisation entropy reduces to zero.

For a given histogram, $A$, the midisation varies against the computable sum of the entropies of the idealisation and the surrealisation,

$$
\operatorname{entropy}\left(A^{\mathrm{M}(T)}\right) \sim-\left(\operatorname{entropy}\left(A * T * T^{\dagger A}\right)+\operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)\right)
$$

Conjecture that the sum of the entropies of the idealisation and the surrealisation is greater than or equal to the sum of the entropies of the histogram and the independent

$$
\begin{aligned}
\operatorname{entropy}\left(A * T * T^{\dagger A}\right)+\operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right) & \geq \\
& \text { entropy }(A)+\operatorname{entropy}\left(A^{\mathrm{x}}\right)
\end{aligned}
$$

In the case where the transform is self, for example a value full functional transform $T_{\mathrm{s}}=\left\{\{w\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: w \in V\right\}^{\mathrm{T}}$, the idealisation equals the histogram and the surrealisation equals the independent, so the sums are equal,

$$
\begin{aligned}
& \operatorname{entropy}\left(A * T_{\mathrm{s}} * T_{\mathrm{s}}^{\dagger A}\right)+\operatorname{entropy}\left(\left(A * T_{\mathrm{s}}\right)^{\mathrm{X}} * T_{\mathrm{s}}^{\odot A}\right)= \\
& \quad \operatorname{entropy}(A)+\operatorname{entropy}\left(A^{\mathrm{X}}\right)
\end{aligned}
$$

In the case where the transform is unary, for example $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$, the idealisation equals the independent and the surrealisation equals the histogram, so the sums are equal,

$$
\begin{aligned}
\operatorname{entropy}\left(A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger A}\right)+\operatorname{entropy}\left(\left(A * T_{\mathrm{u}}\right)^{\mathrm{X}} * T_{\mathrm{u}}^{\odot A}\right) & = \\
& \operatorname{entropy}\left(A^{\mathrm{x}}\right)+\operatorname{entropy}(A)
\end{aligned}
$$

Conjecture that there exists some intermediate substrate transform $T_{\mathrm{m}} \in \mathcal{T}_{U, V}$ which is neither self nor unary, $T_{\mathrm{m}} \notin\left\{T_{\mathrm{s}}, T_{\mathrm{u}}\right\}$, such that the sum of the entropies of the idealisation and the surrealisation is maximised,
$T_{\mathrm{m}} \in \operatorname{maxd}\left(\left\{\left(T, \operatorname{entropy}\left(A * T * T^{\dagger A}\right)+\operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)\right): T \in \mathcal{T}_{U, V}\right\}\right)$
So in some cases the mid transform, $T_{\mathrm{m}}$, minimises the midisation entropy,

$$
T_{\mathrm{m}} \in \operatorname{mind}\left(\left\{\left(T, \operatorname{entropy}\left(A^{\mathrm{M}(T)}\right)\right): T \in \mathcal{T}_{U, V}\right\}\right)
$$

The mid idealisation entropy approximates to the mid surrealisation entropy,

$$
\operatorname{entropy}\left(A * T_{\mathrm{m}} * T_{\mathrm{m}}^{\dagger A}\right) \quad \approx \operatorname{entropy}\left(\left(A * T_{\mathrm{m}}\right)^{\mathrm{X}} * T_{\mathrm{m}}^{\odot A}\right)
$$

but the mid idealisation derived entropy is less than or equal to the mid surrealisation derived entropy,

$$
\begin{array}{ll} 
& \operatorname{entropy}\left(A * T_{\mathrm{m}} * T_{\mathrm{m}}^{\dagger A} * T_{\mathrm{m}}\right)=\operatorname{entropy}\left(A * T_{\mathrm{m}}\right) \\
\leq & \operatorname{entropy}\left(\left(A * T_{\mathrm{m}}\right)^{\mathrm{X}} * T_{\mathrm{m}}^{\odot A} * T_{\mathrm{m}}\right)=\operatorname{entropy}\left(\left(A * T_{\mathrm{m}}\right)^{\mathrm{x}}\right)
\end{array}
$$

In the case where the minimisation constrains the formal to be independent,

$$
T_{\mathrm{m}} \in \operatorname{mind}\left(\left\{\left(T, \operatorname{entropy}\left(A^{\mathrm{M}(T)}\right)\right): T \in \mathcal{T}_{U, V}, A^{\mathrm{x}} * T=\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}\right\}\right)
$$

the mid transform tends to be such that the formal equals the abstract, $A^{\mathrm{X}} * T_{\mathrm{m}}=\left(A * T_{\mathrm{m}}\right)^{\mathrm{X}}$. In these cases, the mid derived entropy is less than or equal to the independent mid derived entropy, entropy $\left(A * T_{\mathrm{m}}\right) \leq$ $\operatorname{entropy}\left(\left(A * T_{\mathrm{m}}\right)^{\mathrm{X}}\right)=\operatorname{entropy}\left(A^{\mathrm{X}} * T_{\mathrm{m}}\right)$.

While the minimisation of the midisation entropy, where the formal is independent, does not preclude a decrease in the mid derived entropy, entropy $(A *$ $T_{\mathrm{m}}$ ), conjecture that, overall, the mid component size cardinality relative entropy is nonetheless small, entropyRelative $\left(A * T_{\mathrm{m}}, V^{\mathrm{C}} * T_{\mathrm{m}}\right) \approx 0$. That is, the minimisation of the midisation entropy, where the formal is independent, tends to a partition of the states such that the sizes of the components tend to be synchronised with their cardinalities.

This may be seen by considering the case where the histogram is fully diagonalised, diagonalFull $(U)(A)$, and uniform, $\left|\operatorname{ran}\left(A * A^{\mathrm{F}}\right)\right|=1$. In this case the independent is cartesian, $A^{\mathrm{X}}=V_{z}^{\mathrm{C}}$, where $V_{z}^{\mathrm{C}}=\operatorname{scalar}(z / v) * V^{\mathrm{C}}$. In the case where the transform is a substrate transform, $T \in \mathcal{T}_{U, V}$, and the formal independent equals the abstract, each partition derived must equal the partition formal, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}} \Longleftrightarrow \forall P \in \operatorname{der}(T)\left(A * P^{\mathrm{T}}=A^{\mathrm{X}} * P^{\mathrm{T}}\right)$. This is satisfied by any partition that (i) partitions the effective states along the diagonal into components, $P: \leftrightarrow: A^{\mathrm{F}}$, and (ii) is such that the component cardinalities are uniform, $|\{|C|: C \in P\}|=1$. Let $F \subset \mathcal{T}_{U, V}$ be the set of transforms,

$$
F=\left\{T: T \in \mathcal{T}_{U, V}, \forall P \in \operatorname{der}(T)\left(P: \leftrightarrow: A^{\mathrm{F}} \wedge|\{|C|: C \in P\}|=1\right)\right\}
$$

All of these transforms are such that the formal independent equals the abstract, $\forall T \in F\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}\right)$, and all are such that the cross entropy equals the derived entropy, $\forall T \in F$ (entropyCross $\left(A * T, V^{\mathrm{C}} * T\right)=$ entropy $(A * T)$ ), and so have zero relative entropy, $\forall T \in F$ (entropyRelative $(A *$ $\left.T_{\mathrm{m}}, V^{\mathrm{C}} * T_{\mathrm{m}}\right)=0$ ). Each of the derived variables of the value full functional transform partitions the diagonal and has uniform component cardinality,
$\left\{\{w\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: w \in V\right\}^{\mathrm{T}} \in F$. As the constraints on the histogram are relaxed such that (i) the diagonal is not uniform, so the independent is no longer cartesian, $A^{\mathrm{X}} \neq V_{z}^{\mathrm{C}}$, and (ii) effective off-diagonal states are allowed, so bijections, $P: \leftrightarrow: A^{\mathrm{F}}$ are fewer, the cardinality of transforms that are such that the formal independent equals the abstract decreases, but the sizes of the components still tend to be synchronised with their cardinalities and so relative entropy remains small.

The idealisation independent equals the independent, so the idealisation entropy is less than or equal to the independent entropy, entropy $\left(A^{\mathrm{X}}\right)=$ entropy $\left(\left(A * T * T^{\dagger A}\right)^{\mathrm{X}}\right) \geq \operatorname{entropy}\left(A * T * T^{\dagger A}\right)$. Equality occurs in the case where the transform is unary, entropy $\left(A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger A}\right)=\operatorname{entropy}\left(A^{\mathrm{X}}\right)$. The idealisation entropy is greater than or equal to the histogram entropy, entropy $\left(A * T * T^{\dagger A}\right) \geq$ entropy $(A)$. Equality occurs in the case where the transform is self, entropy $\left(A * T_{\mathrm{s}} * T_{\mathrm{s}}^{\dagger A}\right)=\operatorname{entropy}(A)$. Therefore the mid idealisation entropy is between the independent entropy and the histogram entropy,

$$
\operatorname{entropy}\left(A^{\mathrm{X}}\right) \geq \operatorname{entropy}\left(A * T_{\mathrm{m}} * T_{\mathrm{m}}^{\dagger A}\right) \geq \operatorname{entropy}(A)
$$

The idealisation equals the sum of its independent commponents, $A * T * T^{\dagger A}=$ $\sum_{(, C) \in T^{-1}}(A * C)^{\mathrm{X}}$. Consider the case where the idealisation is integral, for example if it were the histogram of some history. In this case the components are independent and integral,

$$
A * T * T^{\dagger A} \in \mathcal{A}_{\mathrm{i}} \Longrightarrow \forall(\cdot, C) \in T^{-1}\left((A * C)^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}}\right)
$$

As shown in section 'Independent histograms', above, the logarithm of the cardinality of integral independent histograms of a given set of variables $V$ and size $z$ varies against the volume $v=\left|V^{\mathrm{C}}\right|$,

$$
\ln \left|\left\{A: A \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{XF}}=V^{\mathrm{C}}, \operatorname{size}(A)=z, A=A^{\mathrm{X}}\right\}\right| \sim-v
$$

Given that the total component cardinality is the volume, $\sum_{(R,) \in T^{-1}}\left(V^{\mathrm{C}} *\right.$ $T)_{R}=\sum_{(\cdot, C) \in T^{-1}}|C|=v$, and the total component size is the size, $\sum_{(R, \cdot) \in T^{-1}}(A *$ $T)_{R}=\sum_{(\cdot, C) \in T^{-1}} \operatorname{size}(A * C)=z$, a minimisation of the integral idealisation entropy from the mid transform tends to increase the mid component size cardinality cross entropy,

$$
\operatorname{entropyCross}\left(A * T_{\mathrm{m}}, V^{\mathrm{C}} * T_{\mathrm{m}}\right) \sim-\operatorname{entropy}\left(A * T_{\mathrm{m}} * T_{\mathrm{m}}^{\dagger A}\right)
$$

The mid idealisation entropy approximates to the mid surrealisation entropy, $\operatorname{entropy}\left(A * T_{\mathrm{m}} * T_{\mathrm{m}}^{\dagger A}\right) \approx \operatorname{entropy}\left(\left(A * T_{\mathrm{m}}\right)^{\mathrm{X}} * T_{\mathrm{m}}^{\odot A}\right)$, but the mid idealisation
derived entropy is less than or equal to the mid surrealisation derived entropy, entropy $\left(A * T_{\mathrm{m}}\right) \leq \operatorname{entropy}\left(\left(A * T_{\mathrm{m}}\right)^{\mathrm{X}}\right)$. So in the case where the minimisation of the integral idealisation entropy from the mid transform does not increase the derived entropy, entropy $\left(A * T_{\mathrm{m}}\right)$, the mid component size cardinality relative entropy varies against the mid idealisation entropy,

$$
\text { entropyRelative }\left(A * T_{\mathrm{m}}, V^{\mathrm{C}} * T_{\mathrm{m}}\right) \sim-\operatorname{entropy}\left(A * T_{\mathrm{m}} * T_{\mathrm{m}}^{\dagger A}\right)
$$

That is, a minimisation of the integral idealisation entropy starting from the mid transform is a maximisation of the relative entropy. So high size components tend to be low cardinality components and low size components tend to be high cardinality components.

This may be contrasted with the minimisation of the midisation entropy, entropy $\left(A^{\mathrm{M}(T)}\right)$, where the formal is independent, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, which has low relative entropy, entropyRelative $\left(A * T_{\mathrm{m}}, V^{\mathrm{C}} * T_{\mathrm{m}}\right) \approx 0$, because the formal independent approximates to the abstract, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}} \approx(A * T)^{\mathrm{X}}$. That is, a minimisation of the midisation entropy, where the formal is independent, tends to decrease the relative entropy, but a subsequent minimisation of the integral idealisation entropy tends to increase the relative entropy.

The transform-independent, $A^{\mathrm{X}(T)}$, is the maximum likelihood estimate of the distribution histogram of the multinomial probability of membership of the iso-transform-independents,

$$
\left\{A^{\mathrm{X}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

The corresponding the transform-dependent, $A^{\mathrm{Y}(T)}$, is the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, $A$, conditional that it is an iso-transform-independent,

$$
\begin{aligned}
& \left\{\left(A^{\mathrm{Y}(T)}, \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(B): B \in \mathcal{A}_{U \mathrm{i}, \mathrm{y}, T, z}(A)}\right)\right\}= \\
& \quad \max \left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

Conjecture that the logarithm of the maximum conditional multinomial probability varies against the corresponding logarithm of the conditional probability where the distribution histogram is not the dependent analogue, $A^{\mathrm{Y}(T)}$,
but the independent analogue, $A^{\mathrm{X}(T)}$,

$$
\left.\begin{array}{rl}
\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(B): B} \boldsymbol{B} \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)
\end{array}\right)
$$

This may be seen by considering first the conditional probability with respect to the dependent-analogue on the left hand side of this relation. If the independent-analogue is in the iso-set, $A^{\mathrm{X}(T)} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)$, and the histogram is not equal to the independent-analogue, $A \neq A^{\mathrm{X}(T)}$, then the terms of the denominator with respect to the dependent-analogue are such that

$$
\begin{aligned}
0 & <\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)\left(A^{\mathrm{X}(T)}\right) \\
& <\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(A) \\
& <\sum_{1}\left(\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right) \\
& \leq 1
\end{aligned}
$$

That is, the independent-analogue term is less than the numerator,

$$
Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)\left(A^{\mathrm{X}(T)}\right)<Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(A)
$$

Conjecture that independent-analogue term is the least of the denominator,

$$
\forall B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\left(Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)\left(A^{\mathrm{X}(T)}\right) \leq Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(B)\right)
$$

Now consider the conditional probability with respect to the independentanalogue on the right hand side of this relation. Here the terms of the denominator with respect to the independent-analogue are such that

$$
\begin{aligned}
0 & <\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)(A) \\
& <\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)\left(A^{\mathrm{X}(T)}\right) \\
& <\sum_{1}\left(\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right) \\
& \leq 1
\end{aligned}
$$

Conjecture that independent-analogue term is the greatest of this denominator,

$$
\forall B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\left(Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)\left(A^{\mathrm{X}(T)}\right) \geq Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)(B)\right)
$$

Conjecture that the probability of drawing the histogram from the dependentanalogue is greater than that from the independent-analogue, $\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(A)>$
$\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)(A)$, and so the numerator of the right hand side is less than that of the left hand side. Conjecture further, however, that the probability of drawing the independent-analogue from the independent-analogue is greater than the probability of drawing the histogram from the dependent-analogue, $\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(A)<\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)\left(A^{\mathrm{X}(T)}\right)$, and so the denominator of the right hand side is conjectured to be greater than that of the left hand side. Hence the conditional probability with respect to the dependent-analogue is conjectured to vary against the conditional probability with respect to the independent-analogue.

The independent-analogue term is the largest of the denominator with respect to the independent-analogue, $\forall B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\left(Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)\left(A^{\mathrm{X}(T)}\right) \geq\right.$ $\left.Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)(B)\right)$. So the logarithm of the maximum conditional probability is conjectured to vary against the logarithm of the relative probability with respect to the independent-analogue,

$$
\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \sim-\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)(A)}{Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)\left(A^{\mathrm{X}(T)}\right)}
$$

Define the distribution-relative multinomial space of a histogram $A \in \mathcal{A}_{U, V, z}$ with respect to a distribution histogram $E \in \mathcal{A}_{U, V, z}$ as spaceRelative $\in \mathcal{A} \rightarrow$ $(\mathcal{A} \rightarrow \mathbf{R})$, the negative logarithm relative multinomial probability density,

$$
\text { spaceRelative }(E)(A):=-\ln \frac{\operatorname{mpdf}(U)(E, z)(A)}{\operatorname{mpdf}(U)(E, z)(E)}
$$

In the case where the histogram and distribution histogram are integral, $A, E \in \mathcal{A}_{\mathrm{i}}$, the distribution-relative multinomial space is the negative logarithm relative multinomial probability,

$$
\operatorname{spaceRelative}(E)(A):=-\ln \frac{Q_{\mathrm{m}, U}(E, z)(A)}{Q_{\mathrm{m}, U}(E, z)(E)}
$$

So, in this case, the relative space of the histogram with respect to the transform-independent is

$$
\operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)(A):=-\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)(A)}{Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)\left(A^{\mathrm{X}(T)}\right)}
$$

and the logarithm of the maximum conditional probability is conjectured to vary with the relative space,

$$
\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \sim \operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)(A)
$$

Conjecture that in the case where an independent analogue is in the iso-set, and so is in the denominator, the relative space of a histogram with respect to the independent analogue is always positive and less than or equal to the relative space of the corresponding dependent analogue with respect to the independent analogue. So,

$$
\begin{aligned}
A^{\mathrm{X}} \in \mathcal{A}_{\mathbf{i}} \Longrightarrow 0 & \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}}\right)(A) \\
& \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}}\right)\left(A^{\mathrm{Y}}\right) \\
A^{\mathrm{X}(T)} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A) \Longrightarrow 0 & \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)(A) \\
& \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)\left(A^{\mathrm{Y}(T)}\right) \\
A * T * T^{\dagger A} \in \mathcal{A}_{\mathbf{i}} \Longrightarrow 0 & \leq \operatorname{spaceRelative}\left(A * T * T^{\dagger A}\right)(A) \\
& \leq \operatorname{spaceRelative}\left(A * T * T^{\dagger A}\right)\left(A^{\dagger(T)}\right) \\
(A * T)^{\mathrm{X}} * T^{\odot A} \in \mathcal{A}_{\mathbf{i}} \Longrightarrow 0 & \leq \operatorname{spaceRelative}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)(A) \\
& \leq \operatorname{spaceRelative}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)\left(A^{\odot(T)}\right) \\
A * T * T^{\dagger} \in \mathcal{A}_{\mathbf{i}} \Longrightarrow 0 & \leq \operatorname{spaceRelative}\left(A * T * T^{\dagger}\right)(A) \\
& \leq \operatorname{spaceRelative}\left(A * T * T^{\dagger}\right)\left(A^{\mathrm{D}(T)}\right) \\
(A * T)^{\mathrm{X}} * T^{\dagger} \in \mathcal{A}_{\mathbf{i}} \Longrightarrow 0 & \leq \operatorname{spaceRelative}\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)(A) \\
& \leq \operatorname{spaceRelative}\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)\left(A^{\mathrm{W}(T)}\right)
\end{aligned}
$$

Conjecture that the relative space of the dependent is less than or equal to that of the transform-dependent which, in turn, is less than or equal to that of the abstract-dependent,

$$
\begin{aligned}
& \operatorname{spaceRelative}\left(A^{\mathrm{X}}\right)\left(A^{\mathrm{Y}}\right) \\
\leq & \operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)\left(A^{\mathrm{Y}(T)}\right) \\
\leq & \text { spaceRelative }\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)\left(A^{\mathrm{W}(T)}\right)
\end{aligned}
$$

where $A^{\mathrm{X}(T)} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)$.
Conjecture that, in the case where the formal equals the abstract, $A^{\mathrm{X}} * T=$ $(A * T)^{\mathrm{x}}$, the relative space of the idealisation-dependent is less than or equal to that of the derived-dependent, which, in turn, is less than or equal to that of the transform-dependent

$$
\begin{aligned}
& \text { spaceRelative }\left(A * T * T^{\dagger A}\right)\left(A^{\dagger(T)}\right) \\
\leq & \text { spaceRelative }\left(A * T * T^{\dagger}\right)\left(A^{\mathrm{D}(T)}\right) \\
\leq & \text { spaceRelative }\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)\left(A^{\mathrm{Y}(T)}\right)
\end{aligned}
$$

where $(A * T)^{\mathrm{X}} * T^{\dagger} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)$.

Conjecture that the relative space of the surrealisation-dependent is less than or equal to that of the components-dependent,

$$
\begin{aligned}
& \text { spaceRelative }\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)\left(A^{\odot(T)}\right) \\
\leq & \text { spaceRelative }\left(V_{z}^{\mathrm{C}} * T * T^{\odot A}\right)\left(A^{\mathrm{C}(T)}\right)
\end{aligned}
$$

### 3.18 Encoding space

Note that, in the following, the use of the terminology space is in the sense of computational space, i.e. the logarithm of the cardinality of some discrete set of states, rather than in the sense of the structured sets of mathematical spaces, such as topological space. See the appendices 'Coders' and 'Computers' for more formal definitions.

### 3.18.1 History space

The set of histories $\mathcal{H}_{U} \subset \mathcal{X} \rightarrow \mathcal{S}_{U}$ in finite system $U$ is a superset of the histories $\mathcal{H}_{U, X} \subset \mathcal{H}_{U}$ where the domains of the histories are restricted to a finite subset of the event identifiers $X \subset \mathcal{X}$, so that $\mathcal{H}_{U, X} \subset X \rightarrow \mathcal{S}_{U}$. Now $\mathcal{H}_{U, X}$ is finite and can be constructed

$$
\mathcal{H}_{U, X}=\bigcup\{X \rightarrow \operatorname{cartesian}(U)(V): V \subseteq \operatorname{vars}(U)\}
$$

$\mathcal{H}_{U, X}$ includes the empty history $\emptyset$. It also includes non-variate histories if there are any events, $\left|\left\{H: H \in \mathcal{H}_{U, X}, \operatorname{vars}(H)=\emptyset\right\}\right|>0$ where $|X|>0$.

The set of states in a system $U$ is $\mathcal{S}_{U}=\left\{S: V \subseteq \operatorname{vars}(U), S \in V^{\mathrm{CS}}\right\}$. In the case of a regular system $U$, having dimension $n=|U|$ and such that all the variables have the same valency $\{d\}=\{|W|: W \in \operatorname{ran}(U)\}$, the cardinality of the set of states is

$$
\left|\mathcal{S}_{U}\right|=\sum_{k \in\{0 \ldots n\}}\binom{n}{k} d^{k}<2^{n} d^{n} \leq d^{2 n}
$$

where $d \geq 2$. The cardinality of the histories is

$$
\left|\mathcal{H}_{U, X}\right|=1+\sum_{k \in\{0 \ldots n\}}\binom{n}{k} \sum_{z \in\{1 \ldots y\}}\binom{y}{z} d^{k z} \leq 2^{n+y} d^{n y}
$$

where $y=|X|$.

Coders encapsulate the logic of codes of lists of a given coder domain, such that the space of the elements of the coder domain is computable. A coder $C \in \operatorname{coders}(Y)$ on a coder domain $Y$ defines the code, $Y: \leftrightarrow$ $\mathbf{N}$, and the space function, space $(C) \in Y: \rightarrow \ln \mathbf{N}_{>0}$. The encode function, encode $(C) \in \mathcal{L}(Y): \rightarrow \mathbf{N}$, and the decode function, decode $(C) \in$ $\mathbf{N} \times \mathbf{N} \rightarrow: \mathcal{L}(Y)$, are functions of the code and the space such that $\forall L \in$ $\mathcal{L}(Y)(\operatorname{decode}(C)(|L|, \operatorname{encode}(C)(L))=L)$.

The space required to encode a list $L \in \mathcal{L}(Y)$ is the sum of the spaces of the list elements, $\sum_{i \in\{1 \ldots|L|\}} C^{\mathrm{s}}\left(L_{i}\right)$, where $C^{\mathrm{s}}(x):=\operatorname{space}(C)(x)$. The space of a list is always sufficient to encode the list,

$$
\forall L \in \mathcal{L}(Y)\left(\prod_{i \in\{1 \ldots|L|\}} e^{C^{\mathrm{s}}\left(L_{i}\right)}>\operatorname{encode}(C)(L)\right)
$$

A probability function on the coder domain $P \in\left(Y: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$ implies an expected space, expected $(P)(\operatorname{space}(C))$. The expected space is greater than or equal to the entropy of the probability function, expected $(P)(\operatorname{space}(C)) \geq$ entropy $(P)$.

A minimal coder $C_{\mathrm{m}}$ is one where the expected space of a uniform probability function is the logarithm of the cardinality of the coder domain, $\operatorname{expected}(Y \times\{1 /|Y|\})\left(\operatorname{space}\left(C_{\mathrm{m}}\right)\right)=\ln |Y|$. See appendix 'Coders' for a formal definition of coders.

History coders coders $\left(\mathcal{H}_{U, X}\right)$ are coders where the coder domain is the set of all histories in system $U$ and identifier set $X$. When $\left|\mathcal{H}_{U, X}\right|$ is small it is practicable to construct a coder of histories explicitly.

For example, if the system $U$ contains a single, mono-valent variable, $U=$ $\{(v,\{w\})\}$, so that there are only two states $\mathcal{S}_{U}=\{\emptyset, S\}$, where $S=\{(v, w)\}$, and such that there is only one event identifier $X=\{x\}$ then there are only three possible histories, $\mathcal{H}_{U, X}=\{\emptyset,\{(x, \emptyset)\},\{(x, S)\}\}$. Choose an enumeration $N \in \operatorname{enums}\left(\mathcal{H}_{U, X}\right)$ and then we can construct a history coder $C \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$ such that
$\forall(H, i) \in N((\operatorname{encode}(C)(\{(1, H)\})=i-1) \wedge(\operatorname{decode}(C)(1, i-1)=\{(1, H)\}))$
$C$ is a minimal coder if we choose it such that $\forall H \in \mathcal{H}_{U, X}$ (space $(C)(H)=$ $\ln 3$ ), because the total space of $C$ is $\left|\mathcal{H}_{U, X}\right| \ln \left|\mathcal{H}_{U, X}\right|=3 \ln 3$.

Even in the case when the coder domain $\left|\mathcal{H}_{U, X}\right|$ is small, the decode relation of a coder must be defined algorithmically (that is, recursively) because it is an infinite set. (In the case of fixed-width coders where the space is constant, this algorithm is straightforward, however.) The decode function implies constraints on the space, so the code and the space of coders are usually defined algorithmically too. We shall describe several algorithmic coders of histories and their classifications.

Let $D_{\mathrm{x}}$ be an order, $D_{\mathrm{X}} \in \operatorname{enums}(X)$, on the event identifiers $X$ mapping them to the natural numbers, $D_{\mathrm{X}} \in X: \leftrightarrow \mathbf{N}$, by one of the enumerations enums $(X)=X \cdot\{1 \ldots|X|\}$. Given order $D_{\mathrm{X}}$ we can choose an enumeration for any subset $Q \subset X$ such that $\operatorname{order}\left(D_{\mathrm{X}}, Q\right) \in$ enums $(Q)$.

Let $D_{\mathrm{V}}$ be an order $D_{\mathrm{V}} \in \operatorname{enums}(\operatorname{vars}(U))$ on the variables in the system $U$. Given order $D_{\mathrm{V}}$ and subset $V \subset \operatorname{vars}(U)$, we have order $\left(D_{\mathrm{V}}, V\right) \in \operatorname{enums}(V)$. Let $D_{\mathrm{S}}$ be an order $D_{\mathrm{S}} \in \operatorname{enums}\left(\mathcal{S}_{U}\right)$ on the states. See appendix 'Constructing states order from variables and values orders' for an example of how $D_{\mathrm{S}}$ can be constructed. Given order $D_{\mathrm{S}}$ and variables $V$, we have the enumeration of the cartesian set of states

$$
\operatorname{order}\left(D_{\mathrm{S}}, \operatorname{cartesian}(U)(V)\right) \in \operatorname{enums}(\operatorname{cartesian}(U)(V))
$$

Note that the choice of orders on the event identifiers or variables or states can be entirely arbitrary, say, for example, lexical. There are no semantics imposed by any order, nor constraining the order. In particular, the events of a history are not necessarily chronological.

Consider the index coder of histories

$$
C_{\mathrm{H}}=\operatorname{coderHistoryIndex}\left(U, X, D_{\mathrm{V}}, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)
$$

A history $H \in \mathcal{H}_{U, X}$ can be encoded in a tuple $T_{H} \in \mathbf{N}^{2} \times \mathbf{N}^{2} \times \mathcal{L}(\mathbf{N})$. This tuple $T_{H}$ can then be encoded into a natural number $E_{H} \in\left\{0 \ldots S_{H}-1\right\}$. The space of the history is the space of this encoding, space $\left(C_{\mathrm{H}}\right)(H)=$ $\operatorname{space}\left(S_{H}\right)=\ln S_{H}$.

The first pair of the tuple $T_{H}$ encodes the set of variables. Each history $H \in \mathcal{H}_{U, X}$ has a subset $\operatorname{vars}(H) \subseteq \operatorname{vars}(U)$ of the variables of the system. Let $r=|\operatorname{vars}(U)|$. Let $V=\operatorname{vars}(H)$ and $n=|V|$. Given $D_{\mathrm{V}}$ choose an enumeration $N$ in the enumerations of the set of subsets of the variables of cardinality $n$ in system $U$

$$
N \in \operatorname{enums}(\{W: W \in \mathrm{P}(\operatorname{vars}(U)),|W|=n\})
$$

The pair encoding the variables of $H$ is $\left(n, N_{V}\right)$ where $n \in\{0 \ldots r\}$ and

$$
N_{V} \in\left\{1 \ldots \frac{r!}{(r-n)!n!}\right\}
$$

Define the space to encode dimension $n$ in system $U$ as spaceDimension $\in$ $\mathcal{U} \rightarrow \ln \mathbf{N}_{>0}$

$$
\operatorname{spaceDimension}(U):=\ln (|\operatorname{vars}(U)|+1)
$$

Define spaceSubset $\in \mathbf{N} \times \mathbf{N} \rightarrow \ln \mathbf{N}_{>0}$ as the space of a binomial combination

$$
\operatorname{spaceSubset}(a, b):=\ln \binom{a}{b}=\ln \frac{a!}{(a-b)!b!}
$$

where $a \geq b$.
Define the space of the pair encoding a set of variables of dimension $n$ in system $U$ as spaceVariables $(U) \in \mathbf{N} \rightarrow \ln \mathbf{N}_{>0}$

$$
\operatorname{spaceVariables}(U)(n):=\operatorname{spaceDimension}(U)+\operatorname{spaceSubset}(|\operatorname{vars}(U)|, n)
$$

The space of $\left(n, N_{V}\right)$ is spaceVariables $(U)(n)$.
Similarly, the second pair of the tuple $T_{H}$ encodes the set of event identifiers. Each history $H \in \mathcal{H}_{U, X}$ has a subset $\operatorname{ids}(H) \subseteq X$ of the event identifier set. Let $y=|X|$. Let $I=\operatorname{ids}(H)$ and $z=|I|=|H|$. Given $D_{\mathrm{X}}$ choose an enumeration $Z$ of the set of subsets of the event identifiers of cardinality $z$ in system $U$

$$
Z \in \operatorname{enums}(\{Q: Q \in \mathrm{P}(X),|Q|=z\})
$$

The pair encoding the event identifiers of $H$ is $\left(z, Z_{I}\right)$ where $z \in\{0 \ldots y\}$ and

$$
Z_{I} \in\left\{1 \cdots \frac{y!}{(y-z)!z!}\right\}
$$

Define the space of the size, $z$, of the set of event identifiers as spaceSize $\in$ $\mathbf{N} \rightarrow \ln \mathbf{N}_{>0}$

$$
\operatorname{spaceSize}(y):=\ln (y+1)
$$

Define the space of the pair encoding a subset of the set of event identifiers as spaceIds $\in \mathbf{N} \times \mathbf{N} \rightarrow \ln \mathbf{N}_{>0}$

$$
\operatorname{spaceIds}(y, z):=\operatorname{spaceSize}(y)+\operatorname{spaceSubset}(y, z)
$$

The space of $\left(z, Z_{I}\right)$ is $\operatorname{spaceIds}(y, z)$.

Note that an alternative representation of membership of a subset is the use of the fixed width list of bits, $\mathcal{L}$ (bits). In the case of variables, the length of the list is the cardinality of the variables in the system, $|\operatorname{vars}(U)|$, and so the space required would be $r \ln 2$. In the case of the event identifiers the length of the list is the cardinality of the event identifiers, $|X|$, and so the space would be $y \ln 2$. The fixed width representation requires less space where entropy is high, that is where $n \approx r / 2$ and $z \approx y / 2$.

The last element $L \in \mathcal{L}(\mathbf{N})$ of the tuple $T_{H}$ encodes the states of events in a list of fixed width space. Given order $D_{\mathrm{S}}$ and variables $V=\operatorname{vars}(H)$, let $M$ be an enumeration of the cartesian set of states, $M=\operatorname{order}\left(D_{\mathrm{S}}, \operatorname{cartesian}(U)(V)\right)$. Let $v=$ volume $(U)(V)$. Then $|M|=v$ and hence $L \in \mathcal{L}(\{1 \ldots v\})$. Given order $D_{\mathrm{X}}$ and event identifiers $I=\operatorname{ids}(H)$, let $Q$ be an enumeration of the event identifiers, $Q=\operatorname{order}\left(D_{\mathrm{X}}, I\right)$. Then

$$
L=\left\{\left(Q_{x}, M_{S}\right):(x, S) \in H\right\}
$$

Here $M_{S}$ is the index number of the state, $S$, in the enumeration, $M$.

Define the space of the list encoding the events of history $H$ in a system $U$ as spaceEvents $(U) \in \mathcal{H}_{U} \rightarrow \ln \mathbf{N}_{>0}$

$$
\operatorname{spaceEvents}(U)(H):=z \ln v
$$

where $z=|H|, V=\operatorname{vars}(H)$ and $v=\operatorname{volume}(U)(V)$.
Finally the tuple $T_{H}=\left(\left(n, N_{V}\right),\left(z, Z_{I}\right), L\right)$ can be encoded to $E_{H} \in\left\{0 \ldots S_{H}-\right.$ 1 \} where

$$
S_{H}=(r+1) \times \frac{r!}{(r-n)!n!} \times(y+1) \times \frac{y!}{(y-z)!z!} \times v^{z}
$$

The total space of the index coder $C_{\mathrm{H}}$ of a history $H$ is the sum of the variables space, ids space and events space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{H}}\right)(H)= & \text { spaceVariables }(U)(|\operatorname{vars}(H)|)+ \\
& \text { spaceIds }(|X|,|H|)+ \\
& \text { spaceEvents }(U)(H)
\end{aligned}
$$

A variation of the index history coder, $C_{\mathrm{H}}$, is to encode only the effective volume in the fixed width space. Here the history $H \in \mathcal{H}_{U, X}$ is encoded in a tuple $T_{H} \in \mathbf{N}^{2} \times \mathbf{N}^{2} \times \mathbf{N}^{2} \times \mathcal{L}(\mathbf{N})$ that has an extra pair of integers $\left(x, F_{Q}\right) \in$
$\mathbf{N}^{2}$ which encode (i) the effective volume $x=\left|A^{\mathrm{F}}\right|$, where $A=\operatorname{histogram}(H)$, and (ii) the index, $F_{Q}$, into an enumeration of the effective states subsets,

$$
F_{Q} \in\left\{1 \cdots \frac{v!}{(v-x)!x!}\right\}
$$

Now $M$ is an enumeration of the effective set of states, $M=\operatorname{order}\left(D_{\mathrm{S}}, A^{\mathrm{FS}}\right)$. Then $|M|=x$ and hence $L \in \mathcal{L}(\{1 \ldots x\})$.

The tuple $T_{H}=\left(\left(n, N_{V}\right),\left(z, Z_{I}\right),\left(x, F_{Q}\right), L\right)$ can be encoded to $E_{H} \in\left\{0 \ldots S_{H}-\right.$ 1\} where

$$
S_{H}=(r+1) \times \frac{r!}{(r-n)!n!} \times(y+1) \times \frac{y!}{(y-z)!z!} \times v \times \frac{v!}{(v-x)!x!} \times x^{z}
$$

Given the set of effective states, $Q=A^{\mathrm{FS}}$, the effective events need only a space of $z \ln x$. Define the space of the volume, $v=\left|A^{\mathrm{C}}\right|$, as spaceVolume $\in$ $\mathbf{N}_{>0} \rightarrow \ln \mathbf{N}_{>0}$

$$
\operatorname{spaceVolume}(v):=\ln v
$$

Define the effective space of histogram $A$ in a system $U$ as spaceEffective $(U) \in$ $\mathcal{A}_{U} \rightarrow \ln \mathbf{N}_{>0}$

$$
\operatorname{spaceEffective}(U)(A):=\operatorname{spaceVolume}(v)+\operatorname{spaceSubset}(v, x)
$$

where $v=\left|A^{\mathrm{C}}\right|$ and $x=\left|A^{\mathrm{F}}\right|$. The effective space is undefined for zero size, $z=0$.

Define the effective events space as spaceEventsEffective $(U) \in \mathcal{H}_{U} \rightarrow \ln \mathbf{N}_{>0}$

$$
\text { spaceEventsEffective }(U)(H):=z \ln x
$$

where $z=|H|, A=\operatorname{histogram}(H)$ and $x=\left|A^{\mathrm{F}}\right|$.
Define the effective index history coder

$$
C_{\mathrm{H}, \mathrm{~F}}=\operatorname{coderHistoryIndexEffective}\left(U, X, D_{\mathrm{V}}, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)
$$

The total space of the effective index coder $C_{\mathrm{H}, \mathrm{F}}$ of a non-empty history $H \neq \emptyset$ is the sum of the variables space, ids space, effective space and effective events space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{H}, \mathrm{~F}}\right)(H)= & \operatorname{spaceVariables}(U)(|\operatorname{vars}(H)|)+ \\
& \text { spaceIds }(|X|,|H|)+ \\
& \text { spaceEffective }(U)(A)+ \\
& \text { spaceEventsEffective }(U)(H)
\end{aligned}
$$

where $A=\operatorname{histogram}(H)$.
In the case where the histogram is completely effective, $A^{\mathrm{F}}=A^{\mathrm{C}}$, the effective volume equals the volume, $x=v$, so the effective events space equals the events space, spaceEventsEffective $(U)(H)=\operatorname{spaceEvents}(U)(H)$. In this case the space of the effective index coder is greater than or equal to the space of the index coder $C_{\mathrm{H}, \mathrm{F}}^{\mathrm{s}}(H) \geq C_{\mathrm{H}}^{\mathrm{s}}(H)$.

In the case where the histogram is a singleton, $x=|\operatorname{ran}(H)|=\left|A^{\mathrm{F}}\right|=1$, the effective events space is zero, spaceEventsEffective $(U)(H)=0$. The effective space is twice the volume space, spaceEffective $(U)(A)=2 \ln v$, and so does not depend on the size, $z$. In the case where the size is greater than or equal to two, $z \geq 2$, the space of the effective index coder is less than or equal to the space of the index coder $C_{\mathrm{H}, \mathrm{F}}^{\mathrm{s}}(H) \leq C_{\mathrm{H}}^{\mathrm{s}}(H)$.

### 3.18.2 Histogram space

Define the finite set of trimmed integral histograms in system $U$ having size less than or equal to $y \in \mathbf{N}$ as

$$
\mathcal{A}_{U, \mathrm{i}, \leq y}=\left\{\operatorname{trim}(A): A \in \mathcal{A}_{U, \mathrm{i}}, \operatorname{size}(A) \leq y\right\}
$$

In the case of a regular system $U$, having dimension $n=|U|$ and such that all the variables have the same valency $\{d\}=\{|W|: W \in \operatorname{ran}(U)\}$, the cardinality of the set of trimmed integral histograms is such that $\left|\mathcal{A}_{U, \mathrm{i}, \leq y}\right|<$ $y 2^{n}\left|\mathcal{A}_{U, \mathrm{i}, \operatorname{vars}(U), y}\right|$. Hence

$$
\left|\mathcal{A}_{U, \mathrm{i}, \leq y}\right|<y 2^{n} \frac{\left(y+d^{n}-1\right)!}{y!\left(d^{n}-1\right)!}
$$

An explicit minimal coder $C_{\mathrm{A}, \mathrm{m}} \in \operatorname{coders}\left(\mathcal{A}_{U, \mathrm{i}, \leq y}\right)$ exists which, if given an order $D_{\mathrm{A}} \in \mathcal{A}_{U, \mathrm{i}, \leq y} \leftrightarrow \mathbf{N}$ on the histograms in system $U$, simply enumerates the coder domain so that space $\left(C_{\mathrm{A}, \mathrm{m}}\right)(A)=\ln \left|\mathcal{A}_{U, \mathrm{i}, \leq y}\right|$.

Consider a coder of histograms

$$
C_{\mathrm{A}}=\operatorname{coderHistogram}\left(U, y, D_{\mathrm{V}}, D_{\mathrm{S}}\right) \in \operatorname{coders}\left(\mathcal{A}_{U, \mathrm{i}, \leq y}\right)
$$

where $y=|X|$ is the cardinality of the identifier set $X$.
A histogram $A \in \mathcal{A}_{U, i, \leq y}$ can be encoded in a tuple $T_{A} \in \mathbf{N}^{2} \times \mathbf{N} \times \mathbf{N}$. This tuple $T_{A}$ can then be encoded into a natural number $E_{A} \in\left\{0 \ldots S_{A}-1\right\}$.

The space of the histogram is the space of this encoding, space $\left(C_{\mathrm{A}}\right)(A)=$ $\operatorname{space}\left(S_{A}\right)=\ln S_{A}$.

The first pair of the tuple $T_{A}$ encodes the set of variables in the same way as for the history coder, $C_{\mathrm{H}}$. The space of the pair $\left(n, N_{V}\right)$ is spaceVariables $(U)(n)$ where $V=\operatorname{vars}(A)$ and $n=|V|$.

The second element of the tuple $T_{A}$ encodes the size $z=\operatorname{size}(A)$. Then $z \in\{0 \ldots y\}$ and the space of $z$ is spaceSize $(y)=\ln (y+1)$.

The last element of the tuple $T_{A}$ encodes the set of counts of the states. The coder defined here has a coder domain of trimmed histograms rather than complete histograms. So, for example, the histograms of histories, $A=\operatorname{histogram}(H)$, and the histograms of unit transforms $(X, \cdot) \in \mathcal{T}_{\mathrm{U}}$, are members of the coder domain. Let $D_{\mathrm{A}}$ be an order on the coder domain

$$
D_{\mathrm{A}} \in \operatorname{enums}\left(\mathcal{A}_{U, \mathrm{i}, \leq y}\right)
$$

$D_{\mathrm{A}}$ can be chosen arbitrarily, or constructed from $D_{\mathrm{S}}$. The support of a multinomial distribution is the set of complete integral congruent histograms in $\mathcal{A}_{U, \mathrm{i}}$ having variables $V$ and size $z$ in system $U$, previously defined

$$
\mathcal{A}_{U, \mathrm{i}, V, z}:=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}}, B^{\mathrm{U}}=V^{\mathrm{C}}, \operatorname{size}(B)=z\right\}
$$

The integral congruent support consists of complete histograms. It forms a bijective map to the set of trimmed integral congruent histograms

$$
\left\{\operatorname{trim}(B) \in \mathcal{A}_{U, i, V, z}\right\}: \leftrightarrow: \mathcal{A}_{U, \mathrm{i}, V, z}
$$

The integral congruent support implies the equivalence classes in $\mathcal{A}_{U, \mathrm{i}}$ such that $\operatorname{trim}(A) \equiv A+A^{\mathrm{CZ}}$. Thus for any trimmed histogram $A=\operatorname{trim}(A)$ the equivalent complete histogram is in the integral congruent support, $A+A^{\mathrm{CZ}} \in$ $\mathcal{A}_{U, \mathrm{i}, V, z}$. Given $D_{\mathrm{A}}$, choose enumeration $R$ of the enumerations of the trimmed support of the multinomial distribution

$$
R \in \operatorname{enums}\left(\left\{\operatorname{trim}(B): B \in \mathcal{A}_{U, \mathbf{i}, V, z}\right\}\right)
$$

The trimmed support has the same cardinality as the integral congruent support, so the last element of the tuple $T_{A}$ encoding the counts of the states of $A$ is $R_{A}$ which is such that

$$
R_{A} \in\left\{1 \ldots \frac{(z+v-1)!}{z!(v-1)!}\right\}
$$

$R_{A}$ is the weak composition number of $A$. Define the space of a weak composition as spaceCompositionWeak $\in \mathbf{N}_{>0} \times \mathbf{N} \rightarrow \ln \mathbf{N}_{>0}$

$$
\text { spaceCompositionWeak }(k, n):=\ln \left|\mathrm{C}^{\prime}(\{1 \ldots k\}, n)\right|=\ln \frac{(n+k-1)!}{n!(k-1)!}
$$

Define the space of the encoding of the counts of the states of histogram $A$ in a system $U$ as spaceCounts $(U) \in \mathcal{A}_{U, \mathrm{i}} \rightarrow \ln \mathbf{N}_{>0}$

$$
\operatorname{spaceCounts}(U)(A):=\ln \frac{(z+v-1)!}{z!(v-1)!}=\operatorname{spaceCompositionWeak}(v, z)
$$

where $z=\operatorname{size}(A), V=\operatorname{vars}(A)$ and $v=\operatorname{volume}(U)(V)$. The space of $R_{A}$ is spaceCounts $(U)(A)$.

Finally the tuple $T_{A}=\left(\left(n, N_{V}\right), z, R_{A}\right)$ can be encoded to $E_{A} \in\left\{0 \ldots S_{A}-1\right\}$ where

$$
S_{A}=(r+1) \times \frac{r!}{(r-n)!n!} \times(y+1) \times \frac{(z+v-1)!}{z!(v-1)!}
$$

The total space of the coder $C_{\mathrm{A}}$ of a histogram $A$ is the sum of the variables space, size space and counts space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{A}}\right)(A)= & \operatorname{spaceVariables}(U)(|\operatorname{vars}(A)|)+ \\
& \text { spaceSize }(y)+ \\
& \operatorname{spaceCounts}(U)(A)
\end{aligned}
$$

The coder domain $\mathcal{A}_{U, i, \leq y}$ of $C_{\mathrm{A}}$ excludes integral histograms having zero states, $A^{\mathrm{F}} \neq A^{\mathrm{U}}$, where $A \in \mathcal{A}_{U, \mathrm{i}}$ and $\operatorname{size}(A) \leq y$. However the equivalent trimmed histogram, $\operatorname{trim}(A) \equiv A$, will be in the coder domain, $\operatorname{trim}(A) \in$ $\mathcal{A}_{U, \mathrm{i}, \leq y}$, so there is always a means of encoding equivalent histograms although the coder cannot distinguish between them. An example is the empty histogram $\emptyset$ which is encoded, whereas its completed equivalent the zero scalar histogram $\{(\emptyset, 0)\}$ is not. However, $\operatorname{trim}(\{(\emptyset, 0)\})=\emptyset$.

Also, note that the histogram counts space depends only on the size and volume, not the actual counts in a histogram. Nor does it depend on the cardinality of the identifier set.

Consider the counts space spaceCounts $(U)(A)$ of histogram $A$ in system $U$. Scale analysis would suggest that the space of a fixed width encoding $\mathcal{L}(\{1 \ldots z\})$ (similar to that of history events space $\mathcal{L}(\{1 \ldots v\})$ ) would be an upper bound, so that

$$
\operatorname{spaceCounts}(U)(A) \leq v \ln z
$$

where $z=\operatorname{size}(A), z>0, v=\operatorname{volume}(U)(V)$. This is in fact the case where $z>1$ because

$$
\frac{(z+v-1)!}{z!(v-1)!}=\frac{v}{z+v} \prod_{i \in\{1 \ldots v\}} \frac{z+i}{i} \leq z^{v}
$$

By a symmetrical argument, if $z>0$

$$
\operatorname{spaceCounts}(U)(A) \leq z \ln v
$$

This is obvious in the case where $A$ is effectively complete and so $z \geq v$, but also holds if $z<v$ because

$$
\frac{(z+v-1)!}{z!(v-1)!}=\prod_{i \in\{1 \ldots z\}} \frac{v-1+i}{i} \leq v^{z}
$$

Thus if $A$ is the histogram of history $H, A=$ histogram $(H)$, then the history events space is greater than the histogram counts space spaceCounts $(U)(A) \leq$ spaceEvents $(U)(H)$.

In the case where $z=a v^{2}$ where $a \in \mathbf{R}$ and $a \geq 1$

$$
\frac{(z+v-1)!}{z!(v-1)!}=\frac{1}{a v+1} \prod_{i \in\{1 \ldots v\}} \frac{a v^{2}+i}{i} \geq(a v+1)^{v-1}
$$

Hence where $z \geq v^{2}$ and $z>1$

$$
(v-1) \ln v<\operatorname{spaceCounts}(U)(A) \leq v \ln z<z \ln v
$$

In the case where $v=a z^{2}$ where $a \in \mathbf{R}$ and $a \geq 1$ and $z>0$

$$
\frac{(z+v-1)!}{z!(v-1)!}=\prod_{i \in\{1 \ldots z\}} \frac{a z^{2}-1+i}{i} \geq(a z)^{z}
$$

Hence where $v \geq z^{2}$ and $z>0$

$$
z \ln z<\operatorname{spaceCounts}(U)(A) \leq z \ln v
$$

Similarly to the effective index coder $C_{\mathrm{H}, \mathrm{F}}$, above, an effective histogram coder can be defined that encodes the effective states in a pair $\left(x, F_{Q}\right) \in \mathbf{N}^{2}$ added to the tuple, $T_{A} \in \mathbf{N}^{2} \times \mathbf{N} \times \mathbf{N}^{2} \times \mathbf{N}$. The pair encodes (i) the effective volume $x=\left|A^{\mathrm{F}}\right|$ and (ii) the index, $F_{Q}$, into an enumeration of the effective states subsets,

$$
F_{Q} \in\left\{1 \ldots \frac{v!}{(v-x)!x!}\right\}
$$

Given the set of effective states, $Q=A^{\mathrm{FS}}$, the counts can be encoded in a strong composition instead of a weak composition. The last element of the tuple, $R_{A}$, is now the strong composition number of $A$,

$$
R_{A} \in\left\{1 \ldots \frac{(z-1)!}{(z-x)!(x-1)!}\right\}
$$

The tuple $T_{A}=\left(\left(n, N_{V}\right), z,\left(x, F_{Q}\right), R_{A}\right)$ can be encoded to $E_{A} \in\left\{0 \ldots S_{A}-\right.$ 1\} where

$$
S_{A}=(r+1) \times \frac{r!}{(r-n)!n!} \times(y+1) \times v \times \frac{v!}{(v-x)!x!} \times \frac{(z-1)!}{(z-x)!(x-1)!}
$$

Define the space of a strong composition as spaceComposition $\in \mathbf{N}_{>0} \times$ $\mathbf{N}_{>0} \rightarrow \ln \mathbf{N}_{>0}$

$$
\operatorname{spaceComposition}(k, n):=\ln |\mathrm{C}(\{1 \ldots k\}, n)|=\ln \frac{(n-1)!}{(n-k)!(k-1)!}
$$

Define the effective counts space as spaceCountsEffective $(U) \in \mathcal{A}_{U, \mathrm{i}} \rightarrow \ln \mathbf{N}_{>0}$ spaceCountsEffective $(U)(A):=\ln \frac{(z-1)!}{(z-x)!(x-1)!}=\operatorname{spaceComposition}(x, z)$
where $z=\operatorname{size}(A)$ and $x=\left|A^{\mathrm{F}}\right|$. The effective counts space is undefined for zero size, $z=0$.

Define the effective histogram coder

$$
C_{\mathrm{A}, \mathrm{~F}}=\operatorname{coderHistogramEffective}\left(U, y, D_{\mathrm{V}}, D_{\mathrm{S}}\right) \in \operatorname{coders}\left(\mathcal{A}_{U, \mathrm{i}, \leq y}\right)
$$

The total space of the effective histogram coder $C_{\mathrm{A}, \mathrm{F}}$ of a non-zero histogram $A$ is the sum of the variables space, size space, effective space and effective counts space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{A}, \mathrm{~F}}\right)(A)= & \text { spaceVariables }(U)(|\operatorname{vars}(A)|)+ \\
& \text { spaceSize }(y)+ \\
& \text { spaceEffective }(U)(A)+ \\
& \text { spaceCountsEffective }(U)(A)
\end{aligned}
$$

The effective histogram coder space, $C_{\mathrm{A}, \mathrm{F}}^{\mathrm{s}}(A)$, is less than the histogram coder space, $C_{\mathrm{A}}^{\mathrm{s}}(A)$, if spaceEffective $(U)(A)+$ spaceCountsEffective $(U)(A)<$ spaceCounts $(U)(A)$,

$$
\ln v+\ln \frac{v!}{(v-x)!x!}+\ln \frac{(z-1)!}{(z-x)!(x-1)!}<\ln \frac{(z+v-1)!}{z!(v-1)!}
$$

In the case of an effective singleton, $x=\left|A^{\mathrm{F}}\right|=1$, this simplifies to

$$
2 \ln v<\ln \frac{(z+v-1)!}{z!(v-1)!}
$$

In this case the effective histogram coder space does not depend on the size, $z$, so for given volume $v$ there exists some size $z$ such that the effective histogram coder space is less than the histogram coder space, $C_{\mathrm{A}, \mathrm{F}}^{\mathrm{s}}(A)<C_{\mathrm{A}}^{\mathrm{s}}(A)$.

In the case of unit uniform histogram, $\operatorname{trim}(A)=A^{\mathrm{F}}$, the effective volume equals the size, $x=z$, and the inequality simplifies to

$$
\frac{v v!}{(v-z)!}<\frac{(z+v-1)!}{(v-1)!}
$$

In this case the effective histogram coder space is less than the histogram coder space, $C_{\mathrm{A}, \mathrm{F}}^{\mathrm{s}}(A)<C_{\mathrm{A}}^{\mathrm{s}}(A)$, if the size is at least two, $z \geq 2$.

### 3.18.3 Classification space

Classifications are lossless transformations of histories and vice-versa

$$
\begin{array}{r}
\forall H \in \mathcal{H}(\text { history }(\text { classification }(H))=H) \\
\forall G \in \mathcal{G}(\text { classification }(\text { history }(G))=G)
\end{array}
$$

Given a system $U \in \mathcal{U}$ and an identifier set $X \subset \mathcal{X}$, we can define $\mathcal{G}_{U, X} \subseteq$ $\mathcal{S}_{U} \rightarrow(\mathrm{P}(X) \backslash\{\emptyset\})$. Now $\mathcal{G}_{U, X}: \leftrightarrow: \mathcal{H}_{U, X}$ and $\mathcal{H}_{U, X}$ is finite, so $\mathcal{G}_{U, X}$ is finite and can be constructed

$$
\mathcal{G}_{U, X}=\bigcup\{\operatorname{cartesian}(U)(V) \leftrightarrow P: V \subset \operatorname{vars}(U), P \in \mathrm{~B}(X)\} \cup\{\emptyset\}
$$

Consider the classification coder of histories

$$
C_{\mathrm{G}}=\operatorname{coderClassification}\left(U, X, D_{\mathrm{V}}, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)
$$

The coder domain is the same as that of the index coder, $C_{\mathrm{H}}$. A classification $G \in \mathcal{G}_{U, X}$, where $G=$ classification $(H)$ and $H \in \mathcal{H}_{U, X}$, can be encoded in a tuple $T_{G} \in \mathbf{N}^{2} \times \mathbf{N}^{2} \times \mathbf{N} \times \mathbf{N}$. This tuple $T_{G}$ can then be encoded into a natural number $E_{G} \in\left\{0 \ldots S_{G}-1\right\}$. The space of the classification is the space of this encoding, space $\left(C_{\mathrm{G}}\right)(H)=\operatorname{space}\left(S_{G}\right)=\ln S_{G}$.

The first pair of the tuple $T_{G}$ encodes the set of variables in the same way as for the history coder, $C_{\mathrm{H}}$, or the histogram coder, $C_{\mathrm{A}}$. The space of the pair
$\left(n, N_{V}\right)$ is spaceVariables $(U)(n)$ where $A=\operatorname{histogram}(G), V=\operatorname{vars}(A)$ and $n=|V|$.

The second pair of the tuple $T_{G}$ encodes the set of event identifiers in the same way as for the history coder, $C_{\mathrm{H}}$. The space of the pair $\left(z, Z_{I}\right)$ is spaceIds $(y, z)$ where $y=|X|$ and $z=\operatorname{size}(A)$.

The third element of the tuple $T_{G}$ encodes the set of counts of the states in the same way as for the histogram coder, $C_{\mathrm{A}}$. The space of the element $R_{A}$ is spaceCounts $(U)(A)$.

The last element of the tuple $T_{G}$ encodes the classification of the events. Let $Q$ be the partition of event identifiers represented by non-empty $G \neq \emptyset$, $Q=\operatorname{ran}(G)=\{C:(S, C) \in G\} \in \mathrm{B}(\operatorname{ids}(G))$. Given $D_{\mathrm{X}}$, choose enumeration $F$ of the enumerations of the partitions of the event identifiers corresponding to the classification
$F \in \operatorname{enums}(\{P: P \in \mathrm{~B}(\operatorname{ids}(G)), \exists X \in P: \leftrightarrow: Q \forall(Y, Z) \in X(|Y|=|Z|)\})$
The last element of the tuple $T_{G}$ encoding the classification of the event identifiers of $G$ is $F_{Q}$

$$
F_{Q} \in\left\{1 \cdots \frac{z!}{\prod_{S \in \operatorname{dom}(G)}\left|G_{S}\right|!}\right\}
$$

Define the space of the encoding of the classification of the event identifiers of $G$ having histogram $A=\operatorname{histogram}(G)$ as spaceClassification $\in \mathcal{A}_{\mathrm{i}} \rightarrow \ln \mathbf{N}_{>0}$

$$
\operatorname{spaceClassification}(A):=\ln z!-\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!
$$

where $A \neq \emptyset$ and $z=\operatorname{size}(A)$. Define spaceClassification $(\emptyset):=0$. The space of $F_{Q}$ is spaceClassification(histogram $\left.(G)\right)$.

This function can be defined more generically as spaceClassification $\in(\mathcal{X} \rightarrow$ $\mathbf{N}) \rightarrow \ln \mathbf{N}_{>0}$

$$
\operatorname{spaceClassification}(Q):=\ln z!-\sum_{x \in \operatorname{dom}(Q)} \ln Q_{x}!
$$

where $z=\operatorname{sum}(Q)$. With this definition spaceSubset is a special case of spaceClassification where $|Q|=2$.

The events classification space is also called the multinomial space because the spaceClassification(histogram $(G)$ ) is the logarithm of the multinomial coefficient of its histogram

$$
\operatorname{spaceClassification~}(A)=\ln z!-\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!=\ln \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!}
$$

The multinomial coefficient forms part of the multinomial distribution,

$$
Q_{\mathrm{m}}(E, z)(A)=\frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}} E_{S}^{A_{S}}
$$

to count the permutations of the probabilities of the distribution histogram's states. The multinomial coefficient forms part of the classification space by counting the permutations or orders of the events within the partition by state.

Finally the tuple $T_{G}=\left(\left(n, N_{V}\right),\left(z, Z_{I}\right), R_{A}, F_{Q}\right)$ can be encoded to $E_{G} \in$ $\left\{0 \ldots S_{G}-1\right\}$ where
$S_{G}=(r+1) \times \frac{r!}{(r-n)!n!} \times(y+1) \times \frac{y!}{(y-z)!z!} \times \frac{(z+v-1)!}{z!(v-1)!} \times \frac{z!}{\left.\prod_{S \in \operatorname{dom}(G)}\right) G_{S} \mid!}$
where $z>0$, otherwise

$$
S_{G}=(r+1) \times \frac{r!}{(r-n)!n!} \times(y+1)
$$

The total space of a classification coder of a history $H$ is the sum of the variables space, ids space, histogram counts space and events classification space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{G}}\right)(H)= & \text { spaceVariables }(U)(|\operatorname{vars}(H)|)+ \\
& \text { spaceIds }(|X|,|H|)+ \\
& \text { spaceCounts }(U)(A)+ \\
& \text { spaceClassification }(A)
\end{aligned}
$$

where $A=\operatorname{histogram}(H)$.
The space of a non-empty non-scalar integral histogram $A$ in the histogram coder, $C_{\mathrm{A}}$, is less than or equal to the space in the corresponding classification
coder, $C_{\mathrm{G}}$, of its history, $A=$ histogram $(H)$, because the event identifiers are aggregated into counts

$$
S_{G}=(r+1) \times \frac{r!}{(r-n)!n!} \times(y+1) \times \frac{(z+v-1)!}{z!(v-1)!} \times \frac{y!}{(y-z)!\prod_{S \in \operatorname{dom}(G)}\left|G_{S}\right|!}
$$

and so

$$
\operatorname{space}\left(C_{\mathrm{G}}\right)(H)=\operatorname{space}\left(C_{\mathrm{A}}\right)(A)+\ln \frac{y^{\underline{z}}}{\prod_{S \in A^{\mathrm{s}}} A_{S}!}
$$

where $y^{z}$ is the falling factorial, $y!/(y-z)!$. The second term is always positive because $y^{\underline{z}} \geq z$ !. The part of the space of the classification that depends on the volume, and hence the system, is encapsulated in the histogram space.

Define a generic classification coder of histories $C_{\mathrm{G}, \mathrm{A}}$ which is parameterised by an underlying coder of histograms $C \in \operatorname{coders}\left(\mathcal{A}_{U, i, \leq y}\right)$

$$
C_{\mathrm{G}, \mathrm{~A}}=\operatorname{coderClassificationGeneric}\left(C, X, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)
$$

The generic classification coder encodes the variables space, size space and counts space via the underlying coder. It adds the ids space (less size space) and events classification space such that

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{G}, \mathrm{~A}}\right)(H)= & \operatorname{space}(C)(A)+ \\
& \operatorname{spaceIds}(y,|H|)-\operatorname{spaceSize}(y)+ \\
& \operatorname{spaceClassification}(A)
\end{aligned}
$$

where $H \in \mathcal{H}_{U, X}$ and $A=\operatorname{histogram}(H)$. In the case where the underlying coder is $C=C_{\mathrm{A}}$, which is constructed $C_{\mathrm{A}}=\operatorname{coderHistogram}\left(U, y, D_{\mathrm{V}}, D_{\mathrm{S}}\right)$, then the generic classification coder space equals the classification coder space, $\operatorname{space}\left(C_{\mathrm{G}, \mathrm{A}}\right)(H)=\operatorname{space}\left(C_{\mathrm{G}}\right)(H)$.

Define the effective classification coder $C_{\mathrm{G}, \mathrm{F}}$ with the generic classification coder, $C_{\mathrm{G}, \mathrm{A}}$, parameterised by the effective histogram coder, $C_{\mathrm{A}, \mathrm{F}}$,

$$
C_{\mathrm{G}, \mathrm{~F}}=\operatorname{coderClassificationGeneric}\left(C_{\mathrm{A}, \mathrm{~F}}, X, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)
$$

The total space of the effective classification coder $C_{\mathrm{G}, \mathrm{F}}$ of a non-empty history $H \neq \emptyset$ is the sum of the variables space, ids space, effective space, effective counts space and events classification space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{G}, \mathrm{~F}}\right)(H)= & \text { spaceVariables }(U)(|\operatorname{vars}(H)|)+ \\
& \text { spaceIds }(|X|,|H|)+ \\
& \text { spaceEffective }(U)(A)+ \\
& \text { spaceCountsEffective }(U)(A)+ \\
& \text { spaceClassification }(A)
\end{aligned}
$$

where $A=\operatorname{histogram}(H)$.
The effective classification coder space is less than the classification coder space when the effective histogram coder space is less than the histogram coder space,

$$
C_{\mathrm{G}, \mathrm{~F}}^{\mathrm{s}}(H)<C_{\mathrm{G}}^{\mathrm{s}}(H) \Longleftrightarrow C_{\mathrm{A}, \mathrm{~F}}^{\mathrm{s}}(A)<C_{\mathrm{A}}^{\mathrm{s}}(A)
$$

Compare the classification coder, $C_{\mathrm{G}}$, and the index coder, $C_{\mathrm{H}}$, using a couple of special cases.

In the case of singleton classifications, $A=\operatorname{histogram}(G)$ such that $\left|A^{\mathrm{F}}\right|=1$, the space of the classification is less than or equal to the space of the history $H=\operatorname{history}(G)$. That is, $\operatorname{space}\left(C_{\mathrm{G}}\right)(H) \leq \operatorname{space}\left(C_{\mathrm{H}}\right)(H)$

$$
\begin{aligned}
& \operatorname{spEv}(U)(H)-\operatorname{spCt}(U)(A)-\operatorname{spCl}(A) \\
& \quad=z \ln v-\ln \frac{(z+v-1)!}{z!(v-1)!}-\ln \frac{z!}{z!} \geq 0
\end{aligned}
$$

because $\operatorname{spCt}(U)(A) \leq z \ln v$, where $\operatorname{spEv}=$ spaceEvents, $\mathrm{spCt}=$ spaceCounts and $\mathrm{spCl}=$ spaceClassification.

In the case of completely effective uniform classifications, $A=\operatorname{histogram}(G)$ such that $A^{\mathrm{F}}=A^{\mathrm{C}}$ and $|\operatorname{ran}(A)|=1$, the space of the classification is greater than or equal to the space of the history $H=\operatorname{history}(G)$. That is, $\operatorname{space}\left(C_{\mathrm{G}}\right)(H) \geq \operatorname{space}\left(C_{\mathrm{H}}\right)(H)$. Let $z=k v$ where $k \in \mathbf{N}$ and $k \geq 1$

$$
\begin{aligned}
& \operatorname{spEv}(U)(H)-\operatorname{spCt}(U)(A)-\operatorname{spCl}(A) \\
& =\quad z \ln v-\ln \frac{(z+v-1)!}{z!(v-1)!}-\ln \frac{z!}{((z / v)!)^{v}} \\
& =k v \ln v-\ln (k v+v-1)!+\ln (v-1)!+v \ln k! \\
& =\ln \prod_{c \in\{1 . . k v\}} \frac{v \sqrt[k]{k!}}{c+v-1} \leq 0
\end{aligned}
$$

This is obviously true for $k=1$. It is conjectured to be true for other values of $k$. Also the conjecture only applies to the case where there is an integral ratio $z / v \in \mathbf{N}$.

The special case of the singleton classification, $\left|A^{\mathrm{F}}\right|=1$, forms a minimum for the events classification space

$$
\operatorname{spaceClassification}(A) \geq 0
$$

The second case of completely effective uniform classifications, $A=Z_{z / v} * V^{\mathrm{C}}$ where $Z_{x}=\operatorname{scalar}(x)$, forms a maximum

$$
\text { spaceClassification }(A) \leq \ln z!-v \ln (z / v)!
$$

where $z / v \in \mathbf{N}$. This is a local maximum because $(z / v-1)!(z / v+1)!>$ $((z / v)!)^{2}$. Proof that it is everywhere a maximum can be shown by means of sequences of perturbations. See the similar case of the mean of the multinomial probability distribution of a cartesian distribution above. The probability of the mean histogram is the maximum frequency

$$
\hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)(M)=\frac{z!}{\left(\frac{z}{v}!\right)^{v}}\left(\frac{1}{v}\right)^{z}
$$

where $M=\operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)\right)=Z_{z / v} * V^{\mathrm{C}}$.
Apply Stirling's approximation to the maximum case

$$
\begin{aligned}
\ln z!-v \ln (z / v)! & <z \ln z-v\left(\frac{z}{v} \ln \frac{z}{v}-\frac{z}{v}\right) \\
& =z(\ln v+1)
\end{aligned}
$$

Thus

$$
\operatorname{spaceClassification}(A)<z(\ln v+1)
$$

The classification coder and index coder cannot differ by more than $z(\ln v+1)$ and so are always of the same order of complexity

$$
\operatorname{space}\left(C_{\mathrm{G}}\right) \in \mathrm{O}\left(\operatorname{space}\left(C_{\mathrm{H}}\right), 2\right)
$$

The appearance of the multinomial coefficient in the classification coder suggests a relationship with entropy. In fact, the events classification space, spaceClassification, can be approximated by the sized entropy, by the use of Stirling's approximation

$$
\begin{aligned}
\operatorname{spaceClassification}(A) & :=\ln z!-\sum_{S \in A^{\mathrm{S}}} \ln A_{S}! \\
& \approx z \ln z-z-\sum_{S \in A^{\mathrm{FS}}}\left(A_{S} \ln A_{S}-A_{S}\right) \\
& =z \ln z-z \sum_{S \in A^{\mathrm{FS}}} N_{S} \ln z N_{S} \\
& =-z \sum_{S \in A^{\mathrm{FS}}} N_{S} \ln N_{S} \\
& =z \times \operatorname{entropy}(A)
\end{aligned}
$$

where $z>0$ and $N=\operatorname{resize}(1, A)$. Thus events classification space increases with increasing entropy. This is consistent with the two special cases above. In the first case, the singleton histogram has low entropy and the classification coder requires less space than the index coder. In the second case, the uniform histogram has high entropy and hence the reverse is true.

Consider the scaled entropy, $z \times \operatorname{entropy}(A)$, at the break-even space, where the classification coder space equals the index coder space, $C_{\mathrm{G}}^{\mathrm{s}}(H)=C_{\mathrm{H}}^{\mathrm{s}}(H)$,

$$
\begin{aligned}
z \times \operatorname{entropy}(A) & \approx z \ln v-\ln \frac{(z+v-1)!}{z!(v-1)!} \\
& \approx z \ln v-((z+v) \ln (z+v)-z \ln z-v \ln v)
\end{aligned}
$$

That is, if the scaled entropy, $z \times$ entropy $(A)$, of a history, $H$, is greater than the break-even scaled entropy, $z \ln v-((z+v) \ln (z+v)-z \ln z-v \ln v)$, then the index coder requires less space than the classification coder, $C_{\mathrm{G}}^{\mathrm{s}}(H)>C_{\mathrm{H}}^{\mathrm{s}}(H)$, and vice-versa.

Also, entropy can be the basis of a coder. See the Appendix 'Entropy encoding of states'.

The events classification space does not depend on the internal structure of the states in the classification $G$, only that the states form a functional domain. That is, events classification space does not depend on the variables in the states nor their valencies, except in respect of the total volume and the equivalence of states. To demonstrate, create a unit functional transform $T=(X,\{w\})$ with a single derived variable $w$ such that if we choose an enumeration of the cartesian states, $Q \in \operatorname{enums}\left(A^{\mathrm{CS}}\right)$, where $A=\operatorname{histogram}(G)$ and such that $U_{w}=\operatorname{ran}(Q)$ and $X=\{(S \cup\{(w, i)\}, 1):(S, i) \in Q\}$, then we have the same events classification space spaceClassification $(A * T)=$ spaceClassification $(A)$.

Conjecture that neither the index coder nor the classification coder of histories is a minimal coder,

$$
\forall U \in \mathcal{U} \forall X \subset \mathcal{X} \forall C \in\left\{C_{\mathrm{H}}, C_{\mathrm{G}}\right\}\left(\sum_{H \in \mathcal{H}_{U, X}} \operatorname{space}(C)(H)>\left|\mathcal{H}_{U, X}\right| \ln \left|\mathcal{H}_{U, X}\right|\right)
$$

This is the case even for only variate histories. Let

$$
\mathcal{H}_{U, X, \mathrm{v}}=\left\{H: H \in \mathcal{H}_{U, X},|\operatorname{vars}(H)|>0\right\}
$$

The variate histories, $\mathcal{H}_{U, X, \mathrm{v}}$, exclude empty histories, so $z>0$. The space of the coders for the variate coder domain is calculated by subtracting the space required for non-variate

$$
\operatorname{space}\left(C_{\mathrm{G}, \mathrm{v}}\right)(H)=\operatorname{space}\left(C_{G}\right)(H)-\ln \frac{r+1}{r}-\ln \frac{y+1}{y}
$$

However, the total space of the variate-classification coder of histories, $C_{\mathrm{G}, \mathrm{v}}$, is still greater than a minimal coder of $\mathcal{H}_{U, X, \mathrm{v}}$.

A classification $G \in \mathcal{G}_{U, X}$ is the inverse of its corresponding history, $G=$ classification $(H)=H^{-1}$ where $H \in \mathcal{H}_{U, X}$, and so it may be viewed as a relation between (i) the effective states, $\operatorname{dom}(G)=\operatorname{ran}(H)=A^{\mathrm{FS}}$, where $A=$ histogram $(H)$, and (ii) the components of a partition of the event identifiers, $\operatorname{ran}(G) \in \mathrm{B}(\operatorname{dom}(H))$. That is, $G \in A^{\mathrm{FS}}: \rightarrow: \operatorname{ran}(G)$. Thus a classification may be encoded by encoding (i) the effective states, $A^{\mathrm{FS}}$, (ii) the permutation of the components of the partition, $x$ ! where $x=\left|A^{\mathrm{FS}}\right|$, given some order on the states, $D_{\mathrm{S}}$, and (iii) the partition index, $\{1 \ldots \operatorname{stir}(z, x)\}$ where $z=|H|$ and the Stirling number of the second kind is $\operatorname{stir}(n, k):=|\mathrm{S}(\{1 \ldots n\}, k)|$.

Define the partition classification coder,

$$
C_{\mathrm{G}, \mathrm{~B}}=\operatorname{coderClassificationPartition}\left(U, X, D_{\mathrm{V}}, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)
$$

Define the space of the encoding of the permutation and index of the event identifiers components as spaceEventsComponents $(U) \in \mathcal{A}_{U, \mathrm{i}} \rightarrow \ln \mathbf{N}_{>0}$

$$
\text { spaceEventsComponents }(U)(A):=\ln x!+\ln \operatorname{stir}(z, x)
$$

where $x=\left|A^{\mathrm{F}}\right|$ and $z=\operatorname{size}(A)$.
The total space of the partition classification coder $C_{\mathrm{G}, \mathrm{B}}$ of a non-empty history $H \neq \emptyset$ is the sum of the variables space, ids space, effective space, and events components space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{G}, \mathrm{~B}}\right)(H)= & \operatorname{spaceVariables}(U)(|\operatorname{vars}(H)|)+ \\
& \operatorname{spaceIds}(|X|,|H|)+ \\
& \text { spaceEffective }(U)(A)+ \\
& \text { spaceEventsComponents }(U)(A)
\end{aligned}
$$

where $A=\operatorname{histogram}(H)$.

The partition classification coder, $C_{\mathrm{G}, \mathrm{B}}$, is less dependent on the histogram, $A$, than the effective classification coder, $C_{\mathrm{G}, \mathrm{F}}$, because it depends on the effectiveness of the states and the total of the counts, rather than the individual counts of the states. That is, spaceEventsComponents $(U)(A)$, only depends on (i) the size, $z=\operatorname{size}(A)$, and (ii) the effective volume, $x=\left|A^{\mathrm{F}}\right|$, whereas spaceClassification $(A)$ depends on the histogram as a relation, $A \in \mathcal{S} \rightarrow \mathrm{Q}_{\geq 0}$. In this, the partition classification coder, $C_{\mathrm{G}, \mathrm{B}}$, resembles the effective index coder, $C_{\mathrm{H}, \mathrm{F}}$, where the effective events space, spaceEventsEffective $(U)(H):=$ $z \ln x$, only depends on the size, $z$ and effective volume, $x$. Thus the partition classification coder, $C_{\mathrm{G}, \mathrm{B}}$, is intermediate between the effective index coder, $C_{\mathrm{H}, \mathrm{F}}$, and the effective classification coder, $C_{\mathrm{G}, \mathrm{F}}$.

### 3.18.4 Derived history space

In section 'Histogram space', above, the histogram coder is constructed

$$
C_{\mathrm{A}}=\operatorname{coderHistogram}\left(U, y, D_{\mathrm{V}}, D_{\mathrm{S}}\right) \in \operatorname{coders}\left(\mathcal{A}_{U, \mathrm{i}, \leq y}\right)
$$

where $y=|X|$ is the cardinality of the identifier set $X \subset \mathcal{X}$, and $\mathcal{A}_{U, \mathrm{i}, \leq y}$ is the set of trimmed integral histograms in system $U$ having size less than or equal to $y$.

The histogram coder, $C_{\mathrm{A}}$, is defined such that the space of trimmed integral histogram $A \in \mathcal{A}_{U, i, \leq y}$ is

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{A}}\right)(A)= & \text { spaceVariables }(U)(|V|)+ \\
& \text { spaceSize }(y)+ \\
& \operatorname{space\operatorname {Counts}(U)(A)}
\end{aligned}
$$

where $V=\operatorname{vars}(A)$.
The histogram counts space is the weak composition space,

$$
\operatorname{spaceCounts}(U)(A):=\ln \frac{(z+v-1)!}{z!(v-1)!}=\operatorname{spaceCompositionWeak}(v, z)
$$

where $z=\operatorname{size}(A)$, and $v=\operatorname{volume}(U)(V)$. In the case where the size is less than or equal to the volume, $z \leq v$, the counts space may be approximated

$$
\begin{aligned}
\ln \frac{(z+v-1)!}{z!(v-1)!} & =\bar{z} \ln v-\underline{z} \ln z \\
& \approx z \ln \frac{v}{z}
\end{aligned}
$$

by abuse of notation. If the size, $z$, is fixed, the histogram counts space, spaceCounts $(U)(A)$, varies with the logarithm of the volume, $\ln v$.

In the case where the size is greater than the volume, $z>v$, the counts space approximates

$$
\begin{aligned}
\ln \frac{(z+v-1)!}{z!(v-1)!} & \approx \bar{v} \ln z-\underline{v} \ln v \\
& \approx v \ln \frac{z}{v}
\end{aligned}
$$

If the volume, $v$, is fixed, the histogram counts space, $\operatorname{spaceCounts}(U)(A)$, varies with the logarithm of the size, $\ln z$.

The weak composition space may also be analysed by means of Stirling's approximation,

$$
\begin{aligned}
\ln \frac{(z+v-1)!}{z!(v-1)!} \approx & (z+v) \ln (z+v)-z \ln z-v \ln v-\ln \frac{z+v}{v} \\
= & z \ln \frac{z+v}{z}+(v-1) \ln \frac{z+v}{v} \\
\approx & \left(z \ln \frac{v}{z}: z<v\right)+ \\
& (2 z \ln 2: z=v)+ \\
& \left(v \ln \frac{z}{v}: z>v\right)
\end{aligned}
$$

The following discussion considers how the volume, $v$, or size, $z$, may be broken into components by means of partitioning the volume with a transform, in order to reduce the overall counts space. That is, a one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ has an inverse, $T^{-1}=\operatorname{inverse}(T)$, which implies a partition of the volume $T^{\mathrm{P}} \in \mathrm{B}\left(V^{\mathrm{CS}}\right)$ where $T^{\mathrm{P}}=\left\{C^{\mathrm{S}}: C \in \operatorname{ran}\left(T^{-1}\right)\right\}$.

Let the substrate histogram coder $C_{\mathrm{A}, V} \in \operatorname{coders}\left(\mathcal{A}_{U, V, \mathrm{i}, \leq y}\right)$ be a histogram coder, $C_{\mathrm{A}}$, but with given variables $V$. The coder domain, $\mathcal{A}_{U, V, \mathrm{i}, \leq y}$, is the subset of the trimmed integral histograms of size less than or equal to $y$ which are also in variables $V$. The substrate histograms is defined

$$
\mathcal{A}_{U, V, \mathrm{i}, \leq y}=\left\{\operatorname{trim}(A): A \in \mathcal{A}_{U, \mathrm{i}}, \operatorname{size}(A) \leq y, \operatorname{vars}(A)=V\right\}
$$

which has cardinality

$$
\left|\mathcal{A}_{U, V, \mathrm{i}, \leq y}\right|=\sum_{z \in\{1 \ldots y\}} \frac{(z+v-1)!}{z!(v-1)!}
$$

where $v=\left|V^{\mathrm{C}}\right|$.

The substrate histogram coder is such that

$$
\operatorname{space}\left(C_{\mathrm{A}, V}\right)(A)=\operatorname{space}\left(C_{\mathrm{A}}\right)(A)-\operatorname{spaceVariables}(U)(V)
$$

The substrate histogram coder space is

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{A}, V}\right)(A)= & \operatorname{spaceSize}(y)+ \\
& \operatorname{spaceCounts}(U)(A)
\end{aligned}
$$

Now consider the derived substrate histogram coder $C_{\mathrm{A}, V, \mathrm{~T}}$ given one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ in variables $V=\operatorname{und}(T)$. The coder domain is the subset of the trimmed integral histograms of size less than or equal to $y$ which are also in variables $V, \mathcal{A}_{U, V, \mathrm{i}, \leq y}$. The derived substrate histogram coder is instantiated

$$
\begin{aligned}
& C_{\mathrm{A}, V, \mathrm{~T}}= \\
& \quad \text { coderHistogramSubstrateDerived }\left(U, y, T, D_{\mathrm{S}}\right) \in \operatorname{coders}\left(\mathcal{A}_{U, V, \mathrm{i}, \leq y}\right)
\end{aligned}
$$

The histogram, $A \in \mathcal{A}_{U, V, \mathrm{i}, \leq y}$, can be encoded in an intermediate tuple $T_{A}=\left(z, R_{A * T}^{\prime}, L\right) \in \mathbf{N} \times \mathbf{N} \times \mathcal{L}(\mathbf{N})$.

There is no need to encode the variables, $V$, because these are defined by the transform, $T$, in the derived substrate histogram coder parameters. So the first element, $z \in \mathbf{N}$, of the tuple, $T_{A}$, encodes the size $z=\operatorname{size}(A) \in$ $\{0 \ldots y\}$, which has space $\operatorname{spaceSize}(y)=\ln (y+1)$.

The second element, $R_{A * T}^{\prime} \in \mathbf{N}$, of the tuple, $T_{A}$, is the encoding of the counts of the possible derived volume of the derived histogram, $A * T$,

$$
R_{A * T}^{\prime} \in\left\{1 \ldots \frac{\left(z+w^{\prime}-1\right)!}{z!\left(w^{\prime}-1\right)!}\right\}
$$

where $W=\operatorname{der}(T)$, derived volume $w=\left|W^{\mathrm{C}}\right|$ and possible derived volume $w^{\prime}=\left|\left(V^{\mathrm{C}} * T\right)^{\mathrm{F}}\right|=\left|T^{-1}\right| \leq w$. This is similar to the encoding of the counts in the histogram coder, $C_{\mathrm{A}}$, but the derived coder excludes necessarily ineffective states, $W^{\mathrm{CS}} \backslash\left(V^{\mathrm{C}} * T\right)^{\mathrm{FS}}$, that occur when the transform is overlapped, $\operatorname{overlap}(T)$. The derived coder can compute the possible derived volume, $w^{\prime}$, at instantiation because it depends only on the transform, $T$, which is a parameter of the constructor. The space is spaceCountsDerived $(U)(A, T)$
where spaceCountsDerived $(U) \in \mathcal{A}_{U, \mathrm{i}} \times \mathcal{T}_{U, \mathrm{f}, 1} \rightarrow \ln \mathrm{~N}_{>0}$ is defined

$$
\begin{aligned}
\operatorname{spaceCountsDerived}(U)(A, T) & :=\ln \frac{\left(z+w^{\prime}-1\right)!}{z!\left(w^{\prime}-1\right)!} \\
& =\operatorname{spaceCompositionWeak}\left(w^{\prime}, z\right)
\end{aligned}
$$

The possible derived volume is less than or equal to the derived volume, $w^{\prime} \leq w$, so the derived counts space is no greater than the counts space of the derived histogram, spaceCountsDerived $(U)(A, T) \leq \operatorname{spaceCounts}(U)(A * T)$. The possible derived volume equals the derived volume if and only if the transform is non-overlapped, $\neg \operatorname{overlap}(T) \Longleftrightarrow w^{\prime}=w$, because it is only in this case that the transform is right total, $\operatorname{dom}\left(T^{-1}\right)=W^{\mathrm{CS}}$. In this case, the derived counts space equals the counts space of the derived histogram, $\neg \operatorname{overlap}(T) \Longleftrightarrow \operatorname{spaceCountsDerived}(U)(A, T)=\operatorname{spaceCounts}(U)(A * T)$. The possible derived volume is less than or equal to the underlying volume, $w^{\prime} \leq v$, so the derived counts space is no greater than the counts space of the underlying histogram, spaceCountsDerived $(U)(A, T) \leq \operatorname{spaceCounts}(U)(A)$.

The last element, $L \in \mathcal{L}(\mathbf{N})$, of the tuple, $T_{A}$, is a list of the encodings of the counts of each of the components of the transform inverse, $T^{-1}$,

$$
L_{M^{\prime}(R)} \in\left\{1 \ldots \frac{\left((A * T)_{R}+|C|-1\right)!}{(A * T)_{R}!(|C|-1)!}\right\}
$$

where $(R, C) \in T^{-1}, M^{\prime}=\operatorname{order}\left(D_{\mathrm{S}}, W^{\mathrm{CS}}\right) \in \operatorname{enums}\left(W^{\mathrm{CS}}\right)$ and $D_{\mathrm{S}}$ is some order on the states in system $U$. Define the partition components counts space as spaceCountsPartition $\in \mathcal{A} \times \mathcal{T}_{\mathrm{f}} \rightarrow \ln \mathbf{N}_{>0}$

$$
\operatorname{spaceCountsPartition}(A, T):=\sum_{(R, C) \in T^{-1}} \ln \frac{\left((A * T)_{R}+|C|-1\right)!}{(A * T)_{R}!(|C|-1)!}
$$

The partition components counts space required for an ineffective component, $(A * T)_{R}=0$, is zero, regardless of the component's cardinality. That is, spaceCompositionWeak $(|C|, 0)=0$. The partition components counts space is also zero where the component is a singleton, $|C|=1$, regardless of the derived count, spaceCompositionWeak $\left(1,(A * T)_{R}\right)=0$. If all of the derived counts are in singleton components, $\forall(R, C) \in T^{-1}\left((A * T)_{R}>\right.$ $0 \Longrightarrow|C|=1)$, then overall partition components counts space is zero, spaceCountsPartition $(A, T)=0$.

The derived substrate histogram coder space is

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{A}, V, \mathrm{~T}}\right)(A)= & \operatorname{spaceSize}(y)+ \\
& \operatorname{spaceCountsDerived}(U)(A, T)+ \\
& \text { spaceCountsPartition }(A, T)
\end{aligned}
$$

Compare the derived substrate histogram coder, $C_{\mathrm{A}, V, \mathrm{~T}}$, to the substrate histogram coder, $C_{\mathrm{A}, V}$.

In the case of the full functional transform, $T=\left\{\{u\}^{\mathrm{CS}\{ \} \mathrm{T}}: u \in V\right\}^{\mathrm{T}}$, the partition components counts space is zero, spaceCountsPartition $(A, T)=0$, because the derived volume equals the underlying volume, $\left|W^{\mathrm{C}}\right|=\left|V^{\mathrm{C}}\right|$, and the transform is right total, $\forall(\cdot, C) \in T^{-1}(|C|=1)$. In this case the derived counts space equals the underlying counts space,

$$
\operatorname{spaceCountsDerived}(U)\left(A,\left\{\{u\}^{\operatorname{CS}\{ \} \mathrm{T}}: u \in V\right\}^{\mathrm{T}}\right)=\operatorname{spaceCounts}(U)(A)
$$

and so the derived substrate histogram coder space equals the substrate histogram coder space, $C_{\mathrm{A}, V, \mathrm{~T}}^{\mathrm{s}}(A)=C_{\mathrm{A}, V}^{\mathrm{s}}(A)$.

Conversely, in the case of the unary transform, $T=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$, the derived counts space is zero, spaceCountsDerived $(U)(A, T)=0$, because the derived volume is a singleton, $\left|W^{\mathrm{C}}\right|=1$. The partition components counts space equals the underlying counts space,

$$
\operatorname{spaceCountsPartition}\left(A,\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}\right)=\operatorname{spaceCounts}(U)(A)
$$

because there is only one component, $C=V^{\mathrm{C}}$. So in this case also, the derived substrate histogram coder space equals the substrate histogram coder space, $C_{\mathrm{A}, V, \mathrm{~T}}^{\mathrm{s}}(A)=C_{\mathrm{A}, V}^{\mathrm{s}}(A)$.

In the domain where the size is less than or equal to the possible derived volume, $z \leq w^{\prime}$, the derived counts space varies with the log possible derived volume,

$$
\operatorname{spaceCountsDerived}(U)(A, T) \sim \ln w^{\prime}
$$

In the domain where the size is greater than the possible derived volume, $z>w^{\prime}$, the derived counts space varies with the possible derived volume,

$$
\operatorname{spaceCountsDerived}(U)(A, T) \sim w^{\prime}
$$

The partition components counts space can be defined in terms of derived state or component,

$$
\begin{aligned}
\operatorname{spaceCountsPartition}(A, T) & =\sum_{(R, C) \in T^{-1}} \ln \frac{\left((A * T)_{R}+|C|-1\right)!}{(A * T)_{R}!(|C|-1)!} \\
& =\sum_{(R, \cdot) \in T^{-1}} \ln \frac{\left((A * T)_{R}+\left(V^{\mathrm{C}} * T\right)_{R}-1\right)!}{(A * T)_{R}!\left(\left(V^{\mathrm{C}} * T\right)_{R}-1\right)!} \\
& =\sum_{(\cdot, C) \in T^{-1}} \ln \frac{(\operatorname{size}(A * C)+|C|-1)!}{\operatorname{size}(A * C)!(|C|-1)!}
\end{aligned}
$$

This is just the logarithm of the cardinality of the set of integral iso-deriveds,

$$
\operatorname{spaceCountsPartition}(A, T)=\ln \left|D_{U, i, T, z}^{-1}(A * T)\right|
$$

The integral iso-deriveds log-cardinality is discussed in 'Integral iso-sets and entropy', above.

In the case where the volume is much greater than one, $v \gg 1$, the partition components counts space varies against the size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
& \text { spaceCountsPartition }(A, T) \sim \\
& \qquad \begin{array}{l}
-\left((z+v) \times \operatorname{entropy}\left(A * T+V^{\mathrm{C}} * T\right)\right. \\
\\
\left.\quad-z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)\right)
\end{array}
\end{aligned}
$$

In the domain where the size is less than or equal to the volume, $z \leq v$, the partition components counts space varies against the size scaled component size cardinality relative entropy,

$$
\operatorname{spaceCountsPartition}(A, T) \sim-z \times \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)
$$

Similarly, in the domain where the size is greater than the volume, $z>$ $v$, the partition components counts space varies against the volume scaled component cardinality size relative entropy,

$$
\text { spaceCountsPartition }(A, T) \sim-v \times \text { entropyRelative }\left(V^{\mathrm{C}} * T, A * T\right)
$$

In both domains the partition components counts space varies against the relative entropy. That is, partition components counts space is minimised when (a) the cross entropy is maximised and (b) the component entropy is minimised. The cross entropy is maximised when high size components
are low cardinality components and low size components are high cardinality components.

Consider the difference in space betweeen the derived substrate histogram coder, $C_{\mathrm{A}, V, \mathrm{~T}}$, and the substrate histogram coder, $C_{\mathrm{A}, V}$,

$$
\begin{aligned}
C_{\mathrm{A}, V, \mathrm{~T}}^{\mathrm{s}} & (A)-C_{\mathrm{A}, V}^{\mathrm{s}}(A) \\
= & \operatorname{spaceCountsDerived}(U)(A, T)+\operatorname{spaceCountsPartition}(A, T)- \\
& \operatorname{spaceCounts}(U)(A) \\
= & \ln \frac{\left(z+w^{\prime}-1\right)!}{z!\left(w^{\prime}-1\right)!}+\sum_{(R, C) \in T^{-1}} \ln \frac{\left((A * T)_{R}+|C|-1\right)!}{(A * T)_{R}!(|C|-1)!}- \\
& \ln \frac{(z+v-1)!}{z!(v-1)!}
\end{aligned}
$$

for each of three domains. First, in the domain where the size is less than or equal to the possible derived volume, $z \leq w^{\prime} \leq v$, the difference varies with the log possible derived volume and against the component size cardinality relative entropy,

$$
C_{\mathrm{A}, V, \mathrm{~T}}^{\mathrm{s}}(A)-C_{\mathrm{A}, V}^{\mathrm{s}}(A) \sim \ln w^{\prime}-\text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)
$$

In the domain where the size is between the possible derived volume and the volume, $w^{\prime} \leq z \leq v$, the difference varies with the possible derived volume and against the size scaled component size cardinality relative entropy,

$$
C_{\mathrm{A}, V, \mathrm{~T}}^{\mathrm{s}}(A)-C_{\mathrm{A}, V}^{\mathrm{s}}(A) \sim w^{\prime}-z \times \operatorname{entropyRelative}\left(A * T, V^{\mathrm{C}} * T\right)
$$

Last, in the domain where the size is greater than the volume, $w^{\prime} \leq v<z$, the difference varies with the possible derived volume and against the volume scaled component cardinality size relative entropy,

$$
C_{\mathrm{A}, V, \mathrm{~T}}^{\mathrm{s}}(A)-C_{\mathrm{A}, V}^{\mathrm{s}}(A) \sim w^{\prime}-v \times \operatorname{entropyRelative}\left(V^{\mathrm{C}} * T, A * T\right)
$$

So the space of the derived substrate histogram coder, $C_{\mathrm{A}, V, \mathrm{~T}}$, is minimised when (a) the possible derived volume is minimised, (b) the component entropy is minimised, and (c) high size components are low cardinality components and low size components are high cardinality components.

For example, consider the mono-variate tri-valent singleton cardinal substrate histogram $A=\{(\{(u, 1)\}, z)\}$, with binary partition transform $T=$
$\{\{\{(u, 1)\}\},\{\{(u, 2)\},\{(u, 3)\}\}\}^{\mathrm{T}}$ which rolls the ineffective states into a single derived state. The difference in space is exactly

$$
\begin{aligned}
C_{\mathrm{A}, V, \mathrm{~T}}^{\mathrm{s}}(A)-C_{\mathrm{A}, V}^{\mathrm{s}}(A)= & \ln \frac{(z+2-1)!}{z!(2-1)!}+\ln \frac{(z+1-1)!}{z!(1-1)!}+\ln \frac{(0+2-1)!}{0!(2-1)!}- \\
& \ln \frac{(z+3-1)!}{z!(3-1)!} \\
= & -\ln (z+2)+\ln 2 \\
< & 0
\end{aligned}
$$

where $z>0$. This example has high sizes in low cardinalities and vice-versa, unconstrained by domain.

If the derived histogram is independent, $A * T=(A * T)^{\mathrm{X}}$, the derived equals the abstract and the transform is surreal, $A=(A * T)^{\mathrm{X}} * T^{\odot A}$. In this case the derived histogram, $A * T$, may be encoded by means of a perimeter coder of histograms, $C_{\mathrm{A}, \mathrm{p}}$. The space of the encoding of the perimeter is

$$
\operatorname{spacePerimeter}(U)(A * T):=\sum_{u \in W} \ln \frac{\left(z+\left|U_{u}\right|-1\right)!}{z!\left(\left|U_{u}\right|-1\right)!}
$$

When compared to the histogram coder, $C_{\mathrm{A}}$, the counts space of the derived histogram decreases, $C_{\mathrm{A}, \mathrm{p}}^{\mathrm{s}}(A * T)-C_{\mathrm{A}}^{\mathrm{s}}(A * T)=\operatorname{spacePerimeter}(U)(A * T)-$ spaceCounts $(U)(A * T) \leq 0$. The derived histogram is independent and so tends to have higher entropy, entropy $(A * T)=\operatorname{entropy}\left((A * T)^{\mathrm{X}}\right)$. Derived perimeter encoding should be used in derived coders where the derived entropy is expected to be high.

In contrast, if the partition components are independent, $\forall C \in \operatorname{ran}\left(T^{-1}\right)(A *$ $\left.C=(A * C)^{\mathrm{X}}\right)$, the transform is ideal, $A=A * T * T^{\dagger A}$. In this case, each of the components may be encoded by means of a perimeter histogram coder having space

$$
\sum_{(R, C) \in T^{-1}} \sum_{u \in V} \ln \frac{\left(z_{R}+\left|(C \%\{u\})^{\mathrm{F}}\right|-1\right)!}{z_{R}!\left(\left|(C \%\{u\})^{\mathrm{F}}\right|-1\right)!}
$$

Note that the component may be larger than the effective cartesian subvolume

$$
(A * C)^{\mathrm{F}}=(A * C)^{\mathrm{xF}} \leq C
$$

If the component is not a cartesian sub-volume, $C \neq C^{\mathrm{X}}$, the perimeter histogram space of the component may be greater than the histogram space.

Now consider derived substrate history coders given one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ in variables $V=\operatorname{und}(T)$. The substrate coders' domain $\mathcal{H}_{U, V, X} \subset \mathcal{H}_{U}$ is the subset of the histories in system $U$ where the event identifiers are in the event identifiers set $X \subset \mathcal{X}$, and the variables are the given set $V \subseteq \operatorname{vars}(U)$,

$$
\mathcal{H}_{U, V, X}=\left\{H: H \in \mathcal{H}_{U}, \operatorname{ids}(H) \subseteq X, \operatorname{vars}(H)=V\right\}
$$

which has cardinality

$$
\left|\mathcal{H}_{U, V, X}\right|=\sum_{z \in\{1 \ldots y\}}\binom{y}{z} v^{z}
$$

where $v=\left|V^{\mathrm{C}}\right|$.
The derived substrate histogram coder, $C_{\mathrm{A}, V, \mathrm{~T}}$, divides the histogram encoding between (i) a derived histogram encoding, and (ii) a set of component subhistogram encodings. Similarly, the derived substrate history coders divide the history encoding into (i) a derived history encoding, and (ii) a set of component sub-history encodings. The canonical history coders are (i) the index history coder, $C_{\mathrm{H}}$, and (ii) the classification history coder, $C_{\mathrm{G}}$. The index history coder, $C_{\mathrm{H}}$, requires less space to encode high entropy histories than the classification history coder, $C_{\mathrm{G}}$, and vice-versa. Each of the derived history and component sub-histories may be encoded with each of the canonical history coders. So there are four possible derived substrate history coders: (a) the index derived substrate history coder $C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}$, which has index derived and index components, (b) the classification derived substrate history coder $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}$, which has classification derived and classification components, (c) the specialising derived substrate history coder $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, which has classification derived and index components, and (d) the generalising derived substrate history coder $C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{G}}$, which has index derived and classification components.

The index derived substrate history coder is constructed

$$
\begin{aligned}
& C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}= \\
& \quad \text { coderHistorySubstrateDerivedIndex }\left(U, X, T, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, V, X}\right)
\end{aligned}
$$

The index derived substrate history coder, $C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}$, is similar to an index history coder, $C_{\mathrm{H}}$. Let $H \in \mathcal{H}_{U, V, X}$ be a history of the derived substrate history coder domain. The derived history is $H * T$ where $H * T:=\operatorname{transform}(T, H):=$ $\left\{\left(x, P_{S}\right):(x, S) \in H\right\}$ and $P=\operatorname{split}\left(V, \operatorname{his}(T)^{\mathrm{FS}}\right)$. The histogram is $A=$
histogram $(H)$. The event identifiers are encoded in space of spaceIds $(y, z)$, where $y=|X|$ and $z=|H|=\operatorname{size}(A)$. The derived history, $H * T$, is encoded in fixed width space, spaceEventsDerived $(U)(H, T):=z \ln w^{\prime}$, where $W=\operatorname{der}(T), w=\left|W^{\mathrm{C}}\right|$ and $w^{\prime}=\left|\left(V^{\mathrm{C}} * T\right)^{\mathrm{F}}\right|=\left|T^{-1}\right| \leq w$. Then each subhistory, $H_{C}$, corresponding to a component of the partition, $H_{C}=$ filter $((H *$ $\left.T)_{R}^{-1}, H\right)=\operatorname{flip}\left(\operatorname{filter}\left(C^{\mathrm{S}}, \operatorname{flip}(H)\right)\right) \subseteq H$, where $(R, C) \in T^{-1}$, is encoded in a fixed width list. The space of the sub-history is spaceEvents $(U)\left(H_{C}\right)=$ $(A * T)_{R} \ln |C|$. The sub-history fixed width lists are concatenated together into a variable width list.

The history, $H \in \mathcal{H}_{U, V, X}$, can be encoded in an intermediate tuple $T_{H}=$ $\left(\left(z, Z_{I}\right), L^{\prime}, L\right) \in \mathbf{N}^{2} \times \mathcal{L}(\mathbf{N}) \times \mathcal{L}(\mathbf{N})$.

There is no need to encode the variables, $V$, because these are defined by the transform, $T$, in the derived substrate history coder parameters. So the first element, $\left(z, Z_{I}\right) \in \mathbf{N}^{2}$, of the tuple, $T_{H}$, encodes the event identifiers in the same way as the index history coder, $C_{\mathrm{H}}$, above. The space is $\operatorname{spaceIds}(y, z)$, where $y=|X|$ and $z=|H|=\operatorname{size}(A)$.

The second element $L^{\prime} \in \mathcal{L}(\mathbf{N})$ of the tuple $T_{H}$ encodes the states of derived events in a list of fixed width space. Given order $D_{\mathrm{S}}$, let $M^{\prime}$ be an enumeration of the possible derived states, $M^{\prime}=\operatorname{order}\left(D_{\mathrm{S}}, \operatorname{dom}\left(T^{-1}\right)\right)$. Let $w^{\prime}=\left|\left(V^{\mathrm{C}} * T\right)^{\mathrm{F}}\right|=\left|T^{-1}\right|$. Then $\left|M^{\prime}\right|=w^{\prime}$ and hence $L \in \mathcal{L}\left(\left\{1 \ldots w^{\prime}\right\}\right)$. Given order $D_{\mathrm{X}}$ and event identifiers $I=\operatorname{ids}(H)$, let $Q$ be an enumeration of the event identifiers, $Q=\operatorname{order}\left(D_{\mathrm{X}}, I\right)$. Then

$$
L^{\prime}=\left\{\left(Q_{x}, M_{R}^{\prime}\right):(x, R) \in H * T\right\}
$$

The space is spaceEventsDerived $(U)(H, T)$, where spaceEventsDerived $(U) \in$ $\mathcal{H}_{U} \times \mathcal{T}_{U, \mathrm{f}, 1} \rightarrow \ln \mathbf{N}_{>0}$ is defined

$$
\operatorname{spaceEventsDerived}(U)(H, T):=z \ln w^{\prime}
$$

The possible derived volume is less than or equal to the derived volume, $w^{\prime} \leq w$, so the derived events space is no greater than the events space of the derived history, spaceEventsDerived $(U)(H, T) \leq \operatorname{spaceEvents}(U)(H * T)$. The possible derived volume equals the derived volume if and only if the transform is non-overlapped, $\neg \operatorname{overlap}(T) \Longleftrightarrow w^{\prime}=w$, because it is only in this case that the transform is right total, $\operatorname{dom}\left(T^{-1}\right)=W^{\mathrm{CS}}$. In this case, the derived events space equals the events space of the derived history, $\neg \operatorname{overlap}(T) \Longleftrightarrow \operatorname{spaceEventsDerived}(U)(H, T)=\operatorname{spaceEvents}(U)(H * T)$. The possible derived volume is less than or equal to the underlying volume,
$w^{\prime} \leq v$, so the derived events space is no greater than the events space of the history, spaceEventsDerived $(U)(H, T) \leq \operatorname{spaceEvents}(U)(H)$.

The last element $L \in \mathcal{L}(\mathbf{N})$ of the tuple, $T_{H}$, encodes the underlying states of derived events. Given order $D_{\mathrm{S}}$ and variables $V=\operatorname{vars}(H)$, let $M$ be a map of enumerations indexed by derived state

$$
M=\left\{\left(R, \operatorname{order}\left(D_{\mathrm{S}}, C^{\mathrm{S}}\right)\right):(R, C) \in T^{-1}\right\}
$$

Then

$$
L=\left\{\left(Q_{x}, M_{R}(S)\right):(x, S) \in H, \quad R=P_{S}\right\}
$$

where $P=\operatorname{split}\left(V, \operatorname{his}(T)^{\mathrm{S}}\right)$. Define the space of the list, $L$, encoding the partitioned events of history $H$ as spaceEventsPartition $\in \mathcal{A} \times \mathcal{T}_{f} \rightarrow \ln \mathbf{N}_{>0}$

$$
\operatorname{spaceEventsPartition}(A, T):=\sum_{(R, C) \in T^{-1}}(A * T)_{R} \ln |C|
$$

The total space of the index derived substrate history coder, $C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}$, of a history $H \in \mathcal{H}_{U, V, X}$ is the sum of the ids space, derived events space, and partitioned events space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}\right)(H)= & \operatorname{spaceIds}(|X|,|H|)+ \\
& \operatorname{spaceEventsDerived}(U)(H, T)+ \\
& \operatorname{spaceEventsPartition}(A, T)
\end{aligned}
$$

The index derived substrate history coder, $C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}$, may be compared to the index substrate history coder, $C_{\mathrm{H}, V} \in \operatorname{coders}\left(\mathcal{H}_{U, V, X}\right)$. The difference in space for a history $H \in \mathcal{H}_{U, V, X}$ is

$$
\begin{aligned}
& C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H) \\
& = \\
& \quad \operatorname{spaceEventsDerived}(U)(H, T)+\operatorname{spaceEventsPartition}(A, T)- \\
& \quad \text { spaceEvents }(U)(H) \\
& =\quad z \ln w^{\prime}+\sum_{(R, C) \in T^{-1}}(A * T)_{R} \ln |C|- \\
& \quad z \ln v
\end{aligned}
$$

The partitioned events space varies against the component size cardinality cross entropy,

$$
\begin{aligned}
\operatorname{spaceEventsPartition}(A, T) & :=\sum_{(R, C) \in T^{-1}}(A * T)_{R} \ln |C| \\
& \sim-\text { entropyCross }\left(A * T, V^{\mathrm{C}} * T\right)
\end{aligned}
$$

The difference varies with the log possible derived volume and varies against the component size cardinality cross entropy,

$$
C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H) \sim \ln w^{\prime}-\text { entropyCross }\left(A * T, V^{\mathrm{C}} * T\right)
$$

So the space of the index derived substrate history coder, $C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}$, is minimised when (a) the possible derived volume is minimised, and (b) high size components are low cardinality components and low size components are high cardinality components.

For example, consider the mono-variate tri-valent singleton cardinal substrate histogram $A=\{(\{(u, 1)\}, z)\}$, where $\operatorname{vars}(A)=\{u\}$, with binary partition transform $T=\{\{\{(u, 1)\}\},\{\{(u, 2)\},\{(u, 3)\}\}\}^{\mathrm{T}}$ which rolls the ineffective states into a single derived state. The difference in space is

$$
\begin{aligned}
C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H) & =z \ln 2+z \ln 1+0 \ln 2-z \ln 3 \\
& =z \ln 2 / 3 \\
& <0
\end{aligned}
$$

where $z>0$. Equivalently, the expected logarithm of the component cardinality scaled by the derived volume fraction is

$$
\begin{aligned}
C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H) & =z \frac{2}{2} \ln \left(\frac{2}{3} \times 1\right)+z \frac{0}{2} \ln \left(\frac{2}{3} \times 2\right) \\
& =z \ln 2 / 3
\end{aligned}
$$

A transform $T$ that partitions the volume, $T^{\mathrm{P}} \in \mathrm{B}\left(V^{\mathrm{CS}}\right)$, into components having the same cardinality, $\forall C \in \operatorname{ran}\left(T^{-1}\right)\left(|C|=v / w^{\prime}\right)$, and the same size, $\forall C \in \operatorname{ran}\left(T^{-1}\right)\left(\operatorname{size}(A * C)=z / w^{\prime}\right)$, has no space difference

$$
\begin{aligned}
C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H) & =w^{\prime} \frac{z}{w^{\prime}} \ln \frac{w^{\prime}}{v} \frac{v}{w^{\prime}} \\
& =0
\end{aligned}
$$

An example is where the derived histogram is a scaled cartesian, $A * T=$ resize $\left(z, W^{\mathrm{C}}\right)$, and the component cardinalities equal the derived volume factor, $\forall C \in \operatorname{ran}\left(T^{-1}\right)(|C|=v / w)$.

The classification derived substrate history coder is constructed

$$
\begin{aligned}
& C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}= \\
& \text { coderHistorySubstrateDerivedClassification }\left(U, X, T, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \\
& \in \operatorname{coders}\left(\mathcal{H}_{U, V, X}\right)
\end{aligned}
$$

The classification derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}$, is similar to a classification history coder, $C_{\mathrm{G}}$. Let $H \in \mathcal{H}_{U, V, X}$ be a history of the derived substrate history coder domain. The derived history is $H * T$. The histogram is $A=$ histogram $(H)$. The event identifiers are encoded in space of spaceIds $(y, z)$. The derived histogram, $A * T$, is encoded in space of spaceCountsDerived $(U)(A, T)$. The derived history, $H * T$, is encoded as a classification, $(H * T)^{-1}=$ classification $(H * T)$. The classification has space of spaceClassification $(A * T)$. Then each sub-history, $H_{C}$, corresponding to a component of the partition, $H_{C} \subseteq H$, where $(R, C) \in T^{-1}$, is encoded as a component histogram having space spaceCounts $(U)(A * C)$ and a component classification having space spaceClassification $(A * C)$.

The history, $H \in \mathcal{H}_{U, V, X}$, can be encoded in an intermediate tuple $T_{H}=$ $\left(\left(z, Z_{I}\right), R_{A * T}^{\prime}, F_{Q^{\prime}}^{\prime}, L, M\right) \in \mathbf{N}^{2} \times \mathbf{N} \times \mathbf{N} \times \mathcal{L}(\mathbf{N}) \times \mathcal{L}(\mathbf{N})$.

The first element, $\left(z, Z_{I}\right) \in \mathbf{N}^{2}$, of the tuple, $T_{H}$, encodes the event identifiers in the same way as the index history coder, $C_{\mathrm{H}}$, above. The space is $\operatorname{spaceIds}(y, z)$, where $y=|X|$ and $z=|H|=\operatorname{size}(A)$.

The second element, $R_{A * T}^{\prime} \in \mathbf{N}$, of the tuple, $T_{H}$, is the encoding of the derived counts as in the derived histogram coder, $C_{\mathrm{A}, V, \mathrm{~T}}$, above,

$$
R_{A * T}^{\prime} \in\left\{1 \ldots \frac{\left(z+w^{\prime}-1\right)!}{z!\left(w^{\prime}-1\right)!}\right\}
$$

where $W=\operatorname{der}(T), w=\left|W^{\mathrm{C}}\right|$ and $w^{\prime}=\left|\left(V^{\mathrm{C}} * T\right)^{\mathrm{F}}\right|=\left|T^{-1}\right| \leq w$. The space is spaceCountsDerived $(U)(A, T)$.

The third element, $F_{Q^{\prime}}^{\prime} \in \mathbf{N}$, of the tuple, $T_{H}$, is the encoding of the classification of the derived history $(H * T)^{-1}$, as in the classification history coder, $C_{\mathrm{G}}$, above. Here $Q^{\prime}$ is the partition of event identifiers, $Q^{\prime}=\operatorname{ran}\left((H * T)^{-1}\right) \in$ $\mathrm{B}(\mathrm{ids}(H))$, and $F^{\prime}$ is an enumeration of the possible partitions of corresponding component cardinalities,
$F^{\prime} \in \operatorname{enums}\left(\left\{P: P \in \mathrm{~B}(\mathrm{ids}(H)), \exists X \in P: \leftrightarrow: Q^{\prime} \forall(Y, Z) \in X(|Y|=|Z|)\right\}\right)$
so that

$$
\begin{aligned}
F_{Q^{\prime}}^{\prime} & \in\left\{1 \cdots \frac{z!}{\prod_{R \in \operatorname{dom((H*T)^{-1})}}\left|(H * T)_{R}^{-1}\right|!}\right\} \\
& =\left\{1 \cdots \frac{z!}{\prod_{R \in(A * T)^{\mathrm{s}}}(A * T)_{R}!}\right\}
\end{aligned}
$$

The space is spaceClassification $(A * T)$.
The fourth element $L \in \mathcal{L}(\mathbf{N})$ of the tuple, $T_{H}$, encodes the counts of components. For all $(R, C) \in T^{-1}$ let

$$
R_{R}(A * C) \in\left\{1 \ldots \frac{\left((A * T)_{R}+|C|-1\right)!}{(A * T)_{R}!(|C|-1)!}\right\}
$$

Then

$$
L=\left\{\left(M_{R}^{\prime}, R_{R}(A * C)\right):(R, C) \in T^{-1}\right\}
$$

The space is spaceCountsPartition $(A, T)$.
The last element $M \in \mathcal{L}(\mathbf{N})$ of the tuple, $T_{H}$, encodes the classifications of components. For all $(R, C) \in T^{-1}$ let $Q_{R}=\operatorname{ran}\left(H_{C}^{-1}\right) \in \mathrm{B}\left(\operatorname{ids}\left(H_{C}\right)\right)$ and $F_{R} \in \operatorname{enums}\left(\left\{P: P \in \mathrm{~B}\left(\operatorname{ids}\left(H_{C}\right)\right), \exists X \in P: \leftrightarrow: Q_{R} \forall(Y, Z) \in X(|Y|=|Z|)\right\}\right)$
so that

$$
F_{R}\left(Q_{R}\right) \in\left\{1 \cdots \frac{(A * T)_{R}!}{\prod_{S \in C^{S}} A_{S}!}\right\}
$$

in

$$
M=\left\{\left(M_{R}^{\prime}, F_{R}\left(Q_{R}\right)\right):(R, C) \in T^{-1}\right\}
$$

Define the space of the list, $M$, encoding the partitioned classifications of the sub-histories of $H$ as spaceClassificationPartition $\in \mathcal{A} \times \mathcal{T}_{\mathrm{f}} \rightarrow \ln \mathbf{N}_{>0}$

$$
\begin{aligned}
& \text { spaceClassificationPartition }(A, T):=\sum_{(R, C) \in T^{-1}}\left(\ln (A * T)_{R}!-\sum_{S \in C^{\mathrm{S}}} \ln A_{S}!\right) \\
&=\sum_{(R, \cdot) \in T^{-1}}\left(\ln (A * T)_{R}!\right)-\sum_{S \in A^{\mathrm{S}}}\left(\ln A_{S}!\right)
\end{aligned}
$$

which is such that

$$
\begin{aligned}
\operatorname{spaceClassification}(A)= & \operatorname{spaceClassification}(A * T)+ \\
& \text { spaceClassificationPartition }(A, T)
\end{aligned}
$$

The total space of the classification derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}$, of a history $H \in \mathcal{H}_{U, V, X}$ is the sum of the ids space, derived counts space,
derived classification space, partitioned counts space, and partitioned classification space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}\right)(H)= & \operatorname{spaceIds}(|X|,|H|)+ \\
& \operatorname{spaceCountsDerived}(U)(A, T)+ \\
& \text { spaceClassification }(A * T)+ \\
& \text { spaceCountsPartition }(A, T)+ \\
& \operatorname{spaceClassificationPartition~}(A, T) \\
= & \operatorname{spaceIds}(|X|,|H|)+ \\
& \text { spaceCountsDerived }(U)(A, T)+ \\
& \operatorname{spaceCountsPartition}(A, T)+ \\
& \operatorname{spaceClassification~}(A)
\end{aligned}
$$

The classification derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}$, may be compared to the classification substrate history coder, $C_{\mathrm{G}, V} \in \operatorname{coders}\left(\mathcal{H}_{U, V, X}\right)$. The difference in space for a history $H \in \mathcal{H}_{U, V, X}$ equals the difference in space between the derived substrate histogram coder, $C_{\mathrm{A}, V, \mathrm{~T}}$, and the substrate histogram coder, $C_{\mathrm{A}, V}$, for the histogram $A=\operatorname{histogram}(H)$,

$$
\begin{aligned}
& C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}^{\mathrm{s}}(G)-C_{\mathrm{G}, V}^{\mathrm{s}}(G) \\
&= \operatorname{space} \operatorname{CountsDerived}(U)(A, T)+\operatorname{spaceCountsPartition}(A, T)- \\
&= C_{\mathrm{A}, V, \mathrm{~T}}^{\mathrm{s}}(A)-C_{\mathrm{A}, V}^{\mathrm{s}}(A) \\
&= \ln \frac{\left(z+w^{\prime}-1\right)!}{z!\left(w^{\prime}-1\right)!}+\sum_{(R, C) \in T^{-1}} \ln \frac{\left((A * T)_{R}+|C|-1\right)!}{(A * T)_{R}!(|C|-1)!}- \\
& \ln \frac{(z+v-1)!}{z!(v-1)!}
\end{aligned}
$$

So the space of the classification derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}$, is minimised when (a) the possible derived volume is minimised, (b) the component entropy is minimised, and (c) high size components are low cardinality components and low size components are high cardinality components.

The specialising derived substrate history coder is constructed
$C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}=$
$\quad$ coderHistorySubstrateDerivedSpecialising $\left(U, X, T, D_{\mathrm{S}}, D_{\mathrm{X}}\right)$

$$
\in \operatorname{coders}\left(\mathcal{H}_{U, V, X}\right)
$$

The specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, is intermediate between a classification history coder, $C_{\mathrm{G}}$, and an index history coder, $C_{\mathrm{H}}$. Let $H \in \mathcal{H}_{U, V, X}$ be a history of the derived substrate history coder domain. The derived history is $H * T$. The histogram is $A=\operatorname{histogram}(H)$. The event identifiers are encoded in space of spaceIds $(y, z)$. The derived histogram, $A * T$, is encoded in space of spaceCountsDerived $(U)(A, T)$. The derived history, $H * T$, is encoded as a classification, $(H * T)^{-1}=$ classification $(H * T)$, having space of spaceClassification $(A * T)$. Then each sub-history, $H_{C}$, corresponding to a component of the partition, $H_{C} \subseteq H$, where $(R, C) \in T^{-1}$, is encoded in a fixed width list. The space of the sub-history is spaceEvents $(U)\left(H_{C}\right)=$ $(A * T)_{R} \ln |C|$. The sub-history fixed width lists are concatenated together into a variable width list which has space spaceEventsPartition $(A, T)$.

The history, $H \in \mathcal{H}_{U, V, X}$, can be encoded in an intermediate tuple $T_{H}=$ $\left(\left(z, Z_{I}\right), R_{A * T}^{\prime}, F_{Q^{\prime}}^{\prime}, L\right) \in \mathbf{N}^{2} \times \mathbf{N} \times \mathbf{N} \times \mathcal{L}(\mathbf{N})$.

The first element, $\left(z, Z_{I}\right) \in \mathbf{N}^{2}$, of the tuple, $T_{H}$, encodes the event identifiers in the same way as the index history coder, $C_{\mathrm{H}}$, above. The space is $\operatorname{spaceIds}(y, z)$, where $y=|X|$ and $z=|H|=\operatorname{size}(A)$.

The second element, $R_{A * T}^{\prime} \in \mathbf{N}$, and the third element, $F_{Q^{\prime}}^{\prime} \in \mathbf{N}$, of the tuple, $T_{H}$, are encoded as in the classification derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}$, above. The space is

$$
\operatorname{spaceCountsDerived}(U)(A, T)+\operatorname{spaceClassification}(A * T)
$$

The last element $L \in \mathcal{L}(\mathbf{N})$ of the tuple, $T_{H}$, encodes the underlying states of derived events in the same way as for the index derived substrate history coder, $C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}$, above. The space is spaceEventsPartition $(A, T)$.

The total space of the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, of a history $H \in \mathcal{H}_{U, V, X}$ is the sum of the ids space, derived counts space, derived classification space, and partitioned events space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\right)(H)= & \operatorname{spaceIds}(|X|,|H|)+ \\
& \text { spaceCountsDerived }(U)(A, T)+ \\
& \text { spaceClassification }(A * T)+ \\
& \text { spaceEventsPartition }(A, T)
\end{aligned}
$$

The space of the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, is minimised for a history $H \in \mathcal{H}_{U, V, X}$ which has a single state $S_{1}, H \in$
$X \rightarrow\left\{S_{1}\right\}$, in the case of one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ which (i) is non-overlapping, $\neg \operatorname{overlap}(T)$, so the possible derived volume equals the derived volume, $w^{\prime}=w$ where $w^{\prime}=\left|T^{-1}\right|, W=\operatorname{der}(T)$, and $w=\left|W^{\mathrm{CS}}\right|$, (ii) has two derived states, $\left\{R_{1}, R_{2}\right\}=W^{\mathrm{CS}}$, of which only one is effective, $(A * T)_{R_{1}}=A_{S_{1}}=z$ and $(A * T)_{R_{2}}=0$ where $A=\operatorname{histogram}(H)$ and $z=|H|$, and (iii) is such that the component $C_{1}=\left\{S_{1}\right\}^{\mathrm{U}}$ corresponding to the effective derived state, $R_{1}$, is a singleton, $\left|C_{1}\right|=1$, and the remaining volume, $\left|C_{2}\right|=v-1$, corresponds to the ineffective derived state, $R_{2}$, where $\left\{\left(R_{1}, C_{1}\right),\left(R_{2}, C_{2}\right)\right\}=T^{-1}$, and $v=\left|V^{\mathrm{CS}}\right|$.

The partitioned events space varies against the component size cardinality cross entropy,

$$
\begin{aligned}
\operatorname{spaceEventsPartition}(A, T) & :=\sum_{(R, C) \in T^{-1}}(A * T)_{R} \ln |C| \\
& =z \ln v-z \times \operatorname{entropyCross}\left(A * T, V^{\mathrm{C}} * T\right)
\end{aligned}
$$

The partitioned events space is minimised when high size components are low cardinality components and low size components are high cardinality components. In the case of single state history, $H$, and single effective derived state transform, $T$, all of the size is in a singleton component, $\operatorname{size}\left(A * C_{1}\right)=$ $(A * T)_{R_{1}}=A_{S_{1}}=z$, and hence the partitioned events space is zero.

The derived counts space,

$$
\operatorname{spaceCountsDerived}(U)(A, T):=\ln \frac{\left(z+w^{\prime}-1\right)!}{z!\left(w^{\prime}-1\right)!}
$$

is minimised for fixed size, $z$, when the possible derived volume is smallest, $w^{\prime}=1$. Then the derived counts space is zero. In that case, however, the partitioned events space would be $z \ln v$. In the case of the transform, $T$, the possible derived volume is two, $w^{\prime}=2$, the derived counts space is $\ln (z+1)<z \ln v$, and so the overall space is smaller.

In the domain where the size is less than or equal to the possible derived volume, $z \leq w^{\prime}$, the derived counts space varies with the log possible derived volume,

$$
\operatorname{spaceCountsDerived}(U)(A, T) \sim \ln w^{\prime}
$$

In the domain where the size is greater than the possible derived volume, $z>w^{\prime}$, the derived counts space varies with the possible derived volume,

$$
\operatorname{spaceCountsDerived}(U)(A, T) \sim w^{\prime}
$$

The derived classification space varies with the derived entropy

$$
\begin{aligned}
\operatorname{spaceClassification}(A * T) & :=\ln z!-\sum_{(R, \cdot) \in T^{-1}} \ln (A * T)_{R}! \\
& \sim z \times \operatorname{entropy}(A * T)
\end{aligned}
$$

So the derived classification space is minimised when the derived entropy or component size entropy, entropy $(A * T)$, is minimised. This is the case here of single effective derived state, $\left|(A * T)^{\mathrm{F}}\right|=1$, which has zero entropy, entropy $(A * T)=0$ and zero derived classification space, spaceClassification $(A *$ $T)=0$.

The transform, $T$, described above only minimises the space where the history has one state, $A=\left\{\left(S_{1}, z\right)\right\}$. If there is more than one effective state, $\left|A^{\mathrm{F}}\right|>$ 1 , the derived classification space is non-zero, spaceClassification $(A * T)>0$, and so there is a balance between the increasing derived entropy, entropy $(A *$ $T)$, and the increasing derived counts space, spaceCountsDerived $(U)(A, T)$, caused by increasing possible derived volume, $w^{\prime}$. Also the partitioned events space, spaceEventsPartition $(A, T)$, may be non-zero if the components are not all singletons.

The space of the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, is

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\right)(H)= & \operatorname{spaceIds}(|X|,|H|)+ \\
& \operatorname{spaceCountsDerived}(U)(A, T)+ \\
& \text { spaceClassification }(A * T)+ \\
= & \operatorname{spaceEventsPartition}(A, T) \\
& \operatorname{spaceIds}(|X|,|H|)+ \\
& \ln \frac{\left(z+w^{\prime}-1\right)!}{z!\left(w^{\prime}-1\right)!}+ \\
& \ln z!-\sum_{R \in(A * T)^{\mathrm{s}}} \ln (A * T)_{R}!+ \\
& \sum_{(R, C) \in T^{-1}}(A * T)_{R} \ln |C|
\end{aligned}
$$

The space of the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, varies (i) with the possible derived volume, $w^{\prime}$, where the possible derived volume is less than the size, $w^{\prime}<z$, otherwise with the size scaled log possible derived volume, $z \ln w^{\prime}$, and (ii) against the size scaled component size cardinality
relative entropy,

$$
\begin{aligned}
C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H) \sim & \\
& \left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right) \\
- & z \times \operatorname{entropyRelative}\left(A * T, V^{\mathrm{C}} * T\right)
\end{aligned}
$$

So the space of the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, is minimised when (a) the possible derived volume is minimised, (b) the derived entropy or component size entropy is minimised, and (c) high size components are low cardinality components and low size components are high cardinality components.

Compare the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, to the index derived substrate history coder, $C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}$. The difference in space of the history, $H$, is

$$
C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)
$$

In the case of non-overlapping transform, $\neg \operatorname{overlap}(T)$, the difference in space of the history, $H$, equals the difference in space of the derived history, $H * T$, between the classification history coder, $C_{\mathrm{G}}$, and the index history coder, $C_{\mathrm{H}}$,

$$
C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)=C_{\mathrm{G}}^{\mathrm{s}}(H * T)-C_{\mathrm{H}}^{\mathrm{s}}(H * T)
$$

As shown in section 'Classification space', above, the classification coder, $C_{\mathrm{G}}$, may require less space than the index coder, $C_{\mathrm{H}}$, in the case of low entropy. So if the derived histogram, $A * T$, has low entropy, then the specialising coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, may have smaller space than the index derived coder, $C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}$. For example, a regular pluri-derived-variate transform $T_{1}$, of derived valency $d$ and derived dimension $n>1$, where the derived histogram is uniformly diagonalised, has lower entropy than a transform $T_{2}$ which has uniform cartesian congruent derived histogram,

$$
\begin{aligned}
\operatorname{entropy}\left(A * T_{1}\right)-\operatorname{entropy}\left(A * T_{2}\right) & =\left(-\ln \frac{1}{d}\right)-\left(-\ln \frac{1}{d^{n}}\right) \\
& =-(n-1) \ln d \\
& <0
\end{aligned}
$$

The difference in space between the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, and the index substrate history coder, $C_{\mathrm{H}, V}$, is

$$
C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)
$$

In the case of non-overlapping transform, $\neg$ overlap $(T)$, this simplifies to

$$
\begin{aligned}
C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)= & C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)+ \\
= & C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H) \\
= & C_{\mathrm{G}}^{\mathrm{s}}(H * T)-C_{\mathrm{H}}^{\mathrm{s}}(H * T)+ \\
& C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)
\end{aligned}
$$

The difference in space between the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, and the classification derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}$, equals the difference in summed space between the index history coder, $C_{\mathrm{H}}$, and the classification history coder, $C_{\mathrm{G}}$, for each of the components,

$$
C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}^{\mathrm{s}}(H)=\sum_{(\cdot, C) \in T^{-1}} C_{\mathrm{H}}^{\mathrm{s}}\left(H_{C}\right)-C_{\mathrm{G}}^{\mathrm{s}}\left(H_{C}\right)
$$

where the sliced-history is defined $H_{C}=\left\{(x, S):(x, S) \in H,\{S\}^{\mathrm{U}} * C \neq\right.$ $\emptyset\} \subseteq H$. The space of the components will be lower in the index history coder, $C_{\mathrm{H}}$, if their entropies are high. This is the case, for example, if the transform is ideal, $A=A * T * T^{\dagger A}$, and the histogram is completely effective, $A^{\mathrm{F}}=V^{\mathrm{C}}$. A special case is the frame full functional transform, $T=\left\{\{u\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: u \in V\right\}^{\mathrm{T}}$. In this case the difference in summed component space is zero.

The difference in space between the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, and the classification substrate history coder, $C_{\mathrm{G}, V}$, is

$$
\begin{aligned}
C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)= & C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}^{\mathrm{s}}(H)+ \\
= & \sum_{\substack{(\cdot, C) \in T^{-1}}}^{C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)}\left(C_{\mathrm{H}}^{\mathrm{s}}\left(H_{C}\right)-C_{\mathrm{G}}^{\mathrm{s}}\left(H_{C}\right)\right)+ \\
& C_{\mathrm{A}, V, \mathrm{~T}}^{\mathrm{s}}(A)-C_{\mathrm{A}, V}^{\mathrm{s}}(A)
\end{aligned}
$$

Given some substrate history $H \in \mathcal{H}_{U, V, X}$, the transform $T$ in the parameters of the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, may be chosen to minimise the encoding space with respect to the space in either of the canonical history coders, (i) the index history coder, $C_{\mathrm{H}}$, and (ii) the classification history coder, $C_{\mathrm{G}}$. That is, the transform is chosen to minimise

$$
\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)\right)+\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)\right)
$$

In the case of non-overlapping transform, $\neg \operatorname{overlap}(T)$, this simplifies to

$$
\begin{aligned}
&\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)\right)+\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)\right) \\
&=\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)\right)+\left(C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)\right)+ \\
&=\left(C_{\mathrm{G}, V, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}^{\mathrm{s}}(H)\right)+\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)\right) \\
&=\left(C_{\mathrm{G}}^{\mathrm{s}}(H * T)-C_{\mathrm{H}}^{\mathrm{s}}(H * T)\right)+\left(C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)\right)+ \\
& \sum_{(\cdot, C) \in T^{-1}}\left(C_{\mathrm{H}}^{\mathrm{s}}\left(H_{C}\right)-C_{\mathrm{G}}^{\mathrm{s}}\left(H_{C}\right)\right)+\left(C_{\mathrm{A}, V, \mathrm{~T}}^{\mathrm{s}}(A)-C_{\mathrm{A}, V}^{\mathrm{s}}(A)\right)
\end{aligned}
$$

The first term, $C_{\mathrm{G}}^{\mathrm{s}}(H * T)-C_{\mathrm{H}}^{\mathrm{s}}(H * T)$, varies with the derived entropy or component size entropy,

$$
C_{\mathrm{G}}^{\mathrm{s}}(H * T)-C_{\mathrm{H}}^{\mathrm{s}}(H * T) \sim \operatorname{entropy}(A * T)
$$

The third term, $\sum_{(\cdot, C) \in T^{-1}}\left(C_{\mathrm{H}}^{\mathrm{s}}\left(H_{C}\right)-C_{\mathrm{G}}^{\mathrm{s}}\left(H_{C}\right)\right)$, varies against the size expected component entropy

$$
\begin{aligned}
\sum_{(\cdot, C) \in T^{-1}}\left(C_{\mathrm{H}}^{\mathrm{s}}\left(H_{C}\right)\right. & \left.-C_{\mathrm{G}}^{\mathrm{s}}\left(H_{C}\right)\right) \\
& \sim-\sum_{(R, C) \in T^{-1}}(\hat{A} * T)_{R} \times \operatorname{entropy}(A * C) \\
& =- \text { entropyComponent }(A, T)
\end{aligned}
$$

The second term, $C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)$, varies with the log possible derived volume and varies against the component size cardinality cross entropy,

$$
C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H) \sim \ln w^{\prime}-\text { entropyCross }\left(A * T, V^{\mathrm{C}} * T\right)
$$

The fourth term, $C_{\mathrm{A}, V, \mathrm{~T}}^{\mathrm{s}}(A)-C_{\mathrm{A}, V}^{\mathrm{s}}(A)$, varies as follows. First, in the domain where the size is less than or equal to the possible derived volume, $z \leq w^{\prime} \leq v$, the difference varies with the log possible derived volume and against the component size cardinality relative entropy,

$$
C_{\mathrm{A}, V, \mathrm{~T}}^{\mathrm{s}}(A)-C_{\mathrm{A}, V}^{\mathrm{s}}(A) \sim \ln w^{\prime}-\text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)
$$

In the domain where the size is between the possible derived volume and the volume, $w^{\prime} \leq z \leq v$, the difference varies with the possible derived volume and against the size scaled component size cardinality relative entropy,

$$
C_{\mathrm{A}, V, \mathrm{~T}}^{\mathrm{s}}(A)-C_{\mathrm{A}, V}^{\mathrm{s}}(A) \sim w^{\prime}-z \times \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)
$$

Last, in the domain where the size is greater than the volume, $w^{\prime} \leq v<z$, the difference varies with the possible derived volume and against the volume scaled component cardinality size relative entropy,

$$
C_{\mathrm{A}, V, \mathrm{~T}}^{\mathrm{s}}(A)-C_{\mathrm{A}, V}^{\mathrm{s}}(A) \sim w^{\prime}-v \times \text { entropyRelative }\left(V^{\mathrm{C}} * T, A * T\right)
$$

The specialising-index space difference is

$$
\begin{aligned}
C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)= & \text { spaceCountsDerived }(U)(A, T)+ \\
& \text { spaceClassification }(A * T)+ \\
& \text { spaceEventsPartition }(A, T)- \\
& \text { spaceEvents }(U)(A, T) \\
= & \ln \frac{\left(z+w^{\prime}-1\right)!}{z!\left(w^{\prime}-1\right)!} \\
+ & \ln z!-\sum_{R \in(A * T)^{\mathrm{s}}} \ln (A * T)_{R}! \\
+ & \sum_{(R, C) \in T^{-1}}(A * T)_{R} \ln |C|- \\
- & z \ln v
\end{aligned}
$$

This varies just as the specialising space, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)$. That is, the specialisingindex space difference varies (i) with the possible derived volume, $w^{\prime}$, where the possible derived volume is less than the size, $w^{\prime}<z$, otherwise with the size scaled $\log$ possible derived volume, $z \ln w^{\prime}$, and (ii) against the size scaled component size cardinality relative entropy,

$$
\begin{aligned}
C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H) \sim & \\
& \left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right) \\
- & z \times \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)
\end{aligned}
$$

The specialising-classification space difference is

$$
\begin{aligned}
C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)= & \text { spaceCountsDerived }(U)(A, T)+ \\
& \text { spaceClassification }(A * T)+ \\
& \text { spaceEventsPartition }(A, T)- \\
& \text { spaceCounts }(U)(A)- \\
& \text { spaceClassification }(A) \\
= & \ln \frac{\left(z+w^{\prime}-1\right)!}{z!\left(w^{\prime}-1\right)!} \\
+ & \ln z!-\sum_{R \in(A * T)^{\mathrm{s}}} \ln (A * T)_{R}! \\
+ & \sum_{(R, C) \in T^{-1}}(A * T)_{R} \ln |C| \\
- & \ln \frac{(z+v-1)!}{z!(v-1)!} \\
- & \left(\ln z!-\sum_{S \in A^{\mathrm{s}}} \ln A_{S}!\right)
\end{aligned}
$$

So the specialising-classification space difference varies as

$$
\begin{aligned}
C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H) & \sim \ln \frac{\left(z+w^{\prime}-1\right)!}{z!\left(w^{\prime}-1\right)!} \\
& +\sum_{(R, C) \in T^{-1}}(A * T)_{R} \ln |C| \\
& -\sum_{(R, C) \in T^{-1}}\left(\ln (A * T)_{R}!-\sum_{S \in C^{\mathrm{S}}} \ln (A * C)_{S}!\right)
\end{aligned}
$$

The specialising-classification space difference varies (i) with the possible derived volume, $w^{\prime}$, where $w^{\prime}<z$, otherwise with the size scaled log possible derived volume, $z \ln w^{\prime}$, (ii) against the size scaled component size cardinality cross entropy and (iii) against the size scaled size expected component entropy,

$$
\begin{aligned}
C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)- & C_{\mathrm{G}, V}^{\mathrm{s}}(H) \sim \\
& \left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right) \\
- & z \times \operatorname{entropyCross}\left(A * T, V^{\mathrm{C}} * T\right) \\
- & z \times \operatorname{entropyComponent}(A, T)
\end{aligned}
$$

Overall, the specialising-canonical space difference, $2 C_{\mathrm{G}, V, T, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)-$ $C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, is the sum of the specialising-index space difference, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-$
$C_{\mathrm{H}, V}^{\mathrm{s}}(H)$, and the specialising-classification space difference, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-$ $C_{\mathrm{G}, V}^{\mathrm{s}}(H)$. The specialising-canonical space difference varies (i) with twice the possible derived volume, $2 w^{\prime}$, where $w^{\prime}<z$, otherwise with twice the size scaled $\log$ possible derived volume, $2 z \ln w^{\prime}$, (ii) with the size scaled derived entropy, (iii) against twice the size scaled component size cardinality cross entropy and (iv) against the size scaled size expected component entropy,

$$
\begin{aligned}
2 C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)- & C_{\mathrm{H}, V}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H) \sim \\
& 2\left(\left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right)\right) \\
& +z \times \operatorname{entropy}(A * T) \\
& -2 z \times \operatorname{entropyCross}\left(A * T, V^{\mathrm{C}} * T\right) \\
& -z \times \operatorname{entropyComponent}(A, T)
\end{aligned}
$$

So the specialising-canonical space difference, $2 C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)-$ $C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, is minimised when (a) the possible derived volume is minimised, (b) the derived entropy is minimised, (c) high size components are low cardinality components and low size components are high cardinality components, and (d) the expected component entropy is maximised.

The canonical term, $C_{\mathrm{H}, V}^{\mathrm{s}}(H)+C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, is independent of the transform, $T$, so properties of the specialising-canonical space difference, $2 C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)$ $C_{\mathrm{H}, V}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, are also properties of the specialising space, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)$. This is because the derived entropy, entropy $(A * T)$, and the size expected component entropy, entropyComponent $(A, T)$, are dual.

The fourth derived coder is the generalising derived substrate history coder, constructed

$$
\begin{aligned}
& C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{G}}= \\
& \quad \text { coderHistorySubstrateDerivedGeneralising }\left(U, X, T, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \\
& \quad \in \operatorname{coders}\left(\mathcal{H}_{U, V, X}\right)
\end{aligned}
$$

The generalising derived substrate history coder, $C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{G}}$, is intermediate between an index history coder, $C_{\mathrm{H}}$ and a classification history coder, $C_{\mathrm{G}}$. Let $H \in \mathcal{H}_{U, V, X}$ be a history of the derived substrate history coder domain. The derived history is $H * T$. The histogram is $A=\operatorname{histogram}(H)$. The event identifiers are encoded in space of spaceIds $(y, z)$. The derived history, $H * T$, is encoded in fixed width space, spaceEventsDerived $(U)(H, T):=z \ln w^{\prime}$, where $w^{\prime}=\left|T^{-1}\right|$. Then each sub-history, $H_{C}$, corresponding to a component of the partition, $H_{C} \subseteq H$, where $(R, C) \in T^{-1}$, is encoded as a component histogram having space spaceCounts $(U)(A * C)$ and a component classification
having space spaceClassification $(A * C)$.
The history, $H \in \mathcal{H}_{U, V, X}$, can be encoded in an intermediate tuple $T_{H}=$ $\left(\left(z, Z_{I}\right), L^{\prime}, L, M\right) \in \mathbf{N}^{2} \times \mathcal{L}(\mathbf{N}) \times \mathcal{L}(\mathbf{N}) \times \mathcal{L}(\mathbf{N})$.

The first element, $\left(z, Z_{I}\right) \in \mathbf{N}^{2}$, of the tuple, $T_{H}$, encodes the event identifiers in the same way as the index history coder, $C_{\mathrm{H}}$, above. The space is spaceIds $(y, z)$, where $y=|X|$ and $z=|H|=\operatorname{size}(A)$.

The second element, $L^{\prime} \in \mathcal{L}(\mathbf{N})$, of the tuple, $T_{H}$, is encoded as in the index derived substrate history coder, $C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}$, above. The space of this element is spaceEventsDerived $(U)(H, T):=z \ln w^{\prime}$.

The third element, $L \in \mathcal{L}(\mathbf{N})$, and the last element, $M \in \mathcal{L}(\mathbf{N})$, of the tuple, $T_{H}$, are encoded as in the classification derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}$, above. The space is

$$
\operatorname{spaceCountsPartition}(A, T)+\operatorname{spaceClassificationPartition}(A, T)
$$

The total space of the generalising derived substrate history coder, $C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{G}}$, of a history $H \in \mathcal{H}_{U, V, X}$ is the sum of the ids space, derived events space, partitioned counts space, and partitioned classification space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{G}}\right)(H)= & \text { spaceIds }(|X|,|H|)+ \\
& \text { spaceEventsDerived }(U)(H, T)+ \\
& \text { spaceCountsPartition }(A, T)+ \\
& \text { spaceClassificationPartition }(A, T)
\end{aligned}
$$

Similar to the specialising coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, above, given some substrate history $H \in \mathcal{H}_{U, V, X}$, the transform $T$ in the parameters of the generalising derived substrate history coder, $C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{G}}$, may be chosen to minimise the encoding space with respect to the space in either of the canonical history coders, (i) the classification history coder, $C_{\mathrm{G}}$, and (ii) the index history coder, $C_{\mathrm{H}}$. That is, the transform is chosen to minimise

$$
\left(C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{G}}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)\right)+\left(C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{G}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)\right)
$$

In the case of non-overlapping transform, $\neg \operatorname{overlap}(T)$, this simplifies to

$$
\begin{aligned}
&\left(C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{G}}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)\right)+\left(C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{G}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)\right) \\
&=\left(C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{G}}^{\mathrm{s}}(H)-C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}^{\mathrm{s}}(H)\right)+\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)\right)+ \\
& \quad\left(C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{G}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)\right)+\left(C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)\right) \\
&=\left(C_{\mathrm{H}}^{\mathrm{s}}(H * T)-C_{\mathrm{G}}^{\mathrm{s}}(H * T)\right)+\left(C_{\mathrm{A}, V, \mathrm{~T}}^{\mathrm{s}}(A)-C_{\mathrm{A}, V}^{\mathrm{s}}(A)\right)+ \\
& \sum_{(\cdot, C) \in T^{-1}}\left(C_{\mathrm{G}}^{\mathrm{s}}\left(H_{C}\right)-C_{\mathrm{H}}^{\mathrm{s}}\left(H_{C}\right)\right)+\left(C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)\right)
\end{aligned}
$$

The first term, $C_{\mathrm{H}}^{\mathrm{s}}(H * T)-C_{\mathrm{G}}^{\mathrm{s}}(H * T)$, equals the negative of the first term of the specialising-canonical space difference. The second term, $C_{\mathrm{A}, V, \mathrm{~T}}^{\mathrm{s}}(A)-$ $C_{\mathrm{A}, V}^{\mathrm{s}}(A)$, equals the fourth term of the specialising-canonical space difference. The third term, $\sum_{(\cdot, C) \in T^{-1}}\left(C_{\mathrm{G}}^{\mathrm{s}}\left(H_{C}\right)-C_{\mathrm{H}}^{\mathrm{s}}\left(H_{C}\right)\right)$, equals the negative of the third term of the specialising-canonical space difference. The fourth term, $C_{\mathrm{H}, V, T, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)$, equals the second term of the specialising-canonical space difference.

Thus, the generalising-canonical space difference, $2 C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{G}}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)-$ $C_{\mathrm{H}, V}^{\mathrm{s}}(H)$, is minimised when (a) the possible derived volume is minimised, (b) the derived entropy or component size entropy is maximised, (c) the expected component entropy is minimised, and (d) high size components are low cardinality components and low size components are high cardinality components.

The four derived substrate history coders, (a) the index derived substrate history coder, $C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}$, (b) the classification derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}$, (c) the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, and (d) the generalising derived substrate history coder, $C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{G}}$, all encode the history by means of a one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ in variables $V=\operatorname{und}(T)$. Now consider extending the model for the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, to (i) fuds, (ii) decompositions, and (iii) fud decompositions.

Given the one functional definition set $F \in \mathcal{F}_{U, 1}$, such that $\operatorname{und}(F)=V$, which is constrained such that only first layer transforms depend on the substrate, $\forall T \in F(\operatorname{und}(T) \nsubseteq V \Longrightarrow \operatorname{und}(T) \cap V=\emptyset)$, a substrate history $H \in$ $\mathcal{H}_{U, V, X}$ could be encoded simply by encoding each of the transforms separately in a specialising coder. The total space of $\operatorname{coder} C(F) \in \operatorname{coders}\left(\mathcal{H}_{U, V, X}\right)$
would be

$$
\begin{aligned}
C(F)^{\mathrm{s}}(H) & =\sum\left(C_{\mathrm{G}, V_{T}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H \% V_{T}\right)-s: T \in F, V_{T} \subseteq V\right) \\
& +\sum_{s}\left(C_{\mathrm{G}, V_{T}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}\right)-s: T \in F, V_{T} \nsubseteq V\right) \\
& +V)
\end{aligned}
$$

where $s=\operatorname{spaceIds}(|X|,|H|), V_{T}=\operatorname{und}(T)$, dep $=$ depends and the specialising derived substrate history coder is constructed
$C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)=\operatorname{coderHistorySubstrateDerivedSpecialising}\left(U, X, T, D_{\mathrm{S}}, D_{\mathrm{X}}\right)$
This method of encoding, however, means that any fud, $F$, requires at least as much space as its bottom layer, $C(F)^{\mathrm{s}}(H) \geq C\left(\left\{T: T \in F, V_{T} \subseteq V\right\}\right)^{\mathrm{s}}(H)$. This is because the bottom layer has complete coverage of the substrate and so the history can be decoded from the decodings of the reduced histories of the bottom layer coders, $\left\{H \% V_{T}: T \in F, V_{T} \subseteq V\right\}$.

Consider a two layer fud $F=\left\{T_{1}, T_{2}\right\}$, where $V_{1}=V$ and $V_{2}=W_{1}$. A specialising coder of the first layer, $C_{\mathrm{G}, V_{1}, \mathrm{~T}, \mathrm{H}}\left(T_{1}\right)$, encodes the derived history, $H * T_{1}$, in a classification coder which has a space of $C_{\mathrm{G}, W_{1}}^{\mathrm{s}}\left(H * T_{1}\right)$ (ignoring ids space). In some cases, however, the first layer derived history may be encoded in less space by means of a specialising coder of the second layer, if $C_{\mathrm{G}, V_{2}, \mathrm{~T}, \mathrm{H}}\left(T_{2}\right)^{\mathrm{s}}\left(H * T_{1}\right)<C_{\mathrm{G}, W_{1}}^{\mathrm{s}}\left(H * T_{1}\right)$. So consider a coder that encodes the layer derived history in the layer above if it exists. The space in this case is the sum of the ids space, second layer derived counts space, second layer derived classification space, second layer partitioned events space and first layer partitioned events space,

$$
\begin{aligned}
C_{\mathrm{G}, V_{1}, \mathrm{~T}, \mathrm{H}}\left(T_{1}\right)^{\mathrm{s}}(H)-C_{\mathrm{G}, W_{1}}^{\mathrm{s}}(H * & \left.T_{1}\right)+C_{\mathrm{G}, V_{2}, \mathrm{~T}, \mathrm{H}}\left(T_{2}\right)^{\mathrm{s}}\left(H * T_{1}\right)= \\
& \text { spaceIds }(|X|,|H|)+ \\
& \text { spaceCountsDerived }(U)\left(A, T_{2}\right)+ \\
& \text { spaceClassification }\left(A * T_{1} * T_{2}\right)+ \\
& \text { spaceEventsPartition }\left(A * T_{1}, T_{2}\right)+ \\
& \text { spaceEventsPartition }\left(A, T_{1}\right)
\end{aligned}
$$

The difference in space is

$$
\begin{aligned}
& C_{\mathrm{G}, V_{2}, \mathrm{~T}, \mathrm{H}}\left(T_{2}\right)^{\mathrm{s}}\left(H * T_{1}\right)-C_{\mathrm{G}, W_{1}}^{\mathrm{s}}\left(H * T_{1}\right)= \\
& \sum_{(\cdot, C) \in T_{2}^{-1}}\left(C_{\mathrm{H}}^{\mathrm{s}}\left(\left(H * T_{1}\right)_{C}\right)-C_{\mathrm{G}}^{\mathrm{s}}\left(\left(H * T_{1}\right)_{C}\right)\right)+ \\
& C_{\mathrm{A}, V_{2}, \mathrm{~T}}\left(T_{2}\right)^{\mathrm{s}}\left(A * T_{1}\right)-C_{\mathrm{A}, V_{2}}^{\mathrm{s}}\left(A * T_{1}\right)
\end{aligned}
$$

which is sometimes negative.
The specialising fud substrate history coder is constructed
$C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)=$
coderHistorySubstrateFudSpecialising $\left(U, X, F, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, V, X}\right)$
The total space of the specialising fud substrate history coder, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}$, of a history $H \in \mathcal{H}_{U, V, X}$ is the sum of the specialising derived substrate history coder space for each transform less the sum of the classification history coder space for each transform which has derived variables that are not in the fud derived variables,

$$
\begin{aligned}
& \operatorname{space}\left(C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)\right)(H)= \\
& \sum\left(C_{\mathrm{G}, V_{T}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H \% V_{T}\right)-s: T \in F, V_{T} \subseteq V\right) \\
&+ \sum\left(C_{\mathrm{G}, V_{T}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}\right)-s: T \in F, V_{T} \nsubseteq V\right) \\
&- \sum_{\mathrm{s}}\left(C_{\mathrm{G}, W_{T}}^{\mathrm{s}}\left(H * \operatorname{dep}\left(F, W_{T}\right)^{\mathrm{T}}\right)-s: T \in F, W_{T} \cap \operatorname{der}(F)=\emptyset\right)
\end{aligned}
$$

This definition can be generalised to allow for fuds having transforms higher than the first layer that have underlying variables in the substrate, $\operatorname{und}(T) \cap$ $V \notin\{\emptyset, \operatorname{und}(T)\}$,

$$
\begin{aligned}
& \operatorname{space}\left(C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)\right)(H)= \\
&\left.\sum_{\mathrm{G}, V_{T}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H_{F} \% V_{T}\right)-s: T \in F\right) \\
&- \sum_{\mathrm{G}, W_{T}}\left(C_{\mathrm{G}}^{\mathrm{s}}\left(H_{F} \% W_{T}\right)-s: T \in F, W_{T} \cap \operatorname{der}(F)=\emptyset\right) \\
&+ s
\end{aligned}
$$

where the history, $H_{F}$, is the expanded history to $\operatorname{vars}(F)$,

$$
H_{F}=\left\{(x, S):(x, R) \in H,(S, \cdot) \in \prod_{(X, \cdot) \in F} X, R \subseteq S\right\}
$$

Note that, given a fud that has underlying variables that are a proper subset of the substrate, $\operatorname{und}(F) \subset V$, the fud can be expanded to the remaining variables $L=V \backslash \operatorname{und}(F)$ by adding a unary partition transform, $\left\{L^{\mathrm{CS}}\right\}^{\mathrm{T}}$, which adds space of $C_{\mathrm{H}, L}^{\mathrm{s}}(H \% L)-s$.

Note also that, given a fud that has a transform $T \in F$ having derived variables that are partially a subset of the fud derived variables, $W_{T} \cap \operatorname{der}(F) \subset$
$W_{T}$, the fud can be altered to save the classification space of the remaining variables $L_{T}=W_{T} \cap \operatorname{der}(F)$ by adding a self partition transform, $L_{T}^{\mathrm{CS}\{ \} \mathrm{T}}$, which subtracts space of $C_{\mathrm{G}, W_{T}}^{\mathrm{s}}\left(H_{F} \% W_{T}\right)-C_{\mathrm{G}, L_{T}}^{\mathrm{s}}\left(H_{F} \%_{T}\right)$.

In the law-like case where the fud has a top transform, $\exists T \in F\left(W_{T}=\right.$ $\operatorname{der}(F))$, the space is

$$
\begin{aligned}
& \operatorname{space}\left(C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)\right)(H)= \\
& \text { spaceIds }(|X|,|H|)+ \\
& \operatorname{spaceCountsDerived}(U)\left(A, F^{\mathrm{T}}\right)+ \\
& \text { spaceClassification }\left(A * F^{\mathrm{T}}\right)+ \\
& \sum_{T \in F} \operatorname{spaceEventsPartition}\left(A * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}, T\right)
\end{aligned}
$$

Let $w^{\prime}$ be the possible derived volume of the transform of the fud, $w^{\prime}=$ $\left|\left(F^{\mathrm{T}}\right)^{-1}\right|$. The space of the specialising fud substrate history coder, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}$, varies (i) with the possible fud derived volume, $w^{\prime}$, where the possible fud derived volume is less than the size, $w^{\prime}<z$, otherwise with the size scaled $\log$ possible fud derived volume, $z \ln w^{\prime}$, (ii) with the size scaled transform fud derived entropy and (iii) against the sum of the size scaled component size cardinality cross entropies of the transforms of the fud,

$$
\begin{aligned}
C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H) & \sim \\
& \left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right) \\
+ & z \times \operatorname{entropy}\left(A * F^{\mathrm{T}}\right) \\
- & z \times \sum_{T \in F} \operatorname{entropyCross}\left(A * \operatorname{dep}\left(F, W_{T}\right)^{\mathrm{T}}, V_{T}^{\mathrm{C}} * T\right)
\end{aligned}
$$

So the space of the specialising fud substrate history coder, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}$, is minimised when (a) the possible fud derived volume is minimised, (b) the derived entropy or component size entropy of the fud transform is minimised, and (c) high size components are low cardinality components and low size components are high cardinality components for each of the fud transforms.

Consider a transform $T$ added to the top of a fud $F$. As mentioned above, in some cases the specialising space of the transform, $T$, is less than the classification space of its underlying. The change in the specialising fud coder space equals the difference between the specialising space and the underlying classification space of the transform,

$$
\begin{aligned}
& C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F \cup\{T\})^{\mathrm{s}}(H)-C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)= \\
& \quad C_{\mathrm{G}, V_{T}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H * F^{\mathrm{T}}\right)-C_{\mathrm{G}, V_{T}}^{\mathrm{s}}\left(H * F^{\mathrm{T}}\right)
\end{aligned}
$$

Recursing for all transforms, conjecture that the specialising-classification space difference for the fud varies with the sum of the specialising-classification space differences for the transforms,

$$
\begin{aligned}
& C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H) \sim \\
& \quad \sum_{T \in F}\left(C_{\mathrm{G}, V_{T}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}\right)-C_{\mathrm{G}, V_{T}}^{\mathrm{s}}\left(H * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}\right)\right)
\end{aligned}
$$

Conjecture that it is also the case that the specialising-index space difference for the fud varies with the sum of the specialising-index space differences for the transforms,

$$
\begin{aligned}
& C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H) \sim \\
& \quad \sum_{T \in F}\left(C_{\mathrm{G}, V_{T}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}\right)-C_{\mathrm{H}, V_{T}}^{\mathrm{s}}\left(H * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}\right)\right)
\end{aligned}
$$

Together the specialising-canonical space difference for the fud varies with the sum of the specialising-canonical space differences for the transforms,

$$
\begin{aligned}
& 2 C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H) \sim \\
& \sum_{T \in F}\left(2 C_{\mathrm{G}, V_{T}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}\right)\right. \\
& \left.\quad-C_{\mathrm{H}, V_{T}}^{\mathrm{s}}\left(H * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}\right)-C_{\mathrm{G}, V_{T}}^{\mathrm{s}}\left(H * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}\right)\right)
\end{aligned}
$$

The specialising-canonical space difference varies (i) with twice the total possible derived volume of the transforms, where the possible derived volumes are less than the size, otherwise with twice the total size scaled log possible derived volume, (ii) with the sum of the size scaled derived entropies, (iii) against twice the sum of the size scaled component size cardinality cross entropies and (iv) against the sum of the size scaled size expected component entropies,

$$
\begin{aligned}
& 2 C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H) \sim \\
& \quad \sum_{T \in F} 2\left(\left(w_{T}^{\prime}: w_{T}^{\prime}<z\right)+\left(z \ln w_{T}^{\prime}: w_{T}^{\prime} \geq z\right)\right) \\
& \quad+\sum_{T \in F} z \times \operatorname{entropy}\left(A * T_{F}\right) \\
& \quad-\sum_{T \in F} 2 z \times \operatorname{entropyCross}\left(A * T_{F}, V_{T}^{\mathrm{C}} * T\right) \\
& \quad-\sum_{T \in F} z \times \operatorname{entropyComponent}\left(A * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}, T\right)
\end{aligned}
$$

where $w_{T}^{\prime}=\left|T^{-1}\right|$ and $T_{F}=\operatorname{dep}\left(F, W_{T}\right)^{\mathrm{T}}$. So the specialising-canonical space difference, $2 C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, is minimised when (a) the total possible derived volume is minimised, (b) the total derived entropy is minimised, (c) high size components are low cardinality components and low size components are high cardinality components for each transform, and (d) the total expected component entropy is maximised. The canonical terms, $C_{\mathrm{H}, V}^{\mathrm{s}}(H)$ and $C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, are independent of the model, so these properties are also the properties of the specialising derived substrate history coder space, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)$.

If it is the case that the space of the fud, $F$, is less than that of any proper subfud,

$$
\forall G \subset F\left(\operatorname{und}(G)=\operatorname{und}(F) \Longrightarrow C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)<C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(G)^{\mathrm{s}}(H)\right)
$$

then the specialising-classification space differences are always negative,

$$
\begin{aligned}
& \forall T \in F\left(V_{T} \cap V=\emptyset \Longrightarrow\right. \\
& \left.\quad C_{\mathrm{G}, V_{T}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}\right)-C_{\mathrm{G}, V_{T}}^{\mathrm{s}}\left(H * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}\right)<0\right)
\end{aligned}
$$

Let it also be the case that (i) the fud, $F$, consists of a single transform in each layer, $\forall i \in\{1 \ldots l\}\left(F_{i}=\left\{T_{i}\right\}\right)$ where $l=\operatorname{layer}(F, \operatorname{der}(F))$ and $F_{i}=\left\{T: T \in F\right.$, layer $\left.\left(F, W_{T}\right)=i\right\}$, (ii) the fud, $F$, is a linear fud which is such that the underlying variables of each layer are the derived variables of the layer immediately below, $\forall i \in\{2 \ldots l\}\left(V_{i}=W_{i-1}\right)$ where $V_{i}=\operatorname{und}\left(F_{i}\right)$ and $W_{i}=\operatorname{der}\left(F_{i}\right)$, and (iii) the size is greater than the derived volume of each of the intermediate layers, $\forall i \in\{1 \ldots l\}\left(z>\left|W_{i}^{\mathrm{C}}\right|\right)$. Let the cumulative fud $F_{\{1 \ldots i\}}=\bigcup_{j \in\{1 \ldots i\}} F_{j}=\operatorname{dep}\left(F, W_{i}\right)$. Then conjecture that, in general, (i) the derived entropy decreases up the layers,

$$
\forall i \in\{2 \ldots l\}\left(\operatorname{entropy}\left(A * F_{\{1 \ldots i\}}^{\mathrm{T}}\right)<\operatorname{entropy}\left(A * F_{\{1 \ldots i-1\}}^{\mathrm{T}}\right)\right)
$$

(ii) the possible derived volume decreases up the layers,

$$
\forall i \in\{2 \ldots l\}\left(\left|W_{i}^{\mathrm{C}}\right|<\left|W_{i-1}^{\mathrm{C}}\right|\right)
$$

(iii) the expected component entropy increases up the layers,

$$
\begin{aligned}
& \forall i \in\{2 \ldots l\} \\
& \quad\left(\operatorname{entropyComponent}\left(A, F_{\{1 \ldots i\}}^{\mathrm{T}}\right)>\operatorname{entropyComponent}\left(A, F_{\{1 \ldots i-1\}}^{\mathrm{T}}\right)\right)
\end{aligned}
$$

and (iv) the component size cardinality cross entropy increases up the layers,

$$
\begin{aligned}
& \forall i \in\{2 \ldots l\} \\
& \quad\left(\text { entropy } \operatorname{Cross}\left(A * F_{\{1 \ldots i\}}^{\mathrm{T}}, V^{\mathrm{C}} * F_{\{1 \ldots i\}}^{\mathrm{T}}\right)>\right. \\
& \left.\quad \quad \text { entropy } \operatorname{Cross}\left(A * F_{\{1 \ldots i-1\}}^{\mathrm{T}}, V^{\mathrm{C}} * F_{\{1 \ldots i-1\}}^{\mathrm{T}}\right)\right)
\end{aligned}
$$

Terms (i) and (iv) together are equivalent to the component size cardinality relative entropy increasing up the layers,

$$
\begin{aligned}
& \forall i \in\{2 \ldots l\} \\
& \quad\left(\text { entropyRelative }\left(A * F_{\{1 \ldots i\}}^{\mathrm{T}}, V^{\mathrm{C}} * F_{\{1 \ldots i\}}^{\mathrm{T}}\right)>\right. \\
& \left.\quad \quad \text { entropyRelative }\left(A * F_{\{1 \ldots i-1\}}^{\mathrm{T}}, V^{\mathrm{C}} * F_{\{1 \ldots i-1\}}^{\mathrm{T}}\right)\right)
\end{aligned}
$$

Therefore to minimise specialising fud space, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)$, by varying the fud, in the case where the first layer has complete coverage of the substrate, $V_{1}=V$, it is sufficient to (a) maximise the component size cardinality cross entropy and the expected component entropy, and (b) minimise the derived entropy and possible derived volume, for each layer in sequence from the first layer upwards. Thus the optimisation of a fud without a layer limit may be made computable by building the fud layer by layer, minimising the specialising space at each step, until the addition of a layer fails to reduce the specialising space.

The space of the specialising fud substrate history coder, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)$, is related to the space of the specialising derived substrate history coder parameterised by the transform of the fud, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(F^{\mathrm{T}}\right)^{\mathrm{s}}(H)$. In some cases the spaces are equal. For example, consider the case of a single layer fud of unary partition transforms, $\forall T \in F\left(\left(V_{T} \subseteq V\right) \wedge\left(T=\left\{V_{T}^{\mathrm{CS}}\right\}^{\mathrm{T}}\right)\right)$, when applied to a scaled cartesian histogram, $A=V^{\mathrm{CS}} \times\{z / v\}$ where $z=|H|$ and $v=\left|V^{\mathrm{C}}\right|$. There is no derived history classification space,

$$
\begin{aligned}
C_{\mathrm{G}}^{\mathrm{s}}\left(H * F^{\mathrm{T}}\right)-s & =\sum_{T \in F}\left(C_{\mathrm{G}}^{\mathrm{s}}(H * T)-s\right) \\
& =0
\end{aligned}
$$

and the partitioned events spaces of the underlying components are equal,

$$
\begin{aligned}
\operatorname{spaceEventsPartition}\left(A, F^{\mathrm{T}}\right) & =\sum_{T \in F} \operatorname{spaceEventsPartition}(A, T) \\
\sum_{(R, C) \in\left(F^{\mathrm{T}}\right)^{-1}}\left(A * F^{\mathrm{T}}\right)_{R} \ln |C| & =\sum_{T \in F} \sum_{(R, C) \in T^{-1}}(A * T)_{R} \ln |C| \\
& =z \ln v
\end{aligned}
$$

so the specialising spaces are equal, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)=C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(F^{\mathrm{T}}\right)^{\mathrm{s}}(H)$.
In the law-like case where the fud has a top transform, $\exists T \in F\left(W_{T}=\right.$
$\operatorname{der}(F))$, the space difference is just the difference in partitioned events space,

$$
\begin{aligned}
C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)- & C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(F^{\mathrm{T}}\right)^{\mathrm{s}}(H)= \\
& \sum_{T \in F} \operatorname{spaceEventsPartition}\left(A * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}, T\right) \\
- & \operatorname{spaceEventsPartition}\left(A, F^{\mathrm{T}}\right)
\end{aligned}
$$

which is the size scaled difference in component size cardinality cross entropies,

$$
\begin{aligned}
C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H) & -C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(F^{\mathrm{T}}\right)^{\mathrm{s}}(H)= \\
& z \times \operatorname{entropy} \operatorname{Cross}\left(A * F^{\mathrm{T}}, V^{\mathrm{C}} * F^{\mathrm{T}}\right) \\
- & z \times \sum_{T \in F} \operatorname{entropyCross}\left(A * \operatorname{dep}\left(F, W_{T}\right)^{\mathrm{T}}, V_{T}^{\mathrm{C}} * T\right)
\end{aligned}
$$

Now consider extending the model for the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, to decompositions. Let a distinct decomposition of one functional transforms $D \in \mathcal{D}_{U}=\mathcal{D} \cap \operatorname{trees}\left(\mathcal{S}_{U} \times \mathcal{T}_{U, \mathrm{f}, 1}\right)$ be such that the fud of each path of the application tree has complete coverage of the substrate,

$$
\forall L \in \operatorname{paths}\left(D^{*}\right)\left(\bigcup_{(\cdot,(T, \cdot)) \in L} V_{T}=V\right)
$$

where $V_{T}=\operatorname{und}(T)$.
The specialising decomposition substrate history coder is constructed

$$
\begin{aligned}
& C_{\mathrm{G}, V, \mathrm{D}, \mathrm{H}}(D)= \\
& \quad \operatorname{coderHistorySubstrateDecompSpecialising}\left(U, X, D, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \\
& \in \operatorname{coders}\left(\mathcal{H}_{U, V, X}\right)
\end{aligned}
$$

The total space of the specialising decomposition substrate history coder, $C_{\mathrm{G}, V, \mathrm{D}, \mathrm{H}}$, of a history $H \in \mathcal{H}_{U, V, X}$ is the sum of the specialising derived substrate history coder space for each transform for each slice,

$$
\begin{aligned}
& \operatorname{space}\left(C_{\mathrm{G}, V, \mathrm{D}, \mathrm{H}}(D)\right)(H)= \\
& \quad \sum_{s}\left(C_{\mathrm{G}, V_{T}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H_{C} \% V_{T}\right)-s:(C, T) \in \operatorname{cont}(D)\right)
\end{aligned}
$$

where $\operatorname{cont}(D)=$ elements $($ contingents $(D))$, the sliced-history is defined $H_{C}=$ $\left\{(x, S):(x, S) \in H,\{S\}^{\mathrm{U}} * C \neq \emptyset\right\}$, and $s=\operatorname{spaceIds}(|X|,|H|)$.

Similarly, consider extending the model for the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, to fud decompositions. Let a distinct fud decomposition of one functional definition sets $D \in \mathcal{D}_{\mathrm{F}, U}=\mathcal{D}_{\mathrm{F}} \cap \operatorname{trees}\left(\mathcal{S}_{U} \times \mathcal{F}_{U, 1}\right)$ be such that the fud of each path of the application tree has complete coverage of the substrate,

$$
\forall L \in \operatorname{paths}\left(D^{*}\right)\left(\bigcup_{(,(F, \cdot)) \in L} V_{F}=V\right)
$$

where $V_{F}=\operatorname{und}(F)$.
The specialising fud decomposition substrate history coder is constructed

$$
\begin{aligned}
& C_{\mathrm{G}, V, \mathrm{D}, \mathrm{~F}, \mathrm{H}}(D)= \\
& \quad \text { coderHistorySubstrateFudDecompSpecialising }\left(U, X, D, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \\
& \\
& \in \operatorname{coders}\left(\mathcal{H}_{U, V, X}\right)
\end{aligned}
$$

The total space of the specialising fud decomposition substrate history coder, $C_{\mathrm{G}, V, \mathrm{D}, \mathrm{F}, \mathrm{H}}$, of a history $H \in \mathcal{H}_{U, V, X}$ is the sum of the specialising fud substrate history coder space for each fud for each slice,

$$
\begin{aligned}
& \operatorname{space}\left(C_{\mathrm{G}, V, \mathrm{D}, \mathrm{~F}, \mathrm{H}}(D)\right)(H)= \\
& \quad \sum_{s}\left(C_{\mathrm{G}, V_{F}, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}\left(H_{C} \% V_{F}\right)-s_{C}:(C, F) \in \operatorname{cont}(D)\right)
\end{aligned}
$$

where $s_{C}=\operatorname{spaceIds}\left(|X|,\left|H_{C}\right|\right)$.
Note that, whereas the optimisation of a fud without a layer limit may be made computable by building the fud layer by layer, this method of optimisation of a fud decomposition merely constructs a decomposition that has singleton fuds with singleton underlying variables, $\forall F \in$ fuds $(D)(|F|=$ $1 \wedge|\operatorname{und}(F)|=1)$. This is because a decomposition fud $F \in \operatorname{fuds}(D)$ is not constrained to cover the substrate, $V_{F} \subseteq V$. Only the union of the fuds of the application paths must have complete coverage. So the first layer of a fud, $F$, is not constrained at least to partition the substrate, $\left\{V_{T}: T \in F_{1}\right\} \in \mathrm{B}(V)$, and the minimisation of specialising space is uninteresting. A way to address this would be to limit the transforms of the fud to have a minimum underlying dimension, $\forall T \in F\left(\left|V_{T}\right| \geq \mathrm{kmin}\right)$ where $\mathrm{kmin} \in \mathbf{N}_{>1}$.

The derived history coders discussed above, such as the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}} \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$, are substrate history coders in that they are restricted to the histories in the underlying variables
of the transform, $\mathcal{H}_{U, V, X}$, where $V=\operatorname{und}(T)$. Now consider how the derived substrate history coders may be generalised to the unrestricted history coder domain where the histories may be in any of the system variables, $\mathcal{H}_{U, X}=\bigcup\left\{X \rightarrow V^{\mathrm{CS}}: V \subseteq \operatorname{vars}(U)\right\}$.

The expanded specialising derived history coder $C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}(T) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$ is derived from the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$. It expands the transform to the history variables, $V_{H}$, where the set of history variables is a superset of the underlying variables, $V=\operatorname{und}(T)$, and otherwise defaults to an index coder,

$$
\begin{aligned}
C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H)= & \left(C_{\mathrm{G}, V_{H}, \mathrm{~T}, \mathrm{H}}\left(T^{\mathrm{P} V_{H} \mathrm{~T}}\right)^{\mathrm{s}}(H)+s_{\left|V_{H}\right|}: V_{H} \supseteq V\right)+ \\
& \left(C_{\mathrm{H}}^{\mathrm{s}}(H): V_{H} \nsupseteq V\right)
\end{aligned}
$$

where $s_{n}=\operatorname{spaceVariables}(U)(n)$. Note that the expansion is equivalent to adding index space for the additional variables, $C_{\mathrm{G}, V_{H}, \mathrm{~T}, \mathrm{H}}\left(T^{\mathrm{P} V_{H} \mathrm{~T}}\right)^{\mathrm{s}}(H)=$ $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H \% V)+C_{\mathrm{H}, V}^{\mathrm{s}}\left(H \%\left(V_{H} \backslash V\right)\right)$. The expansion always adds at least canonical space, minimum $\left(C_{\mathrm{H}}^{\mathrm{s}}\left(H \%\left(V_{H} \backslash V\right)\right), C_{\mathrm{G}}^{\mathrm{s}}\left(H \%\left(V_{H} \backslash V\right)\right)\right)$.

Similarly the expanded specialising fud history coder $C_{\mathrm{G}, \mathrm{F}, \mathrm{H}}(F) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$ is derived from the specialising fud substrate history coder, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}$,

$$
\begin{aligned}
C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)= & \left(C_{\mathrm{G}, V_{H}, \mathrm{~F}, \mathrm{H}}\left(F^{V_{H}}\right)^{\mathrm{s}}(H)+s_{\left|V_{H}\right|}: V_{H} \supseteq V\right)+ \\
& \left(C_{\mathrm{H}}^{\mathrm{s}}(H): V_{H} \nsupseteq V\right)
\end{aligned}
$$

where $F^{V}$ is the expansion that adds a unary transform in the remaining underlying variables, $F \cup\left\{\left\{(V \backslash \operatorname{und}(F))^{\mathrm{CS}}\right\}^{\mathrm{T}}\right\}$. Again, the expansion is equivalent to adding index space for the additional variables.

Lastly the expanded specialising fud decomposition history coder $C_{\mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}(D) \in$ $\operatorname{coders}\left(\mathcal{H}_{U, X}\right)$ is derived from the specialising fud decomposition substrate history coder, $C_{\mathrm{G}, V, \mathrm{D}, \mathrm{F}, \mathrm{H}}$,

$$
\begin{aligned}
C_{\mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}(D)^{\mathrm{s}}(H)= & \left(C_{\mathrm{G}, V_{H}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D^{V_{H}}\right)^{\mathrm{s}}(H)+s_{\left|V_{H}\right|}: V_{H} \supseteq V\right)+ \\
& \left(C_{\mathrm{H}}^{\mathrm{s}}(H): V_{H} \nsupseteq V\right)
\end{aligned}
$$

where $D^{V}$ is the expansion that adds a unary transform in the remaining underlying variables to the leaf fuds in the decomposition tree such that the fud of each path of the application tree has complete coverage of the substrate,

$$
\forall L \in \operatorname{paths}\left(D^{*}\right)\left(\bigcup_{(\cdot,(F, \cdot)) \in L} V_{F}=V\right)
$$

where $V_{F}=\operatorname{und}(F)$.

Given a system $U$ and event identifiers $X$, a history coder domain probability function $P \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$ is defined as entropic with respect to history coder $C \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$ if the coder is an entropy coder. See appendix 'Coders and entropy' for the definition of the entropy coder. The coder is an entropy history coder if and only if the space of a history equals the negative logarithm of the non-zero probability, $\forall H \in \mathcal{H}_{U, X}\left(P_{H}>0 \Longrightarrow\right.$ $C^{\mathrm{s}}(H)=-\ln P_{H}$ ). Then the expected space of the coder equals the entropy of the history probability function.

$$
\begin{aligned}
\operatorname{expected}(P)\left(C^{\mathrm{s}}\right) & =\sum_{H \in \mathcal{H}_{U, X}} P_{H} \times C^{\mathrm{s}}(H) \\
& =-\sum\left(P_{H} \ln P_{H}: H \in \mathcal{H}_{U, X}, P_{H}>0\right) \\
& =\operatorname{entropy}(P)
\end{aligned}
$$

An entropy coder has the smallest expected space of all coders given the probability function.

Note that entropy history coders should be distinguished from the theoretical variable-width history coder $C_{\mathrm{E}}$ that encodes its states in an entropy coder, described in appendix 'Entropy encoding of states'. The variable-width history coder, $C_{\mathrm{E}}$, can only encode the subset of histories for which there exists a states coder that is an entropy coder with respect to the normalised histogram. That is, $\exists C \in \operatorname{coders}\left(A^{\mathrm{FS}}\right) \forall R \in A^{\mathrm{FS}}\left(C^{\mathrm{s}}(R)=-\ln \hat{A}_{R}\right)$ where $H \in \mathcal{H}_{U, X}$ and $A=\operatorname{histogram}(H)$. Even for this subset of the histories for which an entropy states coder, $C$, can be constructed, the space of the variable-width history coder is always greater than or equal to the space of the classification coder, $C_{\mathrm{E}}^{\mathrm{s}}(H) \geq C_{\mathrm{G}}^{\mathrm{s}}(H)$.

Similar to the definition of entropic history probability functions, a history coder domain probability function $P \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$ is defined as structured with respect to derived history coder $C \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$, if the expected space of the derived history coder is less than the expected lesser space of the canonical history coders, (i) index history coder, $C_{\mathrm{H}}$, and (ii) classification history coder, $C_{\mathrm{G}}$,

$$
\operatorname{expected}(P)\left(C^{\mathrm{s}}\right)<\operatorname{expected}(P)\left(\operatorname{minimum}\left(C_{\mathrm{H}}^{\mathrm{s}}, C_{\mathrm{G}}^{\mathrm{s}}\right)\right)
$$

where minimum $\left(C_{\mathrm{H}}^{\mathrm{s}}, C_{\mathrm{G}}^{\mathrm{s}}\right) \in \mathcal{H}_{U, X} \rightarrow \ln \mathbf{N}_{>0}$.
The degree of structure is defined structure $(U, X) \in\left(\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}\right) \times$
$\operatorname{coders}\left(\mathcal{H}_{U, X}\right) \rightarrow \mathbf{Q} \ln \mathbf{Q}_{>0} / \ln \mathbf{Q}_{>0}$ as

$$
\operatorname{structure}(U, X)(P, C):=\frac{\operatorname{canonical}(U, X)(P)-\operatorname{expected}(P)\left(C^{\mathrm{s}}\right)}{\operatorname{canonical}(U, X)(P)-\operatorname{entropy}(P)}
$$

where canonical $(U, X) \in\left(\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}\right) \rightarrow \mathbf{Q}_{\geq 0} \ln \mathbf{N}_{>0}$ is defined

$$
\operatorname{canonical}(U, X)(P):=\operatorname{expected}(P)\left(\operatorname{minimum}\left(C_{\mathrm{H}}^{\mathrm{s}}, C_{\mathrm{G}}^{\mathrm{s}}\right)\right)
$$

The degree of structure is undefined if the canonical coders are already entropic, canonical $(U, X)(P)=\operatorname{entropy}(P)$. The degree of structure is defined for all history coders, not just derived history coders.

Define the compression of coder $C$ with respect to probability function $P$ as a synonym for the degree of structure of probability function $P$ with respect to the coder $C$.

The degree of structure is always less than or equal to one,

$$
\forall P \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}(\text { structure }(U, X)(P, C) \leq 1)
$$

If the degree of structure equals one, structure $(U, X)(P, C)=1$, the coder, $C$, is an entropy coder of the probability function, $P$, $\operatorname{expected}(P)\left(C^{\mathbf{s}}\right)=$ entropy $(P)$.

If the degree of structure less than or equal to zero, structure $(U, X)(P, C) \leq 0$, the probability function, $P$, is structureless with respect to the coder, $C$, or, equivalently, the coder, $C$, is non-compressing with respect to the probability function, $P$. For example, the theoretical variable-width history coder, $C_{\mathrm{E}}$, is non-compressing with respect to all probability functions for which it can be defined, because the space is always greater than or equal to the space of the classification coder, $C_{\mathrm{E}}^{\mathrm{s}}(H) \geq C_{\mathrm{G}}^{\mathrm{s}}(H)$.

Structured history probability functions are less strongly constrained than entropic history probability functions because entropy coders have least expected space, $0<\operatorname{structure}(U, X)(P, C) \leq 1$.

A history coder $C_{\min (\mathrm{H}, \mathrm{G})}$ of the lesser space of the canonical history coders can be implemented with a flag to indicate which of the canonical coders was chosen. The space is $C_{\min (\mathrm{H}, \mathrm{G})}^{\mathrm{s}}(H)=\operatorname{minimum}\left(C_{\mathrm{H}}^{\mathrm{s}}(H), C_{\mathrm{G}}^{\mathrm{s}}(H)\right)+\ln 2$. The lesser canonical history coder, $C_{\min (\mathrm{H}, \mathrm{G})}$, is necessarily structureless,

$$
\forall P \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}\left(\text { structure }(U, X)\left(P, C_{\min (\mathrm{H}, \mathrm{G})}\right)<0\right)
$$

because of the additional space of the flag.
Conjecture that there is no coder such that the uniform history probability function, $\hat{\mathcal{H}}_{U, X}=\mathcal{H}_{U, X} \times\left\{1 /\left|\mathcal{H}_{U, X}\right|\right\} \in \mathcal{P}$, has structure,

$$
\forall C \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)\left(\text { structure }(U, X)\left(\hat{\mathcal{H}}_{U, X}, C\right)<0\right)
$$

where canonical $(U, X)\left(\hat{\mathcal{H}}_{U, X}\right) \neq \operatorname{entropy}\left(\hat{\mathcal{H}}_{U, X}\right)$.

The degree of structure has two arguments, (i) the probability function $P \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$, and (ii) the coder $C \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$. The function can be viewed as (i) a measure of the structure of the histories of the probability function, $P$, with respect to a fixed coder, $C$, or (ii) a measure of the compression, or canonical-entropic relative space, of the coder, $C$, given a probability function, $P$.

### 3.19 Computation time and representation space

The set of computers, computers, is a type class that formalises computation time and representation space. Define the application of a computer, apply $\in$ computers $\rightarrow(\mathcal{X} \rightarrow \mathcal{Y})$. Define the shorthand $I^{*}:=\operatorname{apply}(I)$. Define the domain of the application, domain $\in$ computers $\rightarrow \mathrm{P}(\mathcal{X})$, and the range of the application, range $\in$ computers $\rightarrow \mathrm{P}(\mathcal{Y})$, such that $\forall I \in$ computers ( $I^{*} \in$ domain $(I) \rightarrow$ range $\left.(I)\right)$ and $\forall I \in$ computers $\left(\operatorname{dom}\left(I^{*}\right)=\right.$ domain $(I)$ ). The computation or application time is defined as time $\in$ computers $\rightarrow\left(\mathcal{X} \rightarrow \mathbf{N}_{>0}\right)$. Define the shorthand $I^{t}:=\operatorname{time}(I)$. The representation space is defined as space $\in$ computers $\rightarrow\left(\mathcal{X} \rightarrow \ln \mathbf{N}_{>0}\right)$. Define the shorthand $I^{\mathrm{s}}:=\operatorname{space}(I)$. See appendix 'Computers' for a more formal definition.

### 3.19.1 Computation of histograms

The computation of various operations on histograms depends on the concrete representation or encoding. Consider an array histogram representation. Let $A \in \mathcal{A}_{U}$ and $V=\operatorname{vars}(A)$. Let complete histogram $A^{\prime}=$ $A+A^{\mathrm{CZ}}$. The array is implemented in a list $L_{A} \in \mathcal{L}\left(\mathbf{Q}_{\geq 0}\right)$ such that $\exists X \in L_{A} \leftrightarrow A^{\prime} \forall((i, d),(S, c)) \in X(d=c)$ and $|X|=\left|L_{A}\right|=\left|A^{\prime}\right|=v$ where $v=\operatorname{volume}(U)(V)$. The operation to set a count in the histogram is implemented with the list setter on the positive rationals, $I_{\mathrm{L}, \mathrm{s}}=\operatorname{listSetter}\left(\mathbf{Q}_{\geq 0}\right)$. The operation to access a count is implemented with the corresponding list getter, $I_{\mathrm{L}, \mathrm{g}}=$ listGetter $\left(\mathbf{Q}_{\geq 0}\right)$. The space complexity of the list accessors is the length of the list, which is the volume, $v$.

In order to index the array, define an encoding of the state, index $(U, V) \in$ $\operatorname{enum}\left(V^{\mathrm{CS}}\right) \subset \mathcal{S}_{U} \leftrightarrow \mathbf{N}_{>0}$, which is such that $\forall S \in V^{\mathrm{CS}}$ (index $(U, V)(S) \in$ $\{1 \ldots v\})$. Then $L_{A}$ is such that $\forall S \in V^{\mathrm{CS}}\left(L_{A}(\operatorname{index}(U, V)(S))=A_{S}^{\prime}\right)$. The lookup, $I_{\mathrm{L}, \mathrm{g}}^{*}\left(L_{A}, \operatorname{index}(U, V)(S)\right) \in \mathrm{Q}_{\geq 0}$, has overall time complexity equal to that of the index computation, because the time complexity of the list getter is constant.

If the values of $V$ are constrained such that $\forall w \in V\left(U_{w}=\left\{0 \ldots\left|U_{w}\right|-1\right\}\right)$, then a state $S \in V^{\mathrm{CS}}$ maps to a tuple of values in $\mathbf{N}^{n}$, where dimension $n=|V|$, which is bounded by a tuple of valencies in $\mathbf{N}_{>0}^{n}$. The index function can be defined to map from the tuple of values to the volume, $\{1 \ldots v\}$, by application of the tuple of valencies. Let $M \in \mathrm{~L}(V)$ be the bijective map between positions in the tuples and the variables. $M$ is the inverse of some enumeration of the variables, flip $(M) \in$ enums $(V)$. The tuple of values is $\left\{\left(i, S_{w}\right): i \in\{1 \ldots n\}, w=M_{i}\right\} \in \mathcal{L}(\mathbf{N})$ and the tuple of valencies is $\left\{\left(i,\left|U_{w}\right|\right): i \in\{1 \ldots n\}, w=M_{i}\right\} \in \mathcal{L}\left(\mathbf{N}_{>\mathbf{0}}\right)$. The index function can be defined $\operatorname{index}(U, V)(S)=\operatorname{index}(U, S, M)+1$, and then recursively as

$$
\begin{aligned}
\operatorname{index}(U, S, M) & :=\operatorname{index}(U, S, \operatorname{tail}(M)) *\left|U\left(M_{1}\right)\right|+S\left(M_{1}\right) \\
\operatorname{index}(U, S, \emptyset) & :=0
\end{aligned}
$$

The index method is similar to the encode method of coders.
A concrete implementation of the index function depends on the representation of the state $S$. Consider the case where the state is represented as a list or tuple of variable-value pairs, $K \in \mathcal{L}(V \times \mathbf{N})$ such that $\operatorname{set}(K)=S$ and $|K|=|S|$. That is, $\operatorname{flip}(K) \in \operatorname{enums}(S)$. If $K$ is ordered in the same order as $M, \forall i \in\{1 \ldots n\} \diamond(w, \cdot)=K_{i}\left(M_{i}=w\right)$, then the lists can be zipped together and the time complexity of the index computation is $n$. Let $N$ be the tuple of valencies, $N=\left\{\left(i,\left|U_{w}\right|\right): i \in\{1 \ldots n\}, w=M_{i}\right\}$. Consider the ordered list state representation. Let $I_{\mathrm{S}, \mathrm{o}}=\operatorname{stateOrdered} \operatorname{Indexer}(U, V, M, N) \in$ computers, domain $\left(I_{\mathrm{S}, \mathrm{o}}\right)=\left\{\operatorname{flip}(Q): S \in V^{\mathrm{CS}}, Q \in \operatorname{enums}(S), \forall((w, \cdot), i) \in\right.$ $\left.Q\left(M_{i}=w\right)\right\}$, range $\left(I_{\mathrm{S}, \mathrm{o}}\right)=\left\{1 \ldots\left|V^{\mathrm{CS}}\right|\right\}$ and $\operatorname{apply}\left(I_{\mathrm{S}, \mathrm{o}}\right)(K)=\operatorname{in}(N, L, n)+1$ where $L=\{(i, u):(i,(\cdot, u)) \in K\}, \operatorname{in}(N, L, i):=\operatorname{in}(N, L, i-1) * N_{i}+L_{i}$ and $\operatorname{in}(N, L, 0):=0$. Then $I_{\mathrm{S}, \mathrm{o}}^{\mathrm{t}}(K)>n I_{\times}^{\mathrm{t}}(1,1)+n I_{+}^{\mathrm{t}}(0,0)$ and

$$
\exists m \in \mathbf{N}_{>0}\left(I_{\mathrm{S}, \mathrm{o}}^{\mathrm{t}} \in \mathrm{O}\left(\left\{(K, n): K \in \operatorname{domain}\left(I_{\mathrm{S}, \mathrm{o}}\right), n=|K|\right\}, m\right)\right)
$$

Another implementation of the index function is of the unordered list state representation where $K \in \mathcal{L}(V \times \mathbf{N})$ is not ordered with $M$. Let $I_{\mathrm{S}, \mathrm{u}}=$ stateUnorderedIndexer $(U, V, M, N) \in$ computers. The domain is a superset of the ordered case, domain $\left(I_{\mathrm{S}, \mathrm{u}}\right)=\left\{\operatorname{flip}(Q): S \in V^{\mathrm{CS}}, Q \in \operatorname{enums}(S)\right\}$. In
the unordered case the time complexity of the index computation, $I_{\mathrm{S}, \mathrm{u}}^{\mathrm{t}}$, is $n^{2}$ because the indexer must find each variable within the unordered state list by searching the entire list.

A third implementation of the index function is where the variables of the state are constrained to be natural numbers, $V \subset \mathbf{N}$, then the state, $S \in$ $\mathbf{N} \rightarrow \mathbf{N}$, has a binary map state representation, $B \in \mathcal{B}(\operatorname{ran}(S))$, where $B=\operatorname{mapBinary}(S) . \quad$ Let $I_{\mathrm{S}, \mathrm{B}}=\operatorname{stateMapBinaryIndexer}(U, V, M, N) \in$ computers. Let domain $\left(I_{\mathrm{S}, \mathrm{B}}\right)=\left\{\operatorname{mapBinary}(S): S \in V^{\mathrm{CS}}\right\}$, range $\left(I_{\mathrm{S}, \mathrm{B}}\right)=$ $\left\{1 \ldots\left|V^{\mathrm{CS}}\right|\right\}$ and $\operatorname{apply}\left(I_{\mathrm{S}, \mathrm{B}}\right)(B)=\operatorname{in}(M, N, B, n)+1$ where in $(M, N, B, i):=$ $\operatorname{in}(M, N, B, i-1) * N_{i}+\operatorname{find}\left(B, M_{i}\right)$ and $\operatorname{in}(M, N, B, 0):=0$. In this case the time complexity, $I_{\mathrm{S}, \mathrm{B}}^{\mathrm{t}}$, is $n \ln n$, which intermediate between the ordered, $I_{\mathrm{S}, \mathrm{o}}^{\mathrm{t}}$, and unordered, $I_{\mathrm{S}, \mathrm{u}}^{\mathrm{t}}$, , cases.

Each of the indexers, $I_{\mathrm{S}, \mathrm{o}}, I_{\mathrm{S}, \mathrm{B}}$ and $I_{\mathrm{S}, \mathrm{u}}$, has a corresponding inverse indexer, $J_{\mathrm{S}, \mathrm{o}}, J_{\mathrm{S}, \mathrm{B}}$ and $J_{\mathrm{S}, \mathrm{u}}$. These recursively take the modulus and perform integral division of the given index to obtain the representation of the state. For example, domain $\left(J_{\mathrm{S}, \mathrm{o}}\right)=\left\{1 \ldots\left|V^{\mathrm{CS}}\right|\right\}$ and $\operatorname{apply}\left(J_{\mathrm{S}, \mathrm{o}}\right)(k)=$ $\operatorname{un}(M, N, n, k)$ where un $(M, N, i, k):=\left(\left(M_{i}, k \% N_{i}\right)\right.$, un $\left.\left(M, N, i-1, k / N_{i}\right)\right)$ and $\operatorname{un}(M, N, 0, k):=\emptyset$. Modulus and divide are the natural number operators. The method is similar to the decode method of fixed width coders. Note that the inverse indexer $J_{\mathrm{S}, \mathrm{u}}$ is simply equal to $J_{\mathrm{S}, \mathrm{o}}$ and therefore not a true inverse computer of $I_{\mathrm{S}, \mathrm{u}}$ because the order of the variable-value list is not preserved, $\exists K \in \operatorname{domain}\left(I_{\mathrm{S}, \mathrm{u}}\right)\left(J_{\mathrm{S}, \mathrm{u}}^{*}\left(I_{\mathrm{S}, \mathrm{u}}^{*}(K)\right) \neq K\right)$, although $\forall K \in \operatorname{domain}\left(I_{\mathrm{S}, \mathrm{u}}\right)\left(\operatorname{set}\left(J_{\mathrm{S}, \mathrm{u}}^{*}\left(I_{\mathrm{S}, \mathrm{u}}^{*}(K)\right)\right)=\operatorname{set}(K)\right)$. The time complexity of inverse indexers $J_{\mathrm{S}, \mathrm{o}}$ and $J_{\mathrm{S}, \mathrm{B}}$ is the same as that of the corresponding indexer, $n$ and $n \ln n$ respectively. The time complexity of inverse indexer $J_{\mathrm{S}, \mathrm{u}}$ is that of $J_{\mathrm{S}, \mathrm{o}}, n$. Note that these complexities suggest that it may require less computation to apply the inverse index to an index $k$ than to find the state $S$ indexed by $k$ in a binary map $\mathbf{N} \rightarrow \mathcal{S}$. That is, $J_{\mathrm{S}, \mathrm{o}}^{\mathrm{t}}(k)<I_{\mathrm{B}, \mathrm{g}}^{\mathrm{t}}((B, k))$ where $B \in \mathcal{B}\left(V^{\mathrm{CS}}\right), S=\operatorname{find}(B, k)$ and $I_{\mathrm{B}, \mathrm{g}}=\operatorname{mapBinaryGetter}\left(V^{\mathrm{CS}}\right)$. If the binary map has cardinality $\mid$ function $(B) \mid$ equal to the volume $\left|V^{\mathrm{CS}}\right|$ then the time complexity is $\ln v$ where $v=\left|V^{\mathrm{CS}}\right|$. This complexity is greater than $n$, at least in the case of regular $V$ of valency $d$ when $\ln v=n \ln d$.

Given an ordered list state representation $K$ where $\operatorname{set}(K)=S$, the indexer, $I_{\mathrm{S}, \mathrm{o}}$, has time complexity $n$. So the overall time complexity of an ordered list state representation index operation on an array histogram representation, $I_{\mathrm{L}, \mathrm{g}}^{*}\left(L_{A}, I_{\mathrm{S}, \mathrm{o}}^{*}(K)\right)$, is $n$.

Having considered the array histogram representation and three types of indexers of state representations that index the array, consider a binary map histogram representation. The binary map $B_{A} \in \mathcal{B}\left(\mathbf{Q}_{\geq 0}\right)$ is such that $\exists X \in$ function $\left(B_{A}\right) \leftrightarrow A \forall((i, d),(S, c)) \in X(d=c)$ and $\mid$ function $\left(B_{A}\right)|=|A|$. The operation to set a count in the histogram is implemented with the binary map setter on the positive rationals, $I_{\mathrm{B}, \mathrm{s}}=\operatorname{mapBinarySetter}\left(\mathbf{Q}_{\geq 0}\right)$. The operation to access a count is implemented with the corresponding binary map getter, $I_{\mathrm{B}, \mathrm{g}}=$ mapBinaryGetter $\left(\mathbf{Q}_{\geq 0}\right)$. The space complexity of the binary map accessors is $|A| \ln |A|$. The space complexity of the binary map histogram representation is greater than the array histogram representation if the histogram is complete, $A^{\mathrm{U}}=A^{\mathrm{C}}$, and so $v \log _{2} v \geq v$ where the volume $v>1$. The space of the binary map histogram representation is least for the effective equivalent, $\operatorname{trim}(A) \equiv A$, because $\left|A^{\mathrm{F}}\right| \leq|A|$.

Given an index function, $\operatorname{index}(U, V) \in \operatorname{enum}\left(V^{\mathrm{CS}}\right) \subset \mathcal{S}_{U} \leftrightarrow \mathbf{N}_{>0}$, then $B_{A}$ is such that $\forall(S, c) \in A\left(\operatorname{find}\left(B_{A}, \operatorname{index}(U, V)(S)\right)=c\right)$. The lookup, $I_{\mathrm{B}, \mathrm{g}}^{*}\left(B_{A}\right.$, index $\left.(U, V)(S)\right) \in \mathbf{Q}_{\geq 0}$, has time complexity of the greater of the binary map getter, $\ln |A|$, and that of the index computation. The implementation of the index function may be one of the indexers (above) depending on the representation of the state. Given an ordered list state representation $K \in \mathcal{L}(S)$ such that flip $(K) \in \operatorname{enums}(S)$, the indexer, $I_{\mathrm{S}, \mathrm{o}}$, has time complexity $n$. So the overall time complexity of an ordered list state representation index operation on a binary map histogram representation, $I_{\mathrm{B}, \mathrm{s}}^{*}\left(B_{A}, I_{\mathrm{S}, \mathrm{o}}^{*}(K)\right)$, is $\ln v$ where $v=\left|A^{\mathrm{C}}\right|$. In the case of a regular histogram $A$ of valency $d$, the time complexity of the operation is $n \ln d$. This time complexity of a binary map histogram representation, $n \ln d$, is greater than that for the array histogram representation, $n$. The array histogram representation may require less time, but the array must be of cardinality equal to the volume, and so its space complexity is $v$, which may be greater than that of the effective binary map histogram representation, $\left|A^{\mathrm{F}}\right| \ln \left|A^{\mathrm{F}}\right|$.

Closely related to the binary map histogram representation, having a function indexed by the natural numbers, are the poset binary map histogram representations, which are indexed by state representations and which implement the find operation using corresponding comparators rather than indexers. For example the poset binary map of histogram $A$ on the ordered list state representation $B_{A} \in$ mapBinaryPosets(domain $\left.\left(I_{\mathrm{S}, \mathrm{o}}\right), \mathbf{Q}_{\geq 0}\right)$, where $I_{\mathrm{S}, \mathrm{o}}=\operatorname{stateOrdered} \operatorname{Indexer}(U, V, M, N)$ and $V=\operatorname{vars}(A)$, is such that $\left\{(\operatorname{set}(K), c):(K, c) \in \operatorname{function}\left(B_{A}\right)\right\}=A$. The accessor operations to set and get a count in the histogram are implemented with a poset binary map
setter, $I_{\mathrm{B}, \mathrm{P}, \mathrm{s}}=$ mapBinaryPosetSetter $\left(I_{ \pm}, \operatorname{domain}\left(I_{\mathrm{S}, \mathrm{o}}\right), \mathrm{Q}_{\geq 0}\right)$ and a poset binary map getter, $I_{\mathrm{B}, \mathrm{P}, \mathrm{g}}=$ mapBinaryPosetGetter $\left(I_{ \pm}\right.$, domain $\left.\left(I_{\mathrm{S}, \mathrm{o}}\right), \mathbf{Q}_{\geq 0}\right)$ given some ordered list state comparator $I_{ \pm}$such that domain $\left(I_{ \pm}\right)=\operatorname{domain}\left(I_{\mathrm{S}, \mathrm{o}}\right) \times$ domain $\left(I_{\mathrm{S}, \mathrm{o}}\right)$. The ordered list state comparator compares the values of a pair of ordered list states in sequence, $I_{ \pm}^{*}((K, J)) \in\{-1,0,1\}$ where $K, J \in$ domain $\left(I_{\mathrm{S}, \mathrm{o}}\right)$. The comparators do not have inverse computers unlike the indexers. Assuming the self comparison has the greatest time, the time complexity of the ordered list state comparator is the same as for the ordered list state indexer, $n$, where $n=|V|$. The lookup, $I_{\mathrm{B}, \mathrm{P}, \mathrm{g}}^{*}\left(B_{A}, K\right) \in \mathbf{Q}_{\geq 0}$, has time complexity of $n \ln v$ where $v=\operatorname{volume}(U)(V)$. In the case of a regular histogram $A$ of valency $d$, the time complexity of the operation is $n^{2} \ln d$.

As well as array and binary map representations of histograms there are list histogram representations. For example, consider the list representation of histogram $A$ in variables $V=\operatorname{vars}(A)$ in system $U$ where each state is an ordered list state representation of variable-values, $P_{A} \in \mathcal{L}(\{(\operatorname{ord}(U, D)(S), c)$ : $(S, c) \in A\}) \subset \mathcal{L}\left(\mathcal{L}\left(\mathcal{V}_{U} \times \mathcal{W}_{U}\right) \times \mathbf{Q}_{\geq 0}\right)$ where $D \in \operatorname{enums}(\operatorname{vars}(U))$, and $\operatorname{ord}(U, D)(S) \in \mathcal{L}(S)$. In this case, $\left\{((\operatorname{set}(L), c), i):(i,(L, c)) \in P_{A}\right\} \in$ enums $(A)$. The $\operatorname{ord}(U, D)$ function implies some variables tuple, $\exists M \in$ $\mathcal{L}(V)\left(\operatorname{flip}(M) \in \operatorname{enums}(V) \wedge\left(\forall S \in V^{\mathrm{CS}}(\{(i, w):(i,(w, \cdot)) \in \operatorname{ord}(U, D)(S)\}=\right.\right.$ $M)$ ). Note that the order $D$ is implied if the variables are natural numbers, $V \subset \mathbf{N}$. If the values are also natural numbers, for example if $\forall w \in V\left(U_{w}=\right.$ $\left.\left\{1 \ldots\left|U_{w}\right|\right\}\right)$, then $P_{A} \in \mathcal{L}\left(\mathcal{L}(\mathbf{N} \times \mathbf{N}) \times \mathbf{Q}_{\geq 0}\right)$.

Another example of a list representation of histograms is where variables are natural numbers, $V \subset \mathbf{N}$, and the states are binary map state representations, $Q_{A} \in \mathcal{L}\left(\mathcal{B}\left(\mathcal{W}_{U}\right) \times \mathbf{Q}_{\geq 0}\right)$ which is such that $\{($ function $(B), c):(B, c) \in$ $\left.Q_{A}\right\}=A$. If the values are also natural numbers, then $Q_{A} \in \mathcal{L}\left(\mathcal{B}(\mathbf{N}) \times \mathbf{Q}_{\geq 0}\right)$.

A third example of list representation of histograms is where the state is represented by an index, $R_{A} \in \mathcal{L}(\{(\operatorname{index}(U, V)(S), c):(S, c) \in A\}) \subset \mathcal{L}(\mathbf{N} \times$ $\left.\mathrm{Q}_{\geq 0}\right)$. Here the index state representation is implemented with one of the indexers (above). The histogram is recovered from the representation by means of the corresponding inverse indexer. For example, in the case of the ordered list state representation indexer, flip $\left(R_{A}\right) \in \operatorname{enums}\left(\left\{\left(I_{\mathrm{S}, \mathrm{o}}^{*}(\operatorname{ord}(U, D)(S)), c\right)\right.\right.$ : $(S, c) \in A\})$ and $\left\{\left(\operatorname{set}\left(J_{\widehat{S}, \mathrm{o}}^{*}(k)\right), c\right):(i,(k, c)) \in R_{A}\right\}=A$. This example of a list representation is related to the array representation of histograms, $\operatorname{set}\left(R_{A}\right) \in \mathcal{L}\left(\mathbf{Q}_{\geq 0}\right)$, in the special case where $A$ is complete, $A^{\mathrm{U}}=A^{\mathrm{C}}$. The list representation is also related to the binary map representation of histograms, $\operatorname{set}\left(R_{A}\right)=$ function $(B)$ where $B \in \mathcal{B}\left(\mathbf{Q}_{\geq 0}\right)$.

All of these list histogram representations are such that the cardinality of the list is the same as that of the histogram, $\left|P_{A}\right|=\left|Q_{A}\right|=\left|R_{A}\right|=|A|$. Unlike the array representation, these list representations are not subject to the constraint that the cardinality be equal to the volume, $\left|A^{\mathrm{C}}\right|$. In fact, there are list representations which are not constrained to be in a bijective mapping to the histogram, but which equal the given histogram after a summation. For example, $X_{A} \in \mathcal{L}\left(\left\{\operatorname{ord}(U, D)(S): S \in V^{\mathrm{CS}}\right\} \times \mathbf{Q}_{\geq 0}\right)$ such that $\sum\left(\{(\operatorname{set}(L), c)\}:(i,(L, c)) \in X_{A}\right) \equiv A$. In this case $\exists X_{A} \in \mathcal{L}\left(\mathcal{L}\left(\mathcal{V}_{U} \times \mathcal{W}_{U}\right) \times\right.$ $\left.\mathbf{Q}_{\geq 0}\right)\left(\left\{(\operatorname{set}(L), c):(i,(L, c)) \in X_{A}\right\} \notin \mathcal{S}_{U} \rightarrow \mathbf{Q}_{\geq 0}\right)$. An example is that of a history $H \in \mathcal{H}$ which is such that $\operatorname{ids}(H)=\{1 \ldots|H|\}$, histogram $(H)=A$, $|\operatorname{states}(H)|<|H|$ and $X_{A}=\{(i,(\operatorname{ord}(U, D)(S), 1)):(i, S) \in H\}$. Then $\left|X_{A}\right|=|H|>|A|$. Both the time and space complexities of list histogram representations is the length of the list, which is at least $|A|$. While the space complexity of list histogram representations may be less than that of the binary map representations, the time complexity may be greater.

Given a system $U$ and set of variables $V \subseteq \mathcal{V}_{U}$, consider the computation time to calculate the cartesian set of states, cartesian $(U)(V) \subset \mathcal{S}_{U}$. Let $I_{\mathrm{C}}=$ cartesianer $(U) \in$ computers. Then domain $\left(I_{\mathrm{C}}\right)=\mathrm{P}\left(\mathcal{V}_{U}\right)$, range $\left(I_{\mathrm{C}}\right)=\{Q$ : $\left.Q \subset \mathcal{S}_{U}, \forall S \in Q(\operatorname{vars}(S)=\operatorname{vars}(Q))\right\}$ and $\operatorname{apply}\left(I_{\mathrm{C}}\right)(V)=\operatorname{cartesian}(U)(V)$. If the cartesianer is implemented using a binary map histogram representation on ordered list state representations, then the time complexity is $v \ln v$

$$
\exists m \in \mathbf{N}_{>0}\left(I_{\mathrm{C}}^{\mathrm{t}} \in \mathrm{O}\left(\left\{(V, v \ln v): V \in \operatorname{domain}\left(I_{\mathrm{C}}\right), v=\left|V^{\mathrm{C}}\right|\right\}, m\right)\right)
$$

If $V$ is regular having dimension $n=|V|$ and valency $\{d\}=\left\{\left|U_{w}\right|: w \in V\right\}$ then $v=d^{n}$ and the time complexity is $d^{n} \ln d^{n}=n d^{n} \ln d$.

Given a histogram $A \in \mathcal{A}$ and set of variables $V \subseteq \mathcal{V}$, consider the computation time to reduce the histogram, $A \% V$. Let $I_{\%}=$ reducer $\in$ computers. Then domain $\left(I_{\%}\right)=\mathrm{P}(\mathcal{V}) \times \mathcal{A}$, range $\left(I_{\%}\right)=\mathcal{A}$ and $\operatorname{apply}\left(I_{\%}\right)((V, A))=$ $A \% V$. If the reducer is implemented using a binary map histogram representation on ordered list state representations, then the reducer is constrained to system $U$. That is, $A \in \mathcal{A}_{U}$ and $V \subseteq \operatorname{vars}(U)$. The time complexity is defined

$$
\begin{gathered}
\exists m \in \mathbf{N}_{>0}\left(I_{\%}^{\mathrm{t}} \in \mathrm{O}(\{((V, A), \text { maximum }(y \ln y, n y)):\right. \\
\left.\left.\left.\quad(V, A) \in \operatorname{domain}\left(I_{\%}\right), y=|A|, n=|V|\right\}, m\right)\right)
\end{gathered}
$$

Note that $|A| \geq|A \% V|$ and so $|A|$ has the greater complexity. In the case where $A$ is reduced to a scalar the reducer must compute at least $|A|-1$
additions, $I_{\%}^{\mathrm{t}}((\emptyset, A))>(|A|-1) I_{+}^{\mathrm{t}}((0,0))$. If $A$ is regular in system $U$ having dimension $n=|\operatorname{vars}(A)|$ and valency $\{d\}=\left\{\left|U_{w}\right|: w \in \operatorname{vars}(A)\right\}$ and $A$ is complete, $A^{\mathrm{U}}=A^{\mathrm{C}}$, then $y=d^{n}$ and the time complexity is at most $d^{n} \ln d^{n}=n d^{n} \ln d$.

Given a pair of histograms $A, B \in \mathcal{A}$, consider the computation time of the multiplication, $A * B$. Let $I_{*}=$ multiplicationer $\in$ computers. Then $\operatorname{domain}\left(I_{*}\right)=\mathcal{A} \times \mathcal{A}$, range $\left(I_{*}\right)=\mathcal{A}$ and $\operatorname{apply}\left(I_{*}\right)((A, B))=A * B$. If the multiplicationer is implemented using a binary map histogram representation on ordered list state representations in system $U$, then

$$
\begin{gathered}
\exists m \in \mathbf{N}_{>0}\left(I _ { * } ^ { \mathrm { t } } \in \mathrm { O } \left(\left\{\left((A, B), \operatorname{maximum}\left(x y \ln x y, \operatorname{maximum}\left(n_{A} x, n_{B} y\right)\right)\right):\right.\right.\right. \\
\left.\left.\left.\quad A, B \in \mathcal{A}, x=|A|, y=|B|, n_{A}=|\operatorname{vars}(A)|, n_{B}=|\operatorname{vars}(B)|\right\}, m\right)\right)
\end{gathered}
$$

In the case where $B$ is a scalar the multiplicationer must compute at least $|A|$ multiplications, $I_{*}^{\mathrm{t}}((A$, scalar $(\operatorname{size}(B))))>|A| I_{\times}^{\mathrm{t}}((1,1))$ where $I_{\times}=$multiplier. In the case where the variables of $A$ and $B$ do not intersect, $\operatorname{vars}(A) \cap$ $\operatorname{vars}(B)=\emptyset$, the multiplicationer must compute at least $|A||B|$ multiplications, $I_{*}^{\mathrm{t}}((A, B))>|A||B| I_{\times}^{\mathrm{t}}((1,1))$. If $A$ and $B$ are complete and have volumes $v=\left|A^{\mathrm{C}}\right|$ and $w=\left|B^{\mathrm{C}}\right|$, then the time complexity is at most $v w \ln v w$.

A special case of a multiplicationer is the one functional multiplicationer where the second histogram $B$ is the histogram of some one functional transform $T$. That is, $\exists T \in \mathcal{T}_{U, \mathrm{f}, 1}(\operatorname{his}(T)=B)$. The domain is also constrained such that the underlying variables of the transform $T$ are a subset of the variables of the first histogram $A, \operatorname{und}(T) \subseteq \operatorname{vars}(A)$, and the derived variables of $T$ are disjoint with the variables of $A, \operatorname{der}(T) \cap \operatorname{vars}(A)=\emptyset$. Then the multiplication can be thought of as adding variables to $A$ without changing the cardinality or the counts. That is, $\operatorname{vars}(A * B)=V \cup W=V \cup \operatorname{der}(T)$ and $\{(S \% V, c):(S, c) \in A * B\}=A$ where $V=\operatorname{vars}(A)$ and $W=\operatorname{vars}(B)$. There exists a mapping $Q=\left\{(S, S \cup R): S \in A^{\mathrm{S}}, R \in B^{\mathrm{S}},|S \cap R|=|V \cap W|\right\} \in$ $V^{\mathrm{CS}} \rightarrow(V \cup W)^{\mathrm{CS}}$ which is such that $|Q|=|A|$. The one functional multiplicationer need only remap the states without modifying the counts however they are represented. No multiplications nor additions are computed. Let $I_{* 1}=$ multiplicationOneFunctionaler $\in$ computers. Then domain $\left(I_{* 1}\right)=$ $\left\{(A, \operatorname{his}(T)): U \in \mathcal{U}, A \in \mathcal{A}_{U}, T \in \mathcal{T}_{U, \mathrm{f}, 1}, \quad \operatorname{und}(T) \subseteq \operatorname{vars}(A), \operatorname{der}(T) \cap\right.$ $\operatorname{vars}(A)=\emptyset\}, \operatorname{range}\left(I_{* 1}\right)=\mathcal{A}$ and apply$\left(I_{* 1}\right)((A, B))=A * B$. If the histograms $A$ and $B$ are represented with a binary map histogram representation on ordered list state representations then $I_{* 1}^{\mathrm{t}}((A, B))>|A| \ln |B|$ and $I_{* 1}^{\mathrm{t}}((A, B))>|A| \ln |A|$. The volume of $A$ is greater than or equal to that of the underlying of $T,\left|V^{\mathrm{C}}\right| \geq\left|(V \cap W)^{\mathrm{C}}\right|$, so the time complexity is at most $v \ln v$ where $v=\left|A^{\mathrm{C}}\right|$.

### 3.19.2 Computation of the application of a transform

The application of the transform $T \in \mathcal{T}_{U}$ to a histogram $A \in \mathcal{A}_{U}$ in system $U$ can be implemented by applying a multiplicationer followed by a reducer, $A * T=I_{\%}^{*}\left(\left(W, I_{*}^{*}((A, X))\right)\right)$ where $(X, W)=T$. In the case when the histograms are represented with a binary map histogram representation on ordered list state representations, this method has time complexity, $v w \ln v w$, where $v=\operatorname{volume}(U)(\operatorname{vars}(A))$ and $w=\operatorname{volume}(U)(\operatorname{vars}(T))$. The computation does not assume that the transform is functional and hence is less efficient than an implementation using a one functional multiplicationer.

If the transform is constrained to be one functional, $T \in \mathcal{T}_{U \mathrm{ff}, 1}$, and such that the underlying variables of $T$ are a subset of the histogram $A$, $\operatorname{und}(T) \subseteq \operatorname{vars}(A)$, and the derived variables of $T$ are disjoint with the variables of $A, \operatorname{der}(T) \cap \operatorname{vars}(A)=\emptyset$, then the application can be implemented by applying a one functional multiplicationer followed by a reducer, $A * T=$ $I_{\%}^{*}\left(\left(W, I_{* 1}^{*}((A, X))\right)\right)$. Let $I_{* T}=$ transformer $\in$ computers, domain $\left(I_{* T}\right)=$ $\left\{(T, A): U \in \mathcal{U}, A \in \mathcal{A}_{U}, T \in \mathcal{T}_{U, \mathrm{f}, 1}, \operatorname{und}(T) \subseteq \operatorname{vars}(A), \operatorname{der}(T) \cap \operatorname{vars}(A)=\right.$ $\emptyset\}, \operatorname{range}\left(I_{* \mathrm{~T}}\right)=\operatorname{range}\left(I_{\%}\right)$ and

$$
\operatorname{apply}\left(I_{* \mathrm{~T}}\right)((T, A))=\operatorname{transform}(T, A)=I_{\%}^{*}\left(\left(W, I_{* 1}^{*}((A, X))\right)\right)
$$

where $(X, W)=T$. Then $I_{* T}^{\mathrm{t}}((T, A))>|A| \ln |X|$ and $I_{* T}^{\mathrm{t}}((T, A))>|A| \ln |A|$. The overall time complexity is $v \ln v$ where $v=\operatorname{volume}(U)(V)$ and $V=$ vars $(A)$. If $A$ is a regular histogram of dimension $n=|V|$ and valency $\{d\}=\left\{\left|U_{w}\right|: w \in V\right\}$ then $v=d^{n}$ and the time complexity is $d^{n} \ln d^{n}$.

### 3.19.3 Computation of functional definition sets

A functional definition set $F$ is a set of unit functional transforms, $F \in$ $\mathcal{F} \subset \mathrm{P}\left(\mathcal{T}_{\mathrm{U}} \cap \mathcal{T}_{\mathrm{f}}\right)$. The equivalent transform, $F^{\mathrm{T}}$, is defined $\operatorname{transform}(F):=$ ( $\left.\prod \operatorname{his}(F) \%(V \cup W), W\right) \in \mathcal{T}_{\mathrm{U}} \cap \mathcal{T}_{\mathrm{f}}$, where $W=\operatorname{der}(F)$ and $V=\operatorname{und}(F)$. Let $L \in \mathcal{L}(\mathcal{A})$ be a list of the histograms of a non-empty fud $F$ such that the inverse is an enumeration of the histograms, flip $(L) \in \operatorname{enums}(\operatorname{his}(F))$. Then the product can be computed by application of a multiplicationer recursing on $L$. Let $\operatorname{mul}(L):=I_{*}^{*}\left(\left(\operatorname{mul}(\operatorname{tail}(L)), L_{1}\right)\right)$ and $\operatorname{mul}(\{(1, A)\}):=A$. Let $I_{\mathrm{F}, \mathrm{T}}=$ fudsTransformer $\in$ computers. Then range $\left(I_{\mathrm{F}, \mathrm{T}}\right)=\mathcal{T}_{\mathrm{U}} \cap \mathcal{T}_{\mathrm{f}}$, $\operatorname{domain}\left(I_{\mathrm{F}, \mathrm{T}}\right)=\mathcal{F} \backslash\{\emptyset\}$ and $\operatorname{apply}\left(I_{\mathrm{F}, \mathrm{T}}\right)(F)=\left(I_{\%}^{*}((V \cup W, \operatorname{mul}(L))), W\right)=$ $F^{\mathrm{T}}$ where $\operatorname{flip}(L) \in$ enums $(\operatorname{his}(F))$. The cardinality of the intermediate histogram $\left|\prod \operatorname{set}\left(L_{\{1 \ldots i\}}\right)\right|$, and hence the computation times of subsequent multiplications, $I_{*}^{\mathrm{t}}\left(\left(\prod_{\operatorname{set}}\left(L_{\{1 \ldots i\}}\right), L_{i+1}\right)\right)$, depends on the order in which the multiplications take place in $L$. If the fud transformer is implemented where
$L$ is chosen such that the intermediate equivalent transform is always functional, $\forall i \in\{1 \ldots|L|\}\left(\left(X_{\{1 \ldots i\}}, \operatorname{vars}\left(X_{\{1 \ldots i\}}\right) \backslash V\right) \in \mathcal{T}_{f}\right)$, where $X_{\{1 \ldots i\}}=$ $\prod \operatorname{set}\left(L_{\{1 \ldots i\}}\right)$, then the time complexity of the fud transformer is at most the time complexity of the reducer, $v \ln u$ where $v=\operatorname{volume}(U)(V)$ and $u=\operatorname{volume}(U)(\operatorname{vars}(F))$. If $L$ is chosen arbitrarily then the time complexity of the fud transformer is at most $u \ln u$.

The partition set transformer $I_{\mathrm{N}, \mathrm{T}}=$ partitionSetsTransformer $\in$ computers is a variation of the fud transformer which has a domain of partition sets, domain $\left(I_{\mathrm{N}, \mathrm{T}}\right)=\mathrm{P}(\mathcal{R}) \backslash\{\emptyset\}$. The application promotes each partition to a transform and the computes the equivalent fud, apply $\left(I_{\mathrm{N}, \mathrm{T}}\right)(Q)=\left\{P^{\mathrm{T}}: \in\right.$ $Q\}^{\mathrm{T}}$. The time complexity of the partition set transformer is the same as the fud transformer, $v \ln y$.

Direct application of functional definition sets to histograms, apply $\in$ $\mathcal{F} \times \mathcal{A} \rightarrow \mathcal{A}$, reduces computation time and space by navigating through the fud reducing any non-derived variables as soon as possible. If the fud is constrained to be one functional, $F \in \mathcal{F}_{U, 1} \subset \mathrm{P}\left(\mathcal{T}_{U, \mathrm{f}, 1}\right)$, then the implementation may use the one functional multiplicationer rather than the multiplicationer and the reduction can optionally be left to the end without increasing the cardinality of the cumulative histogram product. The one functional multiplicationer must be applied in sequence such that the intermediate equivalent transform is always functional. Let $M \in \mathcal{L}\left(\mathcal{T}_{U, f, 1}\right)$ be a list of the transforms of $F$ such that flip $(M) \in$ enums $(F)$ and such that $\operatorname{und}\left(M_{1}\right) \subseteq V$ and $\operatorname{der}\left(M_{1}\right) \cap V=\emptyset$ where $V=\operatorname{vars}(A)$ and $\forall i \in$ $\{2 \ldots|M|\} \diamond Q=\operatorname{vars}\left(\operatorname{set}\left(M_{\{1 \ldots i-1\}}\right)\right)\left(\operatorname{und}\left(M_{i}\right) \subseteq Q \wedge \operatorname{der}\left(M_{i}\right) \cap Q=\emptyset\right)$. Let $\operatorname{mul1}(A, M):=I_{* 1}^{*}\left(\left(\operatorname{mul1}(A, \operatorname{tail}(M)), \operatorname{his}\left(M_{1}\right)\right)\right)$ and $\operatorname{mul1}(A, \emptyset):=A$.

First define the application without reduction. Let $I_{* \mathrm{X}}=$ applier $\in$ computers in system $U$. Then domain $\left(I_{* \mathrm{X}}\right)=\left\{(F, A): U \in \mathcal{U}, A \in \mathcal{A}_{U}, F \in\right.$ $\left.\mathcal{F}_{U, 1}, \quad \operatorname{und}(F) \subseteq \operatorname{vars}(A), \operatorname{vars}(F) \backslash \operatorname{und}(F) \cap \operatorname{vars}(A)=\emptyset\right\}, \operatorname{range}\left(I_{* \mathrm{X}}\right)=\mathcal{A}$ and $I_{* \mathrm{X}}^{*}((F, A))=\operatorname{mul1}(A$, reverse $(M))$. Then $I_{* \mathrm{X}}^{\mathrm{t}}((F, A))>r|A|$ where $r=|\operatorname{vars}(F)|$, and $I_{* \mathrm{X}}^{\mathrm{t}}((F, A))>f|A| \ln |A|$ where $f=|F|$.

Now define the application with reduction. Let $I_{* \mathrm{~F}}=$ fuder $\in$ computers in system $U$. Then domain $\left(I_{* \mathrm{~F}}\right)=$ domain $\left(I_{* \mathrm{X}}\right)$, range $\left(I_{* \mathrm{~F}}\right)=\operatorname{range}\left(I_{\%}\right)$ and $I_{* \mathrm{~F}}^{*}((F, A))=\operatorname{apply}(F, A)=I_{\%}^{*}\left(\left(W, I_{* \mathrm{X}}^{*}((F, A))\right)\right)$ where $W=\operatorname{der}(F)$.

### 3.19.4 Computation of independent

Given a histogram $A$ consider the computation time to calculate its independent $A^{\mathrm{X}}$. Let $I_{\mathrm{X}}=$ independenter $\in$ computers. Let domain $\left(I_{\mathrm{X}}\right)=$ $\operatorname{range}\left(I_{\mathrm{X}}\right)=\mathcal{A}$, and apply $\left(I_{\mathrm{X}}\right)(A)=A^{\mathrm{X}}$. Consider non-zero histogram $A \in \mathcal{A}$ having size $z=\operatorname{size}(A)$, variables $V=\operatorname{vars}(A)$, and dimension $n=|V|$. In order to calculate $A^{\mathrm{X}}$ the independenter must calculate ( $n-1$ ) additions for each effective state, $A^{\mathrm{F}}$, to construct the reductions $R=\{(v, A \%\{v\})$ : $v \in V\}=\left\{\left(v, \sum(\{(S \%\{v\}, c)\}:(S, c) \in A, c>0)\right): v \in V\right\}$. Then the independenter must calculate $n$ multiplications for each state of the effective cartesian sub-volume $A^{\mathrm{XF}}, A^{\mathrm{X}}=\left\{\left(S, \prod\left(R_{v}(S \%\{v\}): v \in V\right) / z^{n-1}\right): S \in\right.$ $\left.\operatorname{states}\left(\prod\left\{R_{v}^{\mathrm{F}}: v \in V\right\}\right)\right\}$. Thus $I_{\mathrm{X}}^{\mathrm{t}}(A)>\left|A^{\mathrm{F}}\right|(n-1) I_{+}^{\mathrm{t}}(0,0)+\left|A^{\mathrm{XF}}\right| n I_{\times}^{\mathrm{t}}(1,1)$ where $I_{+}=$adder and $I_{\times}=$multiplier. Implementing the histograms with an array histogram representation on ordered list state representations

$$
\exists m \in \mathbf{N}_{>0}\left(I_{\mathrm{X}}^{\mathrm{t}} \in \mathrm{O}\left(\left\{(A, n y): A \in \mathcal{A}, y=\left|A^{\mathrm{XF}}\right|, n=|\operatorname{vars}(A)|\right\}, m\right)\right)
$$

In other words, the time to calculate the independent histogram $A^{\mathrm{X}}$ is of complexity of $n y$ where $y$ is the effective independent cartesian sub-volume. If $A$ is a regular histogram in a system $U$ of dimension $n=|V|$ and valency $\{d\}=\left\{\left|U_{v}\right|: v \in V\right\}$ for which the independent is completely effective, $A^{\mathrm{XF}}=A^{\mathrm{C}}$, then $y$ is the volume, $\left|V^{\mathrm{C}}\right|$ and the time complexity is $n d^{n}$.

If the independent is completely effective, $A^{\mathrm{XF}}=A^{\mathrm{C}}$, then the space complexity of an array histogram representation, $v$, is less than the space complexity of a binary map histogram representation, $v \ln v$.

## 4 Alignment

### 4.1 Definition

The alignment of a histogram $A$ is defined, alignment $\in \mathcal{A} \rightarrow \mathbf{R}$

$$
\operatorname{alignment}(A):=\sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}-\sum_{S \in A^{\mathrm{xS}}} \ln \Gamma_{!} A_{S}^{\mathrm{X}}
$$

where the unit-translated gamma function is defined $\left(\Gamma_{!}\right) \in \mathbf{R} \rightarrow \mathbf{R}$ as $\Gamma_{!} x=\Gamma(x+1)$ which is such that $\forall i \in \mathbf{N}(\Gamma!i=i!)$. The alignment of the empty histogram is defined as zero, alignment $(\emptyset):=0$. The first term of the expression, $\sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}$, is called the non-independent term. The second term, $\sum_{S \in A^{\mathrm{xS}}} \ln \Gamma_{!} A_{S}^{X}$, is the independent term.

In the case where $A, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$ then

$$
\operatorname{alignment}(A)=\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!-\sum_{S \in A^{\mathrm{XS}}} \ln A_{S}^{\mathrm{X}}!\in \ln \mathbf{Q}_{>0}
$$

In the following, the alignment function will sometimes be abbreviated, algn $=$ alignment.

The alignments of equivalent histograms are equal, $\forall A, B \in \mathcal{A}(A \equiv B \Longrightarrow$ $\operatorname{alignment}(A)=\operatorname{alignment}(B)$ ).

For each histogram $A \in \mathcal{A}_{U}$ in system $U$ there exists a set of cardinal substrate permutations which are non-literal frame mappings $X \in \mathcal{V} \leftrightarrow$ $\left(\mathbf{N}_{>0} \times\left(\mathcal{W} \leftrightarrow \mathbf{N}_{>0}\right)\right)$ such that the reframed histogram is a cardinal substrate histogram, $\operatorname{reframe}(X, A) \in \mathcal{A}_{c}$. The alignment of each of the cardinal substrate histograms under permutation equals the alignment of the histogram, $\operatorname{alignment}(\operatorname{reframe}(X, A))=\operatorname{alignment}(A)$. There are $|V|!\prod_{w \in V}\left|U_{w}\right|!$ cardinal substrate permutations of histogram $A$. These cardinal substrate histograms are isomorphic with respect to alignment.

The alignment of an independent histogram, $A=A^{\mathrm{X}}$, is zero. The alignment of each of the following is zero because in each of these cases the histogram is equivalent to its independent histogram, $A \equiv A^{\mathrm{X}}$ : (i) zero histograms, $\operatorname{size}(A)=0$, (ii) scalar histograms, $\operatorname{vars}(A)=\emptyset$, (iii) monovariate histograms, $|\operatorname{vars}(A)|=1$, (iv) uniform cartesian histograms, $A=$ $\operatorname{scalar}(q) * A^{\mathrm{C}}$ where $q \in \mathbf{Q}_{\geq 0}$, (v) uniform full planar histograms, (vi) uniform linear histograms, (vii) singleton histograms, $|A|=1$, and (viii) uniform cartesian sub-volumes, $A=\operatorname{scalar}(q) * A^{\mathrm{XF}}$.

Conjecture that the alignment of an integral histogram is zero if and only if it is independent, $\forall A \in \mathcal{A}_{\mathrm{i}}\left(A=A^{\mathrm{X}} \Longleftrightarrow \operatorname{algn}(A)=0\right)$. The set of integral iso-independents of histogram $A$ of size $z$ and variables $V$ in system $U$ is $Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right) \subset \mathcal{A}_{U, \mathrm{i}, V, z}$. It contains at most one independent histogram, $\left|\left\{B: B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right), B=B^{\mathrm{X}}\right\}\right| \leq 1$, which, if it exists, has zero alignment, $\operatorname{algn}\left(A^{\mathrm{X}}\right)=0$. The other histograms have alignment not equal zero, $\forall B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\left(B \neq A^{\mathrm{X}} \Longrightarrow \operatorname{algn}(B) \neq 0\right)$.

### 4.2 Derivation

The generalised multinomial probability distribution $\hat{Q}_{\mathrm{m}, U}(E, z) \in\left(\mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow\right.$ $\left.\mathrm{Q}_{\geq 0}\right) \cap \mathcal{P}$ is defined

$$
\hat{Q}_{\mathrm{m}, U}(E, z):=\left\{\left(A, \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}}\left(\frac{E_{S}}{z_{E}}\right)^{A_{S}}\right): A \in \mathcal{A}_{U, i, V, z}\right\}
$$

where $(E, z) \in \mathcal{A}_{U} \times \mathbf{N}, z_{E}=\operatorname{size}(E)>0, V=\operatorname{vars}(E)$ and $E$ is complete, $E^{\mathrm{U}}=E^{\mathrm{C}}$. The domain of the generalised multinomial probability distribution is the finite integral congruent support

$$
\operatorname{dom}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)=\mathcal{A}_{U, \mathrm{i}, V, z}=\left\{A: A \in \mathcal{A}_{U} \cap \mathcal{A}_{\mathrm{i}}, A^{\mathrm{U}}=V^{\mathrm{C}}, \operatorname{size}(A)=z\right\}
$$

The generalised multinomial probability distribution can be further generalised to a probability density function by means of the gamma function. First generalise the support. Let the set of complete congruent histograms in system $U$, of variables $V$ and size $z$ be

$$
\mathcal{A}_{U, V, z}=\left\{A: A \in \mathcal{A}_{U}, A^{\mathrm{U}}=V^{\mathrm{C}}, \operatorname{size}(A)=z\right\}
$$

The complete congruent histograms is an infinite superset of the integral congruent support, $\mathcal{A}_{U, \mathrm{i}, V, z} \subset \mathcal{A}_{U, V, z}$.

Let $E$ be a complete histogram, $E^{\mathrm{U}}=E^{\mathrm{C}}$, of non-zero size, $\operatorname{size}(E)>0$. Let the multinomial probability density function, $\operatorname{mpdf}(U) \in \mathcal{A}_{U} \times \mathbf{Q}_{\geq 0} \rightarrow$ $\left(\mathcal{A}_{U} \rightarrow \mathbf{R}_{\geq 0}\right)$ be such that $\operatorname{mpdf}(U)(E, z)$ is a real valued function of the complete congruent histograms of size $z$ and variables equal to those of $E$, defined $\operatorname{mpdf}(U)(E, z) \in \mathcal{A}_{U, V, z} \rightarrow \mathbf{R}_{\geq 0}$ as

$$
\operatorname{mpdf}(U)(E, z):=\left\{\left(A, \frac{\Gamma_{!} z}{\prod_{S \in A^{\mathrm{S}}} \Gamma_{!} A_{S}} \prod_{S \in A^{\mathrm{S}}}\left(\frac{E_{S}}{z_{E}}\right)^{A_{S}}\right): A \in \mathcal{A}_{U, V, z}\right\}
$$

The generalised multinomial probability distribution is a subset of the multinomial probability density function

$$
\hat{Q}_{\mathrm{m}, U}(E, z) \subset \operatorname{mpdf}(U)(E, z)
$$

The infinite domain of the multinomial probability density function, which is the set of congruent histograms, $\operatorname{dom}(\operatorname{mpdf}(U)(E, z))=\mathcal{A}_{U, V, z}$, corresponds to the finite domain of the generalised multinomial probability distribution, which is the integral congruent support, $\operatorname{dom}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)=\mathcal{A}_{U, \mathrm{i}, V, z}$.

The scaled distribution histogram $M=\operatorname{scalar}\left(z / z_{E}\right) * E$ is in the domain of the multinomial probability density function, $M \in \operatorname{dom}(\operatorname{mpdf}(U)(E, z))=$ $\mathcal{A}_{U, V, z}$. The mean of the generalised multinomial probability distribution equals the scaled distribution histogram, mean $\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)=M=\operatorname{scalar}\left(z / z_{E}\right) *$ $E$ where the draw size $z$ is integral. Thus the mean of the generalised multinomial probability distribution is in the domain of the multinomial probability density function even if the mean is not itself integral, $M \notin \mathcal{A}_{\mathrm{i}}$.

The independent histogram of each of the histograms in the domain of the multinomial probability density function are also in the domain because the independent histogram is congruent, $\forall A \in \mathcal{A}_{U, V, z}\left(A^{\mathrm{X}} \in \mathcal{A}_{U, V, z}\right)$.

The scaled uniform histogram $\operatorname{resize}\left(z, V^{\mathrm{C}}\right)$ is in the domain of the multinomial probability density function, $\operatorname{scalar}(z / v) * V^{\mathrm{C}} \in \mathcal{A}_{U, V, z}$, where $v=\left|V^{\mathrm{C}}\right|$.

Similarly to the generalised multinomial probability distribution, the multinomial probability density function can be approximated by means of the Stirling approximation

$$
\operatorname{mpdf}(U)(E, z)(A)=\Gamma!z \prod_{S \in A^{\mathrm{S}}} \frac{\hat{E}_{S}^{A_{S}}}{\Gamma_{!} A_{S}} \approx \prod_{S \in A^{\mathrm{FS}}}\left(\frac{\hat{E}_{S}}{\hat{A}_{S}}\right)^{A_{S}}
$$

where $\hat{E}=\operatorname{resize}(1, E)$ and $\hat{A}=\operatorname{resize}(1, A)$. The approximation is best for high entropy sample histograms for which the multinomial coefficient is largest.

Compare this approximation to the same term for a scaled draw size $k z$ and scaled sample histogram $\operatorname{scalar}(k) * A$ where $k \in \mathbf{Q}_{>0}$

$$
\begin{aligned}
\operatorname{mpdf}(U)(E, k z)(\operatorname{scalar}(k) * A) & =\Gamma_{!} k z \prod_{S \in A^{\mathrm{S}}} \frac{\hat{E}_{S}^{k A_{S}}}{\Gamma_{!} k A_{S}} \\
& \approx\left(\prod_{S \in A^{\mathrm{FS}}}\left(\frac{\hat{E}_{S}}{\hat{A}_{S}}\right)^{A_{S}}\right)^{k} \\
& =(\operatorname{mpdf}(U)(E, z)(A))^{k}
\end{aligned}
$$

The parameterised multinomial probability density function, $\operatorname{mpdf}(U)(E, z)$, does not have a continuous domain. Rather, its domain is countably infinite, $\mathcal{A}_{U, V, z} \leftrightarrow \mathbf{N}$, consisting as it does of histograms which are rational valued
functions of finite domain. The integration of the multinomial probability density function, which is the cumulative density function, when summed over the whole domain equals one. The integration is defined here in terms of the scaled multinomial probability density function. The scaled complete integral congruent histograms equals the complete congruent histograms in the limit

$$
\lim _{k \rightarrow \infty}\left\{A / Z_{k}: A \in \mathcal{A}_{U, \mathrm{i}, V, k z}\right\}=\mathcal{A}_{U, V, z}
$$

where $k \in \mathbf{N}_{>0}$ and $Z_{k}=\operatorname{scalar}(k)$. Therefore define the integration

$$
\begin{aligned}
& \int_{A \in \mathcal{A}_{U, V, z}} \operatorname{mpdf}(U)(E, z)(A) d A= \\
& \quad \lim _{k \rightarrow \infty} \sum\left(\operatorname{mpdf}(U)(E, k z)\left(Z_{k} * A\right): A \in \mathcal{A}_{U, V, z}, Z_{k} * A \in \mathcal{A}_{\mathrm{i}}\right)
\end{aligned}
$$

In the case where the distribution histogram is integral, $E \in \mathcal{A}_{\mathrm{i}}$ and the draw size $z$ is integral and non-zero, $z \in \mathbf{N}_{>0}$

$$
\begin{aligned}
& \sum\left(\operatorname{mpdf}(U)(E, k z)\left(Z_{k} * A\right): A \in \mathcal{A}_{U, V, z}, Z_{k} * A \in \mathcal{A}_{\mathrm{i}}\right)= \\
& \quad \sum\left(\operatorname{mpdf}(U)(E, k z)(A): A \in \mathcal{A}_{U, \mathrm{i}, V, k z}\right)= \\
& \quad \sum\left(\hat{Q}_{\mathrm{m}, U}(E, k z)(A): A \in \mathcal{A}_{U, \mathrm{i}, V, k z}\right)=1
\end{aligned}
$$

Thus the integration can be approximated by a finite summation for some large $k$, with the approximation improving as $k$ is increased. A further approximation is to take the $k$-th power of the unscaled density

$$
\begin{aligned}
& \int_{A \in \mathcal{A}_{U, V, z}} \operatorname{mpdf}(U)(E, z)(A) d A \approx \\
& \quad \lim _{k \rightarrow \infty} \sum\left((\operatorname{mpdf}(U)(E, z)(A))^{k}: A \in \mathcal{A}_{U, V, z}, Z_{k} * A \in \mathcal{A}_{\mathrm{i}}\right)
\end{aligned}
$$

When $k=z^{n-1}$, where $n=|V|$, all of the independent histograms of the integral sample histograms are approximated

$$
\left\{A^{\mathrm{X}}: A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\} \subset\left\{A / \operatorname{scalar}\left(z^{n-1}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z^{n}}\right\}
$$

because $\left\{\operatorname{scalar}\left(z^{n-1}\right) * A^{\mathrm{X}}: A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\} \subset \mathcal{A}_{\mathrm{i}}$.
The definition of the unit-translated gamma function, $\left(\Gamma_{!}\right) \in \mathbf{R} \rightarrow \mathbf{R}$, is such that the minimum value of positive real arguments is less than one, approximately ( $0.4616,0.8856$ ). In fact, $\forall x \in \mathbf{R}\left(0<x<1 \Longrightarrow 0!>\Gamma_{!} x<1!\right)$.

However, all integral histograms have multinomial probability density function less than or equal to one

$$
\forall A \in \mathcal{A}_{U, V, z}\left(A \in \mathcal{A}_{\mathrm{i}} \Longrightarrow \operatorname{mpdf}(U)(E, z)(A)=\hat{Q}_{\mathrm{m}, U}(E, z)(A) \leq 1\right)
$$

where $E$ is integral and complete.
The condition for an independent histogram $A^{\mathrm{X}}$ to contain at least one fractional count, $\operatorname{minr}\left(\operatorname{trim}\left(A^{\mathrm{X}}\right)\right)<1$, is

$$
\prod_{v \in V} \operatorname{minr}(\operatorname{trim}(A) \%\{v\})<z^{n-1}
$$

where $V=\operatorname{vars}(A), n=|V|, n>0$ and $z=\operatorname{size}(A)>0$. For some histograms the independent term of the alignment expression is negative, $\sum_{S \in A^{\mathrm{xS}}} \ln \Gamma_{!} A_{S}^{\mathrm{X}}<0$. For example, let $A=\operatorname{resize}\left(0.4616 v, V^{\mathrm{C}}\right)$ where $v=$ $\left|V^{\mathrm{C}}\right| \geq 1$, then

$$
\sum_{S \in A^{\mathrm{xS}}} \ln \Gamma_{!} A_{S}^{\mathrm{X}}=v \ln \Gamma_{!} 0.4616 \approx-0.1215 v
$$

If the sample histogram is integral, $A \in \mathcal{A}_{\mathrm{i}}$, and the independent term is negative, $\sum_{S \in A^{\mathrm{XS}}} \ln \Gamma_{!} A_{S}^{\mathrm{X}}<0$, then the alignment must be positive, $\operatorname{algn}(A) \geq 0$.

Consider the complete integral congruent support sample histogram $A \in$ $\mathcal{A}_{U, \mathrm{i}, V, z}$. In the case where (a) the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, and therefore also in the integral congruent support, $A^{\mathrm{X}} \in \mathcal{A}_{U, \mathrm{i}, V, z}$, and (b) the distribution histogram $E$ is as effective as the independent, $E^{\mathrm{F}} \geq A^{\mathrm{XF}}$, then the generalised multinomial probability of the sample histogram, $\hat{Q}_{\mathrm{m}, U}(E, z)(A)$, may be decomposed into (i) the independent multinomial probability and (ii) relative dependent multinomial probability

$$
\hat{Q}_{\mathrm{m}, U}(E, z)(A)=\hat{Q}_{\mathrm{m}, U}(E, z)\left(A^{\mathrm{x}}\right) \times \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\hat{Q}_{\mathrm{m}, U}(E, z)\left(A^{\mathrm{x}}\right)}
$$

The relative dependent multinomial probability is

$$
\begin{aligned}
\frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\hat{Q}_{\mathrm{m}, U}(E, z)\left(A^{\mathrm{X}}\right)} & =\frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}}\left(\frac{E_{S}}{z_{E}}\right)^{A_{S}} / \frac{z!}{\prod_{S \in A^{\mathrm{XS}}} A_{S}!} \prod_{S \in A^{\mathrm{XS}}}\left(\frac{E_{S}}{z_{E}}\right)^{A_{S}^{\mathrm{X}}} \\
& =\prod_{S \in A^{\mathrm{XS}}} \frac{A_{S}^{\mathrm{X}}!}{A_{S}!} \frac{E_{S}^{A_{S}}}{E_{S}^{A_{S}^{\mathrm{X}}}}
\end{aligned}
$$

In some cases the relative dependent multinomial probability may be greater than $1, \hat{Q}_{\mathrm{m}, U}(E, z)(A) / \hat{Q}_{\mathrm{m}, U}(E, z)\left(A^{\mathrm{X}}\right)>1$. Therefore relative probability is not strictly speaking a probability per se.

In the case where the sample histogram is independent, $A=A^{\mathrm{X}}$, the relative dependent multinomial probability is 1

$$
\frac{\hat{Q}_{\mathrm{m}, U}(E, z)\left(A^{\mathrm{x}}\right)}{\hat{Q}_{\mathrm{m}, U}(E, z)\left(A^{\mathrm{X}}\right)}=1
$$

The relative dependent multinomial probability may be generalised to cases where the independent is not integral, $A^{\mathrm{X}} \notin \mathcal{A}_{\mathrm{i}}$, and therefore not in the finite integral congruent support, $A^{\mathrm{X}} \notin \mathcal{A}_{U, \mathrm{i}, V, z}$, by considering the multinomial probability density function, $\operatorname{mpdf}(U)(E, z)$. Here the sample histogram need not be integral either, but is a complete congruent histogram, $A \in \mathcal{A}_{U, V, z}$. Decompose the multinomial probability density into (i) the independent multinomial probability density and (ii) relative dependent multinomial probability density

$$
\operatorname{mpdf}(U)(E, z)(A)=\operatorname{mpdf}(U)(E, z)\left(A^{\mathrm{X}}\right) \times \frac{\operatorname{mpdf}(U)(E, z)(A)}{\operatorname{mpdf}(U)(E, z)\left(A^{\mathrm{X}}\right)}
$$

Again, the distribution histogram must be as effective as the independent, $E^{\mathrm{F}} \geq A^{\mathrm{XF}}$, so that the relative independent multinomial probability density is non-zero, $\operatorname{mpdf}(U)(E, z)\left(A^{\mathrm{X}}\right)>0$. The relative dependent multinomial probability density is

$$
\begin{aligned}
& \frac{\operatorname{mpdf}(U)(E, z)(A)}{\operatorname{mpdf}(U)(E, z)\left(A^{\mathrm{X}}\right)} \\
& \quad=\frac{\Gamma_{!} z}{\prod_{S \in A^{\mathrm{S}}} \Gamma_{!} A_{S}} \prod_{S \in A^{\mathrm{S}}}\left(\frac{E_{S}}{z_{E}}\right)^{A_{S}} / \frac{\Gamma_{!} z}{\prod_{S \in A^{\mathrm{XS}}} \Gamma_{!} A_{S}} \prod_{S \in A^{\mathrm{XS}}}\left(\frac{E_{S}}{z_{E}}\right)^{A_{S}^{\mathrm{X}}} \\
& \quad=\prod_{S \in A^{\mathrm{XS}}} \frac{\Gamma_{!} A_{S}^{\mathrm{X}}}{\Gamma!A_{S}} \frac{E_{S}^{A_{S}}}{E_{S}^{A_{S}^{\mathrm{X}}}}
\end{aligned}
$$

The negative logarithm relative dependent multinomial probability density is

$$
\begin{aligned}
&- \ln \\
& \quad \frac{\operatorname{mpdf}(U)(E, z)(A)}{\operatorname{mpdf}(U)(E, z)\left(A^{\mathrm{X}}\right)} \\
&=\sum_{S \in A^{\mathrm{xS}}} \ln \Gamma_{!} A_{S}-\sum_{S \in A^{\mathrm{xS}}} \ln \Gamma_{!} A_{S}^{\mathrm{X}}-\sum_{S \in A^{\mathrm{xS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln E_{S} \\
&=\sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}-\sum_{S \in A^{\mathrm{XS}}} \ln \Gamma_{!} A_{S}^{\mathrm{X}}-\sum_{S \in A^{\mathrm{XS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln E_{S}
\end{aligned}
$$

because

$$
\sum_{S \in A^{\mathrm{xS}}} \ln \Gamma_{!} A_{S}=\sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}
$$

In the case where the sample histogram is independent, $A=A^{\mathrm{X}}$, the negative logarithm relative dependent multinomial probability density is 0

$$
-\ln \frac{\operatorname{mpdf}(U)(E, z)\left(A^{\mathrm{X}}\right)}{\operatorname{mpdf}(U)(E, z)\left(A^{\mathrm{X}}\right)}=0
$$

In the special case where the distribution histogram, $E$, from which the sample histogram is drawn, is a scaled uniform cartesian distribution histogram $E=\operatorname{resize}\left(z_{E}, V^{\mathrm{C}}\right)$, then the negative logarithm relative dependent multinomial probability density simplifies to

$$
\begin{aligned}
& -\ln \frac{\operatorname{mpdf}(U)\left(\operatorname{resize}\left(z_{E}, V^{\mathrm{C}}\right), z\right)(A)}{\operatorname{mpdf}(U)\left(\operatorname{resize}\left(z_{E}, V^{\mathrm{C}}\right), z\right)\left(A^{\mathrm{X}}\right)} \\
& \quad=-\ln \frac{\operatorname{mpdf}(U)\left(V^{\mathrm{C}}, z\right)(A)}{\operatorname{mpdf}(U)\left(V^{\mathrm{C}}, z\right)\left(A^{\mathrm{X}}\right)}=\sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}-\sum_{S \in A^{\mathrm{XS}}} \ln \Gamma_{!} A_{S}^{\mathrm{X}}
\end{aligned}
$$

because

$$
\operatorname{mpdf}(U)\left(\operatorname{resize}\left(z_{E}, V^{\mathrm{C}}\right), z\right)=\operatorname{mpdf}(U)\left(V^{\mathrm{C}}, z\right)
$$

and

$$
\sum_{S \in A^{\mathrm{XS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln V_{S}^{\mathrm{C}}=\ln \frac{1}{v} \sum_{S \in A^{\mathrm{XS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right)=0
$$

where volume $v=\left|V^{\mathrm{C}}\right|$. Thus, in this case the negative logarithm relative dependent multinomial probability density does not depend on the distribution histogram.

In fact, the negative logarithm relative dependent multinomial probability density simplifies to the same expression under the weaker constraint that the distribution histogram is independent, $E=E^{\mathrm{X}}$,

$$
-\ln \frac{\operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)(A)}{\operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}=\sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}-\sum_{S \in A^{\mathrm{xS}}} \ln \Gamma_{!} A_{S}^{\mathrm{X}}
$$

To prove this it is necessary to show that

$$
\sum_{S \in A^{\mathrm{S}}} A_{S} \ln \hat{E}_{S}^{\mathrm{X}}=\sum_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}} \ln \hat{E}_{S}^{\mathrm{X}}
$$

where $\hat{E}=\operatorname{resize}(1, E) \in \mathcal{P}$. Define $\ln \in \mathcal{A} \rightarrow\left(\mathcal{S} \rightarrow \ln \mathbf{Q}_{>0}\right)$ as $\ln (A):=$ $\left\{\left(S, \ln A_{S}\right): S \in A^{\mathrm{FS}}\right\}$, in

$$
\begin{aligned}
\sum_{S \in A^{\mathrm{S}}} A_{S} \ln \hat{E}_{S}^{\mathrm{X}} & =\sum_{S \in A^{\mathrm{S}}} A_{S} \ln \left(\hat{E}^{\mathrm{X}}\right)(S) \\
& =\sum_{S \in A^{\mathrm{S}}} A_{S} \sum_{v \in V} \ln \left(\hat{E}^{\mathrm{X}} \%\{v\}\right)(S \%\{v\}) \\
& =\sum_{v \in V} \sum_{S \in A^{\mathrm{S}}} A_{S} \ln \left(\hat{E}^{\mathrm{X}} \%\{v\}\right)(S \%\{v\}) \\
& =\sum_{v \in V} \sum_{R \in(A \%\{v\})^{\mathrm{S}}} A \%\{v\}(R) \ln \left(\hat{E}^{\mathrm{X}} \%\{v\}\right)(R) \\
& =\sum_{v \in V} \sum_{R \in\left(A^{\mathrm{X}} \%\{v\}\right)^{\mathrm{S}}} A^{\mathrm{X}} \%\{v\}(R) \ln \left(\hat{E}^{\mathrm{X}} \%\{v\}\right)(R) \\
& =\sum_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}} \ln \hat{E}_{S}^{\mathrm{X}}
\end{aligned}
$$

In this case, where the distribution histogram is independent, $E=E^{\mathrm{X}}$, the negative logarithm relative dependent multinomial probability density does not depend on the distribution histogram.

The alignment may be derived from the negative logarithm relative dependent multinomial probability density in the case when the distribution histogram is independent, $E=E^{\mathrm{X}}$,

$$
\begin{aligned}
-\ln \frac{\operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)(A)}{\operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)} & =\sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}-\sum_{S \in A^{\mathrm{xS}}} \ln \Gamma_{!} A_{S}^{\mathrm{X}} \\
& =\operatorname{alignment}(A)
\end{aligned}
$$

That is, the alignment is the negative logarithm independently-distributed relative dependent multinomial probability density.

The alignment, alignment $(A)$, does not depend on the distribution histogram,
$\forall E \in \mathcal{A}_{U, V, z_{E}}\left(E^{\mathrm{XF}} \geq A^{\mathrm{XF}} \Longrightarrow-\ln \frac{\operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)(A)}{\operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}=\operatorname{alignment}(A)\right)$
The alignment, alignment $(A)$, does not depend on the completeness or otherwise of the sample histogram, $A$,

$$
\forall U \in \mathcal{U} \forall A, B \in \mathcal{A}_{U}(A \equiv B \Longrightarrow \operatorname{alignment}(A)=\operatorname{alignment}(B))
$$

If the distribution histogram equals the independent sample, $E=A^{\mathrm{X}}$, then the negative logarithm independent-sample-distributed relative dependent multinomial probability density equals the alignment

$$
-\ln \frac{\operatorname{mpdf}(U)\left(A^{\mathrm{X}}, z\right)(A)}{\operatorname{mpdf}(U)\left(A^{\mathrm{x}}, z\right)\left(A^{\mathrm{X}}\right)}=\operatorname{alignment}(A)
$$

If the distribution histogram equals the cartesian histogram, $E=V^{\mathrm{C}}$, then the negative logarithm cartesian-distributed relative dependent multinomial probability density equals the alignment

$$
-\ln \frac{\operatorname{mpdf}(U)\left(V^{\mathrm{C}}, z\right)(A)}{\operatorname{mpdf}(U)\left(V^{\mathrm{C}}, z\right)\left(A^{\mathrm{X}}\right)}=\operatorname{alignment}(A)
$$

In the case where both the sample histogram and the independent sample are integral, $A, A^{\mathrm{X}} \in \mathcal{A}_{U, \mathrm{i}, V, z}$, and the distribution histogram is independent, $E=E^{\mathrm{X}}$, and sufficiently effective, $E^{\mathrm{F}} \geq A^{\mathrm{XF}}$, then the negative logarithm independently-distributed relative dependent multinomial probability equals the alignment expressed in terms of factorials,

$$
\begin{aligned}
-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)} & =\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!-\sum_{S \in A^{\mathrm{XS}}} \ln A_{S}^{\mathrm{X}}! \\
& =\operatorname{alignment}(A)
\end{aligned}
$$

In this case the alignment is the difference of the logarithms of the multinomial coefficients of the independent histogram and the sample histogram

$$
\operatorname{alignment}(A)=\ln \frac{z!}{\prod_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}}!}-\ln \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!}
$$

In this case, also, it is conjectured below ('Minimum alignment') that the alignment is always positive,

$$
\left(A, A^{\mathrm{X}} \in \mathcal{A}_{U, \mathrm{i}, V, z}\right) \wedge\left(E=E^{\mathrm{X}}\right) \Longrightarrow \operatorname{alignment}(A) \geq 0
$$

and so the relative dependent multinomial probability must be less than or equal to one,

$$
0<\frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)} \leq 1
$$

Therefore in this case relative probability is a probability per se.
In the case where both the sample histogram and the independent sample
are integral, $A, A^{\mathrm{X}} \in \mathcal{A}_{U, \mathrm{i}, V, z}$, and the distribution histogram is equal to the scaled independent, $E=\operatorname{resize}\left(z_{E}, A^{\mathrm{X}}\right)$, then the independent is the modal mean, $A^{\mathrm{X}}=\operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\right) \in \operatorname{modes}\left(\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\right)$. In this case the alignment is the negative logarithm modal-independently-distributed relative dependent multinomial probability,

$$
\operatorname{alignment}(A)=-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(A)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}
$$

In the cases where the distribution histogram is not independent, $E \neq E^{\mathrm{X}}$, then the alignment may not be equal to the negative logarithm relative dependent multinomial probability density. The difference is the mis-alignment $\sum\left(\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln E_{S}: S \in A^{\mathrm{XS}}\right)$. That is,

$$
-\ln \frac{\operatorname{mpdf}(U)(E, z)(A)}{\operatorname{mpdf}(U)(E, z)\left(A^{\mathrm{X}}\right)}=\operatorname{alignment}(A)-\sum_{S \in A^{\mathrm{xS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln E_{S}
$$

The mis-alignment does depend on the distribution histogram, but not its size, $z_{E}$

$$
\forall q \in \mathbf{Q}_{>0}\left(\sum_{S \in A^{\mathrm{XS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln \left(Z_{q} * E\right)(S)=\sum_{S \in A^{\mathrm{XS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln E_{S}\right)
$$

where $Z_{q}=\operatorname{scalar}(q)$.
In the derivations of alignment above, the starting point has been to take a distribution histogram $E$ and then to show that if the distribution histogram is independent, $E=E^{\mathrm{X}}$, then the alignment can be derived from it but does not depend on it. In fact, the alignment can be derived without reference to a distribution histogram at all. Consider the classification coder of histories

$$
C_{\mathrm{G}}=\operatorname{coderClassification}\left(U, X, D_{\mathrm{V}}, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)
$$

The coder domain is the finite set of histories $\mathcal{H}_{U, X} \subset \mathcal{H}_{U}$ in system $U$ where the domains of the histories are restricted to a finite subset of the event identifiers $X \subset \mathcal{X}$. Consider the history $H \in \mathcal{H}_{U, X}$ of size $z=|H|$ and variables $V=\operatorname{vars}(H)$. The total space of a classification coder of a history $H$ is the sum of the variables space, ids space, histogram counts space and events classification space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{G}}\right)(H)= & \operatorname{space\operatorname {Variables}(U)(|V|)+} \\
& \operatorname{space\operatorname {Ids}(|X|,z)+} \\
& \text { spaceCounts }(U)(A)+ \\
& \text { spaceClassification }(A)
\end{aligned}
$$

where $A=\operatorname{histogram}(H)$ and events classification space is defined

$$
\operatorname{spaceClassification}(A):=\ln z!-\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!
$$

In the case where the independent histogram, $A^{\mathrm{X}}$, is in the histograms of the coder domain, $A^{\mathrm{X}} \in\left\{\operatorname{histogram}(G): G \subseteq \mathcal{H}_{U, X}\right\}$, and is therefore integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathbf{i}}$, then the classification coder space of history $H$ may be decomposed into (i) the independent classification coder space and (ii) relative dependent classification coder space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{G}}\right)(H)= & \text { spaceVariables }(U)(|V|)+ \\
& \text { spaceIds }(|X|, z)+ \\
& \text { spaceCounts }(U)\left(A^{\mathrm{X}}\right)+ \\
& \text { spaceClassification }\left(A^{\mathrm{X}}\right)+ \\
& (\text { spaceClassification }(A)- \\
& \text { spaceClassification } \left.\left(A^{\mathrm{X}}\right)\right)
\end{aligned}
$$

In this case the negative relative dependent classification coder space equals the alignment

$$
\begin{aligned}
& -\left(\text { spaceClassification }(A)-\operatorname{spaceClassification}\left(A^{\mathrm{X}}\right)\right) \\
& =\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!-\sum_{S \in A^{\mathrm{xS}}} \ln A_{S}^{\mathrm{X}}!=\operatorname{alignment}(A)
\end{aligned}
$$

In the case where the sample histogram is independent, $A=A^{\mathrm{X}}$, the negative relative dependent classification coder space is 0

$$
-\left(\operatorname{spaceClassification}\left(A^{\mathrm{X}}\right)-\operatorname{spaceClassification}\left(A^{\mathrm{X}}\right)\right)=0
$$

Although there is no mention of a distribution histogram in this derivation, it may be viewed as defaulting to the cartesian histogram, $V^{\mathrm{C}}$.

### 4.3 Alignment of types of histogram

### 4.3.1 Diagonal alignment

The alignment of a uniform full diagonal regular histogram of size $z$, dimension $n$ and valency $d$ is

$$
d \ln \Gamma!\frac{z}{d}-d^{n} \ln \Gamma!\frac{z}{d^{n}}
$$

A uniform full diagonal regular histogram is maximally diagonal. If the size is scaled by valency, $z=d x$ where $x$ is the size per value, then the nonindependent term scales with valency for given size per value, $d \ln \Gamma_{!}(z / d)=$ $d \ln \Gamma_{!} x$.

Applying Stirling's approximation, the alignment approximates to $z(n-$ 1) $\ln d$. Thus diagonal alignment increases linearly with increasing size or dimension, and logarithmically with valency. Note that the first term decreases with increasing valency but the second term decreases more rapidly.

A uniform full anti-diagonal histogram is planar and hence its alignment is zero.

### 4.3.2 Crown alignment

The alignment of a uniform full crown histogram of size $z$ and dimension $n>0$ is

$$
n \ln \Gamma!\frac{z}{n}-\sum_{k \in\{0 \ldots n\}} \frac{n!}{k!(n-k)!} \ln \Gamma!\frac{(n-1)^{k} z}{n^{n}}
$$

A uniform full crown histogram is maximally orthogonal. If the size is scaled by dimension, $z=n x$ where $x$ is the size per dimension, then the non-independent term scales with dimension for given size per dimension, $n \ln \Gamma_{!}(z / n)=n \ln \Gamma_{!} x$.

The alignment increases with size and dimension. Valencies greater than two have the same alignment because in each effective state each variable has exactly one of two values, $\forall w \in V\left(\left|A^{\mathrm{F}} \%\{w\}\right|=2\right)$. Thus the cartesian sub-volume of the independent is effectively bi-valent, $\left|A^{\mathrm{XF}}\right|=2^{n}$.

### 4.3.3 Axial alignment

The alignment of a uniform full axial regular histogram missing the pivot of size $z$, dimension $n$ and valency $d$ is

$$
\begin{aligned}
& b \ln \Gamma!\frac{z}{b}-\sum_{k \in\{0 \ldots n\}} \frac{n!}{k!(n-k)!}(d-1)^{k} \ln \Gamma!\frac{(n-1)^{n-k} z}{n^{n}(d-1)^{k}} \\
= & b \ln \Gamma!\frac{z}{b}-\sum_{k \in\{0 \ldots n\}} \frac{n!}{k!(n-k)!}(d-1)^{k} \ln \Gamma!\frac{(b-(d-1))^{n-k} z}{b^{n}}
\end{aligned}
$$

where the cardinality of effective states is $b=n(d-1)$.

The alignment of a uniform full axial regular histogram with a pivot is

$$
c \ln \Gamma!\frac{z}{c}-\sum_{k \in\{0 \ldots n\}} \frac{n!}{k!(n-k)!}(d-1)^{k} \ln \Gamma!\frac{(c-(d-1))^{n-k} z}{c^{n}}
$$

where the cardinality of effective states is $c=b+1$ and the cardinality of non-pivot effective states is $b=n(d-1)$.

In the case of uniform full axial regular histogram missing the pivot, of size $(1-p) z$, plus a singleton of the pivot state, of size $p z$, where the pivot fraction is $p \in \mathbf{Q}$ such that $0 \leq p \leq 1$, the alignment is

$$
b \ln \Gamma!\frac{q z}{b}+\ln \Gamma!p z-\sum_{k \in\{0 \ldots n\}} \frac{n!}{k!(n-k)!}(d-1)^{k} \ln \Gamma!\frac{q^{k}(n-q)^{n-k} z}{n^{n}(d-1)^{k}}
$$

where the cardinality of effective states is $c=b+1$, the cardinality of nonpivot effective states is $b=n(d-1)$ and the non-pivot fraction is $q=1-p$. The alignment varies between (i) zero where the pivot fraction is one, $p=1$, and the histogram is effectively singleton, (ii) the alignment of the with-pivot case where the pivot fraction $p=1 / c$, and (iii) the alignment of the withoutpivot case where the pivot fraction is zero, $p=0$.

A uniform full axial regular histogram missing the pivot is part diagonal and part orthogonal. If the size is scaled by dimension times the non-null valency, $z=n(d-1) x$ where $x$ is the size per dimension per non-null value, then the non-independent term scales with dimension times the non-null valency for given size per dimension per non-null value, $b \ln \Gamma_{!}(z / b)=n(d-1) \ln \Gamma_{!} x$. If the histogram is bi-valent, $d=2$, then the uniform full axial regular histogram missing the pivot is a uniform full crown histogram and therefore orthogonal. Otherwise the uniform full axial regular histogram missing the pivot is partly diagonal. In the case of uniform full axial regular histogram with non-zero pivot count, the histogram is partly singleton.

Axial histograms are intermediate between diagonal, orthogonal and singleton. The smaller the valency, the more orthogonal. The larger the pivot count, the more singleton.

### 4.3.4 Skeletal alignment

A uniform full regular skeleton histogram $A$ can be defined such that the variables $V=\operatorname{vars}(A)$ map to the derived variables of the nullable transform
$D^{\mathrm{T}}$ of a well behaved decomposition $D \in \mathcal{D}_{\mathrm{w}, U}, V \leftrightarrow \operatorname{der}\left(D^{\mathrm{T}}\right)$.
Given valency $d \in \mathbf{N}_{>0}$, let $Q \in \operatorname{trees}(\mathcal{V} \times\{1 \ldots d\})$ be a tree of depth $l \in \mathbf{N}_{>0}$ such that (i) $\forall L \in \operatorname{paths}(Q)(|\operatorname{dom}(\operatorname{set}(L))|=|L|=l)$ and (ii) $\forall X \in\{Q\} \cup \operatorname{ran}(\operatorname{nodes}(Q))(X \neq \emptyset \Longrightarrow(|X|=d) \wedge(|\operatorname{dom}(\operatorname{dom}(X))|=$ 1) $\wedge(\operatorname{ran}(\operatorname{dom}(X))=\{1 \ldots d\}))$. Then a skeletal histogram of size $z$ can be constructed $A=\operatorname{resize}(z,\{S \cup((V \backslash \operatorname{vars}(S)) \times\{\operatorname{null}\}): L \in \operatorname{paths}(Q), S=$ $\left.\operatorname{set}(L)\}^{\mathrm{U}}\right) \in \mathcal{A}$ where $V=\operatorname{dom}(\operatorname{elements}(Q))$ and the null value is null $\in \mathcal{W}$. Then (i) $\operatorname{skeletal}(A)$, (ii) $\operatorname{size}(A)=z$, (iii) $\operatorname{ran}(A)=\left\{z / d^{l}\right\}$ and (iv) $\forall w, u \in$ $V(\operatorname{axial}(A \%\{w, u\}))$. The dimension is $n=|V|=\sum d^{i-1}: i \in\{1 \ldots l\}$. The volume is $v=\left|A^{\mathrm{C}}\right|=d(d+1)^{n-1}$. The effective states $b=\left|A^{\mathrm{F}}\right|=d^{l}$.

The alignment of uniform full regular skeleton histogram $A$ is

$$
\begin{aligned}
& b \ln \Gamma!\frac{z}{b}- \\
& \quad \sum\left(\frac{n!}{p(n-m)!} d^{m} \ln \Gamma!\left(\frac{z}{d^{m}} \prod_{i \in\{1 \ldots l\}} \frac{\left(d^{i-1}-1\right)^{d^{i-1}-K_{i}}}{d^{(i-1) d^{i-1}}}\right):\right. \\
& \left.\quad K \in \prod_{i \in\{1 \ldots l\}}\{i\} \times\left\{1 \ldots d^{i-1}\right\}, m=\sum_{i \in\{1 \ldots l\}} K_{i}, p=\prod_{i \in\{1 \ldots l\}} K_{i}!\right)
\end{aligned}
$$

If the depth, $l$, is constrained such that the counts of the histogram, $A$, are at least one, $l=\lfloor\ln z / \ln d\rfloor$, the skeleton alignment is minimised at integral valency $d=2$. That is, where the regular skeleton tree, $Q$, is a binary tree.

### 4.3.5 Pivoted alignment

The alignment of a uniform full pivoted regular histogram of size z, dimension $n$ and valency $d$ is

$$
b \ln \Gamma!\frac{z}{b}-\sum_{k \in\{0 \ldots n\}}\binom{n}{k}(d-1)^{k} \ln \Gamma!\frac{(d-1)^{k(n-1)} z}{b^{n}}
$$

where the cardinality of effective states is $b=(d-1)^{n}+1$. When the regular histogram is bi-valent, $d=2$, the histogram is diagonalised. So the cardinality of effective states is two, $b=d$, and the alignment equals the diagonal alignment.

A uniform full pivoted regular histogram is roughly volumar. If the size is scaled by volume, $z=d^{n} x$ where $x$ is the size per volume, then the nonindependent term approximately scales with volume for given size per volume,
$b \ln \Gamma_{!}(z / b) \approx d^{n} \ln \Gamma_{!} x$.
The alignment of a full pivoted regular histogram that has uniform non-pivot states and a pivot state of size $p z$, where the pivot fraction is $p \in\{x: x \in$ $\mathbf{Q}, 0 \leq x \leq 1\}$, is
$\ln \Gamma_{!} p z+(d-1)^{n} \ln \Gamma_{!} q z-\sum_{k \in\{0 \ldots n\}}\binom{n}{k}(d-1)^{k} \ln \Gamma_{!}(d-1)^{k(n-1)} q^{k} p^{n-k} z$
where the non-pivot fraction of a single non-pivot state is $q=(1-p) /(d-1)^{n}$.
The alignment of a uniform full anti-pivoted regular histogram of size z, dimension $n$ and valency $d$ is

$$
b \ln \Gamma_{!} \frac{z}{b}-\sum_{k \in\{0 \ldots n\}}\binom{n}{k}(d-1)^{k} \ln \Gamma_{!} \frac{\left(d^{n-1}-(d-1)^{n-1}\right)^{k}\left(d^{n-1}-1\right)^{n-k} z}{b^{n}}
$$

where the cardinality of effective states is $b=d^{n}-\left((d-1)^{n}+1\right)$. When the regular histogram is bi-valent, $d=2$, the histogram is complement diagonal. When the regular histogram is bi-variate, $n=2$, the histogram is axial missing the pivot.

A uniform full anti-pivoted regular histogram is also roughly volumar.

### 4.4 Scaled alignment

The alignment of a scaled histogram $Z_{k} * A$, where $k \in \mathrm{Q}_{\geq 0}$ and $Z_{k}=$ $\operatorname{scalar}(k)$, weakly approximates to the scaled alignment of the histogram, $\operatorname{alignment}\left(Z_{k} * A\right) \approx k \times \operatorname{alignment}(A)$

$$
\begin{aligned}
\operatorname{alignment}\left(Z_{k} * A\right) & =-\ln \frac{\operatorname{mpdf}(U)\left(E^{\mathrm{x}}, k z\right)\left(Z_{k} * A\right)}{\operatorname{mpdf}(U)\left(E^{\mathrm{X}}, k z\right)\left(Z_{k} * A^{\mathrm{X}}\right)} \\
& \approx-\ln \left(\frac{\operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)(A)}{\operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}\right)^{k} \\
& =k \times \operatorname{a\operatorname {lignment}(A)}
\end{aligned}
$$

Thus scale analysis suggests that alignment has the units of size.

The scaled multinomial probability density function

$$
\operatorname{mpdf}(U)\left(E^{\mathrm{X}}, k z\right)\left(Z_{k} * A\right) \approx\left(\operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)(A)\right)^{k}
$$

approximates best for high entropy sample histograms for which the multinomial coefficient is largest. The entropy of the independent histogram is often greater than that of the histogram, entropy $\left(A^{\mathrm{X}}\right) \geq$ entropy $(A)$ (see 'Minimum alignment' below), so the approximation is best for low alignments.

### 4.5 Minimum alignment

If a histogram is integral, $A \in \mathcal{A}_{\mathrm{i}}$, and the independent histogram, $A^{\mathrm{X}}$, is such that all of the counts are fractional, $\forall c \in \operatorname{ran}\left(A^{\mathrm{X}}\right)(0 \leq c \leq 1)$, then the gamma functions of the counts are such that $\forall c \in \operatorname{ran}\left(A^{\mathrm{X}}\right)\left(0!\geq \Gamma_{!} c \leq 1!\right)$. Hence $\sum_{S \in A^{\mathrm{xS}}} \ln \Gamma_{!} A_{S}^{\mathrm{X}} \leq 0$ and so the alignment is positive, $\operatorname{algn}(A) \geq 0$. Note that in this case $z \leq v$ where $z=\operatorname{size}(A)$ and $v=\left|A^{\mathrm{C}}\right|$.

If the independent histogram is integral scaled uniform cartesian, $A^{\mathrm{X}}=$ $Z_{z / v} * V^{\mathrm{C}} \in \mathcal{A}_{\mathrm{i}}$ where $Z_{x}=\operatorname{scalar}(x), V=\operatorname{vars}(A), z=\operatorname{size}(A)$ and $v=\left|V^{\mathrm{C}}\right|$ such that $z / v \in \mathbf{N}_{>0}$, then its multinomial coefficient

$$
\frac{z!}{\prod_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}}!}=\frac{z!}{((z / v)!)^{v}}
$$

is maximised. The classification space is the logarithm of the multinomial coefficient and so it is maximised too

$$
0 \leq \operatorname{spaceClassification}(A) \leq \text { spaceClassification }\left(A^{\mathrm{X}}\right)=\ln z!-v \ln (z / v)!
$$

See 'Classification space' above for a discussion showing that the classification space is maximised at maximum entropy. Thus in this case the alignment is positive

$$
\operatorname{algn}(A)=\operatorname{spaceClassification}\left(A^{\mathrm{X}}\right)-\operatorname{spaceClassification}(A) \geq 0
$$

Note that there exists a non-singleton set of integral iso-independents of integral scaled uniform cartesian independent, $\left|Y_{U, i, V, z}^{-1}\left(Z_{z / v} * V^{\mathrm{C}}\right)\right|>1$, if the histogram is pluri-variate, $|V|>1$, and each variable is pluri-valent, $\forall w \in$ $V\left(\left|U_{w}\right|>1\right)$, for all $z / v \in \mathbf{N}_{>0}$. Of the integral iso-independents set only the independent histogram has zero alignment, $Z_{z / v} * V^{\mathrm{C}} \in Y_{U, \mathrm{i}, V, z}^{-1}\left(Z_{z / v} * V^{\mathrm{C}}\right)$ and $\operatorname{algn}\left(Z_{z / v} * V^{\mathrm{C}}\right)=0$. The others have alignment greater than zero, $\forall B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(Z_{z / v} * V^{\mathrm{C}}\right)\left(B \neq Z_{z / v} * V^{\mathrm{C}} \Longrightarrow \operatorname{algn}(B)>0\right)$.

The minimum alignment conjecture states that if the independent histogram is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, then the minimum alignment is conjectured to be zero,

$$
\forall A \in \mathcal{A}\left(A^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}} \Longrightarrow \operatorname{algn}(A) \geq 0\right)
$$

or $\operatorname{minr}\left(\left\{(A, \operatorname{algn}(A)): A \in \mathcal{A}, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right\}\right) \geq 0$. This is a consequence of the integral mean multinomial probability distribution conjecture which states that if the mean of the multinomial probability distribution is integral then it is also modal, mean $\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right) \in \mathcal{A}_{i} \Longrightarrow \operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right) \in$ $\operatorname{modes}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)$. Thus for complete integral independent histogram $\left(A^{\mathrm{XU}}=\right.$ $\left.A^{\mathrm{C}}\right) \wedge\left(A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right) \Longrightarrow A^{\mathrm{X}} \in \mathcal{A}_{U, \mathrm{i}, V, z}$ and $A^{\mathrm{X}}=\operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\right) \Longrightarrow$ $A^{\mathrm{X}} \in \operatorname{maxd}\left(\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\right)$. Thus

$$
\begin{aligned}
& \forall A \in \mathcal{A}_{U, \mathrm{i}, V, z}\left(A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}} \Longrightarrow\right. \\
& \left.\quad \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}}\left(\frac{A_{S}^{\mathrm{X}}}{z}\right)^{A_{S}} \leq \frac{z!}{\prod_{S \in A^{\mathrm{xS}}} A_{S}^{\mathrm{X}!}} \prod_{S \in A^{\mathrm{xS}}}\left(\frac{A_{S}^{\mathrm{X}}}{z}\right)^{A_{S}^{\mathrm{X}}}\right)
\end{aligned}
$$

where $z=\operatorname{size}(A)>0$. The distribution histogram, $A^{\mathrm{X}}$, is independent so

$$
\forall A \in \mathcal{A}_{U, \mathrm{i}, V, z}\left(A^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}} \Longrightarrow \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \leq \frac{z!}{\prod_{S \in A^{\mathrm{xS}}} A_{S}^{\mathrm{X}!}!}\right)
$$

Alignment does not depend on completeness, $\operatorname{algn}(A)=\operatorname{algn}\left(A+A^{\mathrm{CZ}}\right)=$ $\operatorname{algn}\left(A * A^{\mathrm{F}}\right)$, thus integral independent histogram implies positive alignment, $\forall A \in \mathcal{A}\left(A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}} \Longrightarrow \operatorname{algn}(A) \geq 0\right)$.

Moreover, within the degree to which Stirling's approximation holds, the minimum alignment is zero even for non-integral independent histogram. Utilising the identity

$$
\sum_{S \in N^{\mathrm{FS}}} N_{S} \ln N_{S}^{\mathrm{X}}=\sum_{S \in N^{\mathrm{XFS}}} N_{S}^{\mathrm{X}} \ln N_{S}^{\mathrm{X}}
$$

where $N \in \mathcal{A} \cap \mathcal{P}$, and noting that the relative entropy between the sample histogram and its independent histogram is greater than or equal to zero by Gibbs' inequality, then

$$
\begin{aligned}
\operatorname{alignment}(A) & :=\sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}-\sum_{S \in A^{\mathrm{XS}}} \ln \Gamma_{!} A_{S}^{\mathrm{X}} \\
& \approx z \sum_{S \in N^{\mathrm{FS}}} N_{S} \ln N_{S}-z \sum_{S \in N^{\mathrm{XFS}}} N_{S}^{\mathrm{X}} \ln N_{S}^{\mathrm{X}} \\
& =z \sum_{S \in N^{\mathrm{FS}}} N_{S} \ln N_{S}-z \sum_{S \in N^{\mathrm{FS}}} N_{S} \ln N_{S}^{\mathrm{X}} \\
& =z \sum_{S \in N^{\mathrm{FS}}} N_{S} \ln \frac{N_{S}}{N_{S}^{\mathrm{X}}} \\
& =z \times \operatorname{entropyRelative}\left(N, N^{\mathrm{X}}\right) \\
& \geq 0
\end{aligned}
$$

where $z=\operatorname{size}(A)>0$ and $N=\operatorname{resize}(1, A) \in \mathcal{P}$. Alignment is approximately equal to the scaled difference between the entropy of the independent histogram and the entropy of the histogram, which in this case is the scaled relative entropy between histogram and independent, or scaled mutual entropy

$$
\begin{aligned}
\operatorname{alignment}(A) & \approx z \times \operatorname{entropy}\left(A^{\mathrm{X}}\right)-z \times \operatorname{entropy}(A) \\
& =z \times \operatorname{entropyRelative}\left(A, A^{\mathrm{X}}\right)
\end{aligned}
$$

Thus entropy $\left(A^{\mathrm{X}}\right) \geq \operatorname{entropy}(A)$.
Similar logic was used above to show that the log of the generalised multinomial probability distribution, $\ln \circ \hat{Q}_{\mathrm{m}, U}(E, z) \in \mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathbf{R}$, can be approximated by the negative relative entropy between the sample histogram and the distribution histogram by means of the Stirling approximation

$$
\hat{Q}_{\mathrm{m}, U}(E, z)(A)=z!\prod_{S \in A^{\mathrm{S}}} \frac{P_{S}^{A_{S}}}{A_{S}!} \approx \prod_{S \in A^{\mathrm{FS}}}\left(\frac{P_{S}}{N_{S}}\right)^{A_{S}}
$$

where $P=\operatorname{resize}(1, E)$ and $N=\operatorname{resize}(1, A)$. So

$$
\ln \operatorname{mpdf}(U)(E, z)(A) \approx \sum_{S \in A^{\mathrm{S}}} A_{S} \ln \frac{P_{S}}{N_{S}}=-z \sum_{S \in N^{\mathrm{FS}}} N_{S} \ln \frac{N_{S}}{P_{S}}
$$

where $A^{\mathrm{F}} \leq E^{\mathrm{F}}$. Let the distribution histogram equal the independent histogram, $E=A^{\mathrm{X}}$, then

$$
\begin{aligned}
\ln \operatorname{mpdf}(U)\left(A^{\mathrm{X}}, z\right)(A) & \approx-z \sum_{S \in N^{\mathrm{FS}}} N_{S} \ln \frac{N_{S}}{N_{S}^{\mathrm{X}}} \\
& \approx-\operatorname{alignment}(A) \\
& =\ln \frac{\operatorname{mpdf}(U)\left(A^{\mathrm{X}}, z\right)(A)}{\operatorname{mpdf}(U)\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}
\end{aligned}
$$

which implies that $\operatorname{mpdf}(U)\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right) \approx 1$ within the Stirling approximation and that the alignment is positive.

As shown above, the gamma function is log convex and hence the expected logarithm of the factorial of the counts of the states of the sample histograms is greater than or equal to the logarithm of the factorial of the counts of the states of the mean histogram by Jensen's inequality

$$
\forall S \in V^{\mathrm{CS}}\left(\operatorname{expected}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\left(\left\{\left(A, \ln A_{S}!\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right) \geq \ln \Gamma_{!} M_{S}\right)
$$

where the mean histogram is $M=\operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)$. Consider a draw of size $z$ from independent distribution histogram $E^{\mathrm{X}}$. Let

$$
Y=\left\{\left(S, \operatorname{expected}\left(\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)\right)\left(\left\{\left(A, \ln A_{S}!\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right)\right): S \in V^{\mathrm{CS}}\right\}
$$

and $X=\left\{\left(S, \Gamma_{!}^{-1}\left(e^{y}\right)\right):(S, y) \in Y\right\} \in \mathcal{S}_{U} \rightarrow \mathbf{R}$. Let $X^{\prime}$ be a histogram, which is a rational valued function, that approximates closely to $X$, which is a real valued function, $X^{\prime} \approx X$. Let $z^{\prime}=\operatorname{size}\left(X^{\prime}\right)$. Conjecture that $z^{\prime} \geq z$. Conjecture that $\operatorname{scalar}\left(z / z^{\prime}\right) * X^{\prime} \approx \operatorname{scalar}\left(z / z_{E}\right) * E^{\mathrm{X}}$, but that $\operatorname{algn}\left(\operatorname{scalar}\left(z / z^{\prime}\right) * X^{\prime}\right) \geq 0$. That is, even where the alignment is small, the $\log$ convexity tends to make it positive.

However, alignment is negative for some histograms. For example, the alignment of a uniform full anti-pivoted regular histogram $A$ of size $z=1000$, dimension $n=2$ and valency $d=101$ is

$$
\begin{aligned}
& \operatorname{algn}(A)= \\
& \quad b \ln \Gamma!\frac{z}{b}-\sum_{k \in\{0 \ldots n\}} \frac{n!}{k!(n-k)!}(d-1)^{k} \ln \Gamma!\frac{z(n-1)^{k}}{n^{n}(d-1)^{k}} \approx-277.52
\end{aligned}
$$

where the cardinality of effective states is $b=d^{n}-\left((d-1)^{n}+1\right)=200$. Note that the independent of the example uniform full anti-pivoted regular histogram is non-integral, $A^{\mathrm{X}} \notin \mathcal{A}_{\mathrm{i}}$. The independent cannot be the distribution histogram of a generalised multinomial probability distribution. The independent is not maximal in the multinomial probability density function parameterised by the independent, $\operatorname{mpdf}(U)\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)<\operatorname{mpdf}(U)\left(A^{\mathrm{X}}, z\right)(A)$.

Conjecture that there exist non-integral histograms which are not independent but have zero alignment, $\exists A \in \mathcal{A}\left(A \neq A^{\mathrm{X}} \wedge \operatorname{algn}(A)=0\right)$. However, although the example above, of a uniform full anti-pivoted regular histogram of dimension $n=2$ and valency $d=101$, has a real solution of $z \approx 3850.38 \in \mathbf{R}$ such that alignment equals zero, there may not be a rational solution size $z \in \mathbf{Q}$.

The minimum alignment is sometimes negative, depending on the geometry of the variables $V$ in system $U$, and the size $z$. However, conjecture that the expected alignment is always positive if the sample histograms are drawn from the generalised multinomial probability distribution where the distribution
histogram is independent, $E=E^{\mathrm{X}}$. The expected exponential alignment is

$$
\begin{aligned}
& \operatorname{expected}\left(\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)\right)\left(\left\{(A, \exp (\operatorname{algn}(A))): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right) \\
& =\sum_{A \in \mathcal{A}_{U, \mathrm{i}, V, z}} \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}}\left(\frac{E_{S}^{\mathrm{X}}}{z_{E}}\right)^{A_{S}} \frac{\operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}{\operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)(A)} \\
& =\sum_{A \in \mathcal{A}_{U, \mathrm{i}, V, z}} \frac{z!}{\prod_{S \in A^{\mathrm{xS}}} \Gamma_{!} A_{S}^{\mathrm{X}}} \prod_{S \in A^{\mathrm{X}}}\left(\frac{E_{S}^{\mathrm{X}}}{z_{E}}\right)^{A_{S}^{\mathrm{X}}} \\
& =\sum_{A \in \mathcal{A}_{U, \mathrm{i}, V, z}} \operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right) \\
& =\operatorname{expected}\left(\hat{Q}_{\mathrm{u}, U}(V, z)\right)\left(\left\{\left(A, \operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right) \times\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right| \\
& \geq \operatorname{expected}\left(\hat{Q}_{\mathrm{u}, U}(V, z)\right)\left(\left\{\left(A, \operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)(A)\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right) \times\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right| \\
& =\operatorname{sum}\left(\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)\right)=1
\end{aligned}
$$

where $\hat{Q}_{\mathrm{u}, U}(V, z)$ is the uniform probability distribution and $\exp \in \mathbf{R} \rightarrow$ $\mathbf{R}$ is the exponential function. The entropy of the independent histogram is greater than or equal to the entropy of the histogram, entropy $\left(A^{\mathrm{X}}\right) \geq$ entropy $(A)$. So the probability of drawing the independent histogram, $A^{\mathrm{X}}$, from an independent distribution, $E^{\mathrm{X}}$, is expected in the uniform probability distribution, $\hat{Q}_{\mathrm{u}, U}(V, z)$, to be greater than or equal to that of the sample histogram, $A$. If the expected exponential alignment is conjectured to be greater than or equal to 1 then conjecture that the expected alignment is positive

$$
\operatorname{expected}\left(\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)\right)\left(\left\{(A, \operatorname{algn}(A)): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right) \geq 0
$$

However, note that Jensen's inequality implies that the expected alignment is only less than or equal to the logarithm of the expected exponential alignment

$$
\begin{aligned}
& \exp \left(\operatorname{expected}\left(\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{x}}, z\right)\right)\left(\left\{(A, \operatorname{algn}(A)): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right)\right) \\
& \quad \leq \operatorname{expected}\left(\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{x}}, z\right)\right)\left(\left\{(A, \exp (\operatorname{algn}(A))): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right)
\end{aligned}
$$

In the case where $E=V^{\mathrm{C}}$ then the sum must be less than the maximum entropy histogram, $A=\operatorname{resize}\left(z, V^{\mathrm{C}}\right)$

$$
\begin{aligned}
& \operatorname{expected}\left(\hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)\right)\left(\left\{(A, \exp (\operatorname{algn}(A))): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right) \\
& \quad \leq \sum_{A \in \mathcal{A}_{U, \mathrm{i}, V, z}} \frac{z!}{\prod_{S \in V^{\mathrm{CS}}} \Gamma_{!}(z / v)} \prod_{S \in V^{\mathrm{CS}}}\left(\frac{1}{v}\right)^{z / v}=\frac{(z+v-1)!}{(v-1)!} \frac{1}{((z / v)!)^{v}} \frac{1}{v^{z}}
\end{aligned}
$$

where $v=\left|V^{\mathrm{C}}\right|$. Hence, by Jensen's inequality

$$
\begin{aligned}
& \operatorname{expected}\left(\hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)\right)\left(\left\{(A, \operatorname{algn}(A)): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right) \\
& \leq \ln (z+v-1)!-\ln (v-1)!-v \ln (z / v)!-z \ln v
\end{aligned}
$$

If $z \gg v$ then this approximates to $v \ln (z / v)$. Therefore conjecture that expected alignment varies as the volume for constant size greater than the volume

$$
\operatorname{expected}\left(\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)\right)\left(\left\{(A, \operatorname{algn}(A)): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right) \sim v
$$

If $z \ll v$ then the expression above approximates to $z \ln (v / z)$. Conjecture that expected alignment varies as the logarithm of the volume for constant size less than the volume

$$
\operatorname{expected}\left(\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)\right)\left(\left\{(A, \operatorname{algn}(A)): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right) \sim \ln v
$$

The partially independent set $R_{A}$ of histogram $A$ of variables $V=\operatorname{vars}(A)$ is the set of partially independent histograms

$$
R_{A}=\left\{Z_{A} * \prod\left\{\frac{A}{Z_{A}} \% C: C \in P\right\}: P \in \mathrm{~B}(V)\right\}
$$

where $Z_{A}=\operatorname{scalar}(\operatorname{size}(A))$. The independent is a member, $A^{\mathrm{X}} \in R_{A}$. The alignment of the partially independent histograms is such that

$$
\forall B \in R_{A}(0 \leq \operatorname{algn}(B) \leq \operatorname{algn}(A))
$$

in the case where $\operatorname{algn}(A) \geq 0$.

### 4.6 Maximum alignment

The maximum alignment of a histogram $A$ is conjectured to occur when the histogram is both uniform, $|\operatorname{ran}(\operatorname{trim}(A))|=1$, and fully diagonalised, diagonalFull $(U)(A)$. The set of congruent maximum alignment histograms for a set of variables $V$ in system $U$ can be calculated explicitly. There is a uniform histogram of size $z$ for each of the subsets of the cartesian states having maximum cardinality and which are such that the elements have zero mutual incidence, $\left\{\operatorname{resize}(z, A): A \in \mathrm{P}\left(V^{\mathrm{C}}\right)\right.$, diagonalFull $\left.(U)(A)\right\}$.

The maximum alignment of a regular histogram $A$ with variables $V$ in system $U$ and size $z=\operatorname{size}(A)$, dimension $n=|V|$ and valency $d$, where $\{d\}=\left\{\left|U_{v}\right|: v \in V\right\}$, is

$$
d \ln \Gamma!\frac{z}{d}-d^{n} \ln \Gamma!\frac{z}{d^{n}}
$$

If a histogram is not regular, its maximum alignment is that of a regular histogram of the same size $z$ and dimension $n$ having valency $d$ equal to the minimum valency, $d=\operatorname{minr}\left(\left\{\left(v,\left|U_{v}\right|\right): v \in V\right\}\right)$. This regular histogram is effectively congruent to the independent histogram's cartesian sub-volume, $\left|A^{\mathrm{XF}}\right|=d^{n}$. Define alignmentMaximum $(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathbf{Q}_{\geq 0} \rightarrow \mathbf{R}$

$$
\operatorname{alignmentMaximum}(U)(V, z):=d \ln \Gamma!\frac{z}{d}-d^{n} \ln \Gamma!\frac{z}{d^{n}}
$$

where $n=|V|$ and $d=\operatorname{minr}\left(\left\{\left(v,\left|U_{v}\right|\right): v \in V\right\}\right)$. alignmentMaximum is undefined for scalars, $V=\emptyset$.

If a uniform diagonalised histogram is not fully diagonalised its alignment is equal to the maximum alignment of the regular histogram having the same dimension $n$ and valency $d$ equal to the effective valency of the independent histogram's cartesian sub-volume, $d=\left|A^{\mathrm{XF}}\right|^{1 / n}$.

Applying Stirling's approximation, the maximum alignment approximates to $z(n-1) \ln d$. So maximum alignment increases with increasing size, dimension and valency. For a given set of variables $V$, the alignment is of the same complexity as the size, alignment $\in \mathrm{O}($ size,$m)$ where the multiplier $m$ depends on the dimension and valencies of $V$.

In some special cases, the application of Stirling's approximation is exact, $\operatorname{alignmentMaximum}(U)(V, z)=z(n-1) \ln d$. Zero histograms, $z=0$, and mono-variate histograms, $n=1$, have zero alignment and zero maximum alignment in the approximation. Pluri-variate singleton histograms satisfy the requirement for zero incidence, but the maximum alignment is zero because they are effectively mono-valent, $\ln d=0$.

Consider constructing a single derived variable $w$ of valency equal to the effective cardinality of a diagonalised pluri-variate histogram $A$ in a system $U$ such that $U_{w}=\operatorname{states}\left(A^{\mathrm{F}}\right)$ then we can calculate a mono-variate histogram $B=\{(\{(w, S)\}, c):(S, c) \in \operatorname{trim}(A)\}$ that represents the diagonal of $A$. The events classification space of the derived histogram spaceClassification $(B)$ is maximised when the alignment of the diagonalised histogram is maximised. In other words, the entropy of the diagonal is maximised when alignment is maximised. Let $D$ be the set of diagonalised histograms of size $z$ and variables $V$ in a system $U, D \in \mathrm{P}\left(\mathcal{A}_{U}\right)$

$$
D=\left\{A: A \in \mathcal{A}_{U}, \operatorname{vars}(A)=V, \operatorname{size}(A)=z, \operatorname{diagonal}(A)\right\}
$$

then

$$
\begin{aligned}
\operatorname{maxd}(\{(A, \operatorname{algn}(A)): A \in D\}) & =\operatorname{maxd}(\{(A, \operatorname{spCl}(A)): A \in D\}) \\
& =\operatorname{maxd}(\{(A, \operatorname{entropy}(A)): A \in D\})
\end{aligned}
$$

where algn $=$ alignment and $\mathrm{spCl}=$ spaceClassification. This is counterintuitive because a glance at the definition of alignment would suggest that maximum alignment would increase with decreasing events classification space. But as the maximum is approached the sensitivity to the independent events classification space becomes more important. For example a singleton which has a low events classification space, but also has an equally low independent events classification space and hence zero alignment.

Consider the effective states states $\left(A^{\mathrm{F}}\right)$ of a diagonalised histogram that is not necessarily at maximum alignment. The subsets of the states which are incident on each of the states on the diagonal form a set of exclusive singleton histograms and thus independent histograms
$\forall A \in \mathcal{A}\left(\operatorname{diagonal}(A) \Longrightarrow\left(\forall S \in A^{\mathrm{FS}} \diamond B=A \backslash \operatorname{incidence}(A, S, 0)\left(B=B^{\mathrm{X}}\right)\right)\right)$
In other words, the partition of the volume of diagonalised histogram $A$, $\left\{A \backslash\right.$ incidence $\left.(A, S, 0): S \in A^{\mathrm{FS}}\right\} \in \mathrm{B}\left(A^{\mathrm{CS}}\right)$, which has the components corresponding to each of these singletons, consists of a set of independent histograms.

### 4.7 Dependent alignment

Given a substrate histogram $A \in \mathcal{A}_{U, V, z}$, the independent, $A^{\mathrm{X}} \in \mathcal{A}_{U, V, z}$, is conjectured in section 'Likely histograms', above, to be the maximum likelihood estimate of the sum of the generalised multinomial probabilities of the integral iso-independents of the histogram, A,

$$
\left\{A^{\mathrm{x}}\right\}=\operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

where the integral iso-independents is

$$
Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{x}}=A^{\mathrm{x}}\right\}
$$

The corresponding dependent histogram, $A^{\mathrm{Y}} \in \mathcal{A}_{U, V, z}$, is defined

$$
\left\{A^{\mathrm{Y}}\right\}=\operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

Alignment may be defined as the negative logarithm independent-sampledistributed relative dependent multinomial probability density

$$
\operatorname{algn}(A)=-\ln \frac{\operatorname{mpdf}(U)\left(A^{\mathrm{x}}, z\right)(A)}{\operatorname{mpdf}(U)\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}
$$

which is the independent-distributed-relative multinomial space,

$$
\operatorname{algn}(A)=\operatorname{spaceRelative}\left(A^{\mathrm{X}}\right)(A)
$$

where the distribution-relative multinomial space is defined, in section 'Likely histograms', above, as

$$
\text { spaceRelative }(E)(A):=-\ln \frac{\operatorname{mpdf}(U)(E, z)(A)}{\operatorname{mpdf}(U)(E, z)(E)}
$$

In the case where both the histogram and independent are integral, $A, A^{\mathrm{X}} \in$ $\mathcal{A}_{\mathrm{i}}$, the independent-distributed-relative multinomial space is

$$
\text { spaceRelative }\left(A^{\mathrm{X}}\right)(A):=-\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A)}{Q_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}
$$

The independent-distributed-relative multinomial space of the independent is zero,

$$
\operatorname{spaceRelative}\left(A^{\mathrm{X}}\right)\left(A^{\mathrm{X}}\right)=\operatorname{algn}\left(A^{\mathrm{X}}\right)=0
$$

In section 'Likely histograms', above, it is conjectured that the logarithm of the maximum conditional probability with respect to the dependent analogue varies with the relative space with respect to the independent analogue, which in this case is the alignment,

$$
\begin{aligned}
\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}}, z\right)(B): B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} & \sim-\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A)}{Q_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)} \\
& =\operatorname{spaceRelative}\left(A^{\mathrm{X}}\right)(A) \\
& =\operatorname{algn}(A)
\end{aligned}
$$

In the case where the histogram and independent are integral, $A, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, the independent-distributed-relative multinomial space is conjectured to be greater than or equal to zero and less than or equal to the independent-distributed-relative multinomial space of the dependent,

$$
0 \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}}\right)(A) \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}}\right)\left(A^{\mathrm{Y}}\right)
$$

In the case where the independent of the dependent equals the independent, $A^{\mathrm{YX}}=A^{\mathrm{X}}$, then the inequality is

$$
0 \leq \operatorname{algn}(A) \leq \operatorname{algn}\left(A^{\mathrm{Y}}\right)
$$

This is consistent with the entropies,

$$
\operatorname{entropy}\left(A^{\mathrm{X}}\right) \geq \operatorname{entropy}(A) \geq \operatorname{entropy}\left(A^{\mathrm{Y}}\right)
$$

Conjecture that if the histogram is at maximum alignment the dependent equals the histogram,

$$
\operatorname{algn}(A)=\operatorname{alignmentMaximum}(U)(V, z) \Longrightarrow A^{\mathrm{Y}}=A
$$

### 4.8 Capacity and Alignment density

Functions on the geometry, called capacities, of a histogram $A$ can be formalised in terms of the effective states $A^{\mathrm{FS}}$. Let this set of functions be defined as capacities $\subset \mathrm{P}(\mathcal{S}) \rightarrow \mathbf{R}_{>0}$ such that $\forall K \in$ capacities $\forall Q \in$ $\operatorname{dom}(K) \forall S, T \in Q(\operatorname{vars}(S)=\operatorname{vars}(T))$. The application of capacity function $K$ to the empty set, $K(\emptyset)$, is undefined.

Given some capacity function, $K \in$ capacities, the alignment density of nonzero histogram $A$ is defined as alignment $(A) / K\left(A^{\mathrm{FS}}\right) \in \mathbf{R}$. The alignment density of a zero histogram, $\operatorname{size}(A)=0$, is undefined.

The unit capacity function is constant 1. Define capacityUnit $\in$ capacities as capacityUnit $(Q):=1$. The alignment unit density equals the alignment $\operatorname{alignment}(A) / \operatorname{capacityUnit}\left(A^{\mathrm{FS}}\right)=\operatorname{alignment}(A)$.

The effective capacity is the cardinality of the effective histogram. Define capacityEffective $\in$ capacities as capacityEffective $(Q):=|Q|$.

The volume capacity is the volume of the variables. Define capacityVolume $(U) \in$ capacities as capacityVolume $(U)(Q):=v$ where $v=\operatorname{volume}(U)(\operatorname{vars}(Q))$, and vars $\in \mathrm{P}(\mathcal{S}) \rightarrow \mathrm{P}(\mathcal{V})$ is defined as $\operatorname{vars}(Q)=\bigcup\{\operatorname{vars}(S): S \in Q\}$.

The valency capacity is the geometrical mean of the valencies of the variables. Define capacityValency $(U) \in$ capacities in system $U$ as

$$
\operatorname{capacityValency}(U)(Q):=v^{1 / n}
$$

where $n=|\operatorname{vars}(Q)|$. The alignment valency density is

$$
\frac{\operatorname{alignment}(A)}{\text { capacityValency }(U)\left(A^{\mathrm{FS}}\right)}
$$

The effective valency capacity is similar to the valency capacity except that the interesting volume is the cardinality of the cartesian sub-volume of the effective independent. Define capacityValencyEffective $(U) \in$ capacities in system $U$ as

$$
\text { capacityValencyEffective }(U)(Q):=\left|Q^{\mathrm{UXF}}\right|^{1 / n}
$$

The diagonal capacity is the cardinality of the values of the shortest variable. Define capacityDiagonal $(U) \in$ capacities as capacityDiagonal $(U)(Q):=$ $\operatorname{minr}\left(\left\{\left|U_{w}\right|: w \in \operatorname{vars}(Q)\right\}\right)$.

The maximum alignment of a histogram of size $z$ and variables $V$ approximates to $z(n-1) \ln d$ where $d=\operatorname{minr}\left(\left\{\left|U_{w}\right|: w \in V\right\}\right)$ and $n=|V|$. The aligned capacity is the $\log$ of the valency capacity scaled by $n-1$. Define capacityAligned $(U) \in$ capacities as

$$
\operatorname{capacity} \operatorname{Aligned}(U)(Q):=(1-1 / n) \ln v
$$

The alignment aligned density at maximum alignment of a regular volume, $\{d\}=\left\{\left|U_{w}\right|: w \in V\right\}$, is approximately independent of geometry

$$
\frac{\operatorname{alignmentMaximum~}(U)(V, z)}{\text { capacityAligned }(U)\left(V^{\mathrm{CS}}\right)} \approx \frac{z(n-1) \ln d}{(1-1 / n) \ln v}=z
$$

### 4.9 Alignment and independent histograms

The multinomial probability density of an independent histogram $A^{\mathrm{X}}$ of size $z$ and variables $V$ drawn from an independent distribution $E^{\mathrm{X}}$ is approximately equal to the product of the multinomial probability densities of the reduced independent histogram $A^{\mathrm{X}} \%\{w\}$, where $w \in V$, drawn from the reduced independent distribution $E^{\mathrm{X}} \%\{w\}$

$$
\operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right) \approx \prod_{w \in V} \operatorname{mpdf}(U)\left(E^{\mathrm{X}} \%\{w\}, z\right)\left(A^{\mathrm{X}} \%\{w\}\right)
$$

To see this (i) use the notation $A_{w}=A \%\{w\}$ and $S_{w}=S \%\{w\}$, (ii) let $P^{\mathrm{X}}=\operatorname{resize}\left(1, E^{\mathrm{X}}\right)$, (iii) note that

$$
\sum_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}} \ln P_{S}^{\mathrm{X}}=\sum_{w \in V} \sum_{R \in A_{w}^{\mathrm{XS}}} A_{w, R}^{\mathrm{X}} \ln P_{w, R}^{\mathrm{X}}
$$

which follows from the proof that $\sum_{S \in A^{\mathrm{S}}} A_{S} \ln P_{S}^{\mathrm{X}}=\sum_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}} \ln P_{S}^{\mathrm{X}}$ above, and (iv) apply Stirling's approximation,

$$
\begin{aligned}
\ln & \operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right) \\
& =\ln \Gamma!z-\sum_{S \in A^{\mathrm{XS}}} \ln \Gamma!A_{S}^{\mathrm{X}}+\sum_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}} \ln P_{S}^{\mathrm{X}} \\
& \approx z \ln z-\sum_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}} \ln A_{S}^{\mathrm{X}}+\sum_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}} \ln P_{S}^{\mathrm{X}} \\
& =\sum_{w \in V}\left(z \ln z-\sum_{R \in A_{w}^{\mathrm{XS}}} A_{w, R}^{\mathrm{X}} \ln A_{w, R}^{\mathrm{X}}+\sum_{R \in A_{w}^{\mathrm{XS}}} A_{w, R}^{\mathrm{X}} \ln P_{w, R}^{\mathrm{X}}\right) \\
& \approx \sum_{w \in V}\left(\ln \Gamma_{!} z-\sum_{R \in A_{w}^{\mathrm{XS}}} \ln \Gamma_{!} A_{w, R}^{\mathrm{X}}+\sum_{R \in A_{w}^{\mathrm{XS}}} A_{w, R}^{\mathrm{X}} \ln P_{w, R}^{\mathrm{X}}\right) \\
& =\ln \prod_{w \in V} \operatorname{mpdf}(U)\left(E^{\mathrm{X}} \%\{w\}, z\right)\left(A^{\mathrm{X}} \%\{w\}\right)
\end{aligned}
$$

It can be shown, however, that the multinomial probability density of an independent histogram is not exactly equal to product of the multinomial probability densities, but only approximately equal. For example, in the case of a regular scaled cartesian histogram of size $z$ dimension $n=|V|$ and valency $d, A^{\mathrm{X}}=\operatorname{scalar}\left(z / d^{n}\right) * V^{\mathrm{C}}$ drawn from $V^{\mathrm{C}}$

$$
\begin{aligned}
\ln & \frac{\prod_{w \in V} \operatorname{mpdf}(U)\left(E^{\mathrm{X}} \%\{w\}, z\right)\left(A^{\mathrm{X}} \%\{w\}\right)}{\operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)} \\
= & n \ln \Gamma!z-n d \ln \Gamma!\frac{z}{d}+n z \ln \frac{1}{d} \\
& \quad-\ln \Gamma!z+d^{n} \ln \Gamma!\frac{z}{d^{n}}-z \ln \frac{1}{d^{n}} \\
= & n \ln \Gamma!z-n d \ln \Gamma!\frac{z}{d}-\ln \Gamma!z+d^{n} \ln \Gamma!\frac{z}{d^{n}} \neq 0 \\
\approx & n z \ln d-z \ln d^{n}=0
\end{aligned}
$$

This approximation of the multinomial probability density of an independent histogram is related to the method used by the dimensional classification coder of histories, $C_{\mathrm{G}, \mathrm{n}}$, to encode the reduced classifications. This is a special case where the distribution histogram is cartesian, $E^{\mathrm{X}}=V^{\mathrm{C}}$

$$
\begin{aligned}
\prod_{w \in V} \operatorname{mpdf}(U)\left(\{w\}^{\mathrm{C}}, z\right)\left(A^{\mathrm{X}} \%\{w\}\right) & =n \ln \Gamma_{!} z-\sum_{w \in V} \sum_{R \in A_{w}^{\mathrm{xs}}} \ln \Gamma_{!} A_{w, R}^{\mathrm{X}} \\
& =\sum_{w \in V} \operatorname{spaceClassification}\left(A^{\mathrm{X}} \%\{w\}\right)
\end{aligned}
$$

There is an analogy between the size scaling of alignment and what may be called dimension scaling of the logarithm of the multinomial probability density of an independent histogram. Choose one of the variables $w \in V$ then

$$
\begin{aligned}
\operatorname{alignment}\left(Z_{k} * A\right) & \approx-\ln \left(\frac{\operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)(A)}{\operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}\right)^{k} \\
& =k \operatorname{alignment}(A) \\
\ln \operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right) & \approx \ln \left(\operatorname{mpdf}(U)\left(E^{\mathrm{X}} \%\{w\}, z\right)\left(A^{\mathrm{X}} \%\{w\}\right)\right)^{n} \\
& =n \ln \operatorname{mpdf}(U)\left(E^{\mathrm{X}} \%\{w\}, z\right)\left(A^{\mathrm{X}} \%\{w\}\right)
\end{aligned}
$$

where $k \in \mathbf{Q}_{\geq 0}, Z_{k}=\operatorname{scalar}(k)$ and $n=|V|$.

### 4.10 Independent cartesian sub-volume

The effective states of the independent histogram form a cartesian sub-volume, that is, $A^{\mathrm{XF}}=\prod\left\{(A \%\{v\})^{\mathrm{F}}: v \in V\right\}$. This volume is less than the whole volume if there are volumes incident on the reduced variables such that the incident states have zero count. The union of this set of zero sub-volumes forms the complement of the independent cartesian sub-volume, $\bigcup\left\{C^{\mathrm{U}}: v \in V, w \in\right.$ $U_{v}, S=\{(v, w)\}, B=A+A^{\mathrm{CZ}}, C=B \backslash$ incidence $(B, S, 0)$, size $\left.(C)=0\right\}=$ $A^{\mathrm{C}} \backslash A^{\mathrm{XF}}$. The alignment of the cartesian sub-volume is the same as that for the whole volume, $\operatorname{alignment}\left(A * A^{\mathrm{XF}}\right)=\operatorname{alignment}(A)$.

A unit functional transform that represents the cartesian sub-volume slice having derived variables of truncated valency can be constructed. The transformed histogram has the same alignment. Let $P=\left\{\left(v,(A \%\{v\})^{\mathrm{FS}}\right)\right.$ : $v \in V\}$, such that $\forall v \in V \quad\left(\left(P_{v}, P_{v}\right) \in U\right)$ and transform $T=(\{S \cup$ $\left.\left.\left\{\left(P_{v},(v, w)\right):(v, w) \in S\right\}: S \in \prod \operatorname{ran}(P)\right\}^{\mathrm{U}}, \operatorname{ran}(P)\right)$. Then alignment $(A *$ $T)=\operatorname{alignment}(A)$.

### 4.11 Mis-alignment

The negative relative dependent space of sample histogram $A$ drawn from distribution histogram $E$ equals the alignment minus the mis-alignment

$$
\operatorname{alignment}(A)-\sum_{S \in A^{\mathrm{xS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln E_{S}
$$

where the sample histogram is as complete as the independent, $A^{\mathrm{U}} \geq A^{\mathrm{XU}}$ and the distribution histogram is as effective as the independent, $E^{\mathrm{F}} \geq A^{\mathrm{XU}}$.

In terms of probability density, the negative relative dependent space is the negative logarithm relative dependent multinomial probability density

$$
-\ln \frac{\operatorname{mpdf}(U)(E, z)(A)}{\operatorname{mpdf}(U)(E, z)\left(A^{\mathrm{X}}\right)}=\operatorname{alignment}(A)-\sum_{S \in A^{\mathrm{xs}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln E_{S}
$$

The mis-alignment does depend on the distribution histogram, but not its size, $z_{E}$

$$
\forall q \in \mathbf{Q}_{>0}\left(\sum_{S \in A^{\mathrm{xS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln \left(Z_{q} * E\right)(S)=\sum_{S \in A^{\mathrm{XS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln E_{S}\right)
$$

where $Z_{q}=\operatorname{scalar}(q)$.
The mis-alignment is zero if the sample histogram is independent, $A=A^{\mathrm{x}}$,

$$
\sum_{S \in A^{\mathrm{xS}}}\left(A_{S}^{\mathrm{X}}-A_{S}^{\mathrm{X}}\right) \ln E_{S}=0
$$

The mis-alignment is zero if the distribution histogram is independent, $E=$ $E^{\mathrm{X}}$,

$$
\sum_{S \in A^{\mathrm{XS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln E_{S}^{\mathrm{X}}=0
$$

Now consider some examples of the mis-alignment for non-independent distribution histograms, $E \neq E^{\mathrm{X}}$. First consider the case where the distribution histogram $E$ is equal to the sample histogram $A, E=A$, and where the sample is not independent, $A \neq A^{\mathrm{X}}$, and is as effective as its independent $A^{\mathrm{F}}=A^{\mathrm{XF}}$. In this case the alignment of the distribution distribution equals the sample histogram, $\operatorname{algn}(E)=\operatorname{algn}(A)$, because $E=A$. The misalignment is approximately greater than or equal to the alignment of the sample histogram, $\operatorname{algn}(A)$. So the negative relative dependent space is approximately less than or equal to zero. Applying Gibbs' inequality and then Stirling's approximation,

$$
\begin{aligned}
\sum_{S \in A^{\mathrm{xS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln A_{S} & =\sum_{S \in A^{\mathrm{S}}} A_{S} \ln A_{S}-\sum_{S \in A^{\mathrm{xS}}} A_{S}^{\mathrm{X}} \ln A_{S} \\
& >\sum_{S \in A^{\mathrm{S}}} A_{S} \ln A_{S}-\sum_{S \in A^{\mathrm{xS}}} A_{S}^{\mathrm{X}} \ln A_{S}^{\mathrm{X}} \\
& \approx \sum_{S \in A^{\mathrm{S}}} \ln \Gamma!A_{S}-\sum_{S \in A^{\mathrm{xS}}} \ln \Gamma!A_{S}^{\mathrm{X}} \\
& =\operatorname{algn}(A)
\end{aligned}
$$

In terms of probability density, the probability of drawing histogram $A$ from distribution histogram $A$ is approximately higher than the probability of drawing histogram $A^{\mathrm{X}}$

$$
-\ln \frac{\operatorname{mpdf}(U)(A, z)(A)}{\operatorname{mpdf}(U)(A, z)\left(A^{\mathrm{X}}\right)} \leq 0
$$

and so

$$
\operatorname{mpdf}(U)(A, z)(A) \geq \operatorname{mpdf}(U)(A, z)\left(A^{\mathrm{X}}\right)
$$

When mis-alignment is positive the distribution distribution, $E$, is said to be aligned with the sample histogram $A$.

A similar case is where the distribution histogram is a ratio of the sample and the independent sample, $E=\operatorname{resize}\left(z, A / A^{\mathrm{X}}\right)$, where $A \neq A^{\mathrm{X}}, A^{\mathrm{F}} \geq A^{\mathrm{XF}}$ and $z=\operatorname{size}(A)$. The alignment of the distribution histogram is less than the alignment of the sample, $\operatorname{algn}(E)<\operatorname{algn}(A)$. The mis-alignment is positive, but less than the alignment of the sample, $\operatorname{algn}(A)$,

$$
\begin{aligned}
\sum_{S \in A^{\mathrm{XS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln \frac{A_{S}}{A_{S}^{\mathrm{X}}} & =\sum_{S \in A^{\mathrm{XS}}} A_{S} \ln \frac{A_{S}}{A_{S}^{\mathrm{X}}}+\sum_{S \in A^{\mathrm{xS}}} A_{S}^{\mathrm{X}} \ln \frac{A_{S}^{\mathrm{X}}}{A_{S}} \\
& >0
\end{aligned}
$$

Again the inequality is Gibbs' inequality. The distribution distribution $A / A^{\mathrm{X}}$ is aligned with the sample histogram $A$.

A symmetrical example is where the distribution histogram is a scaled ratio of the independent sample and the sample, $E=\operatorname{resize}\left(z, A^{\mathrm{X}} / A\right)$, where $A \neq A^{\mathrm{X}}$ and $A^{\mathrm{F}} \geq A^{\mathrm{XF}}$. The alignment of the distribution histogram is still less than the alignment of the sample, $\operatorname{algn}(E)<\operatorname{algn}(A)$, but the misalignment is negative

$$
\begin{aligned}
\sum_{S \in A^{\mathrm{XS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln \frac{A_{S}^{\mathrm{X}}}{A_{S}} & =-\sum_{S \in A^{\mathrm{XS}}} A_{S} \ln \frac{A_{S}}{A_{S}^{\mathrm{X}}}-\sum_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}} \ln \frac{A_{S}^{\mathrm{X}}}{A_{S}} \\
& >0
\end{aligned}
$$

The distribution distribution $A^{\mathrm{X}} / A$ is aligned against the sample histogram $A$.
A fourth example of a distribution histogram $E$ derived from the sample histogram $A$ is where $E$ is the independent additive complement defined $E=\operatorname{resize}\left(z,\left(A-A^{\mathrm{X}}\right)^{\mathrm{F}} * A^{\mathrm{X}}+\left(A^{\mathrm{X}}-A\right)^{\mathrm{F}} * A\right)$, where $A^{\mathrm{F}} \geq A^{\mathrm{XF}}$. In this
case, the distribution histogram, E, may be more aligned than the sample, $\operatorname{algn}(E)>\operatorname{algn}(A)$ but the mis-alignment is negative

$$
\begin{aligned}
\sum_{S \in A^{\mathrm{XS}}} & A_{S} \ln E_{S}-\sum_{S \in A^{\mathrm{S}}} A_{S}^{\mathrm{X}} \ln E_{S} \\
= & \sum_{S \in\left(A^{\mathrm{X}}-A\right)^{\mathrm{FS}}} A_{S} \ln A_{S}+\sum_{S \in\left(A-A^{\mathrm{X}}\right)^{\mathrm{F}}} A_{S} \ln A_{S}^{\mathrm{X}}- \\
& \left(\sum_{S \in\left(A^{\mathrm{X}}-A\right)^{\mathrm{FS}}} A_{S}^{\mathrm{X}} \ln A_{S}+\sum_{S \in\left(A-A^{\mathrm{X}}\right)^{\mathrm{FS}}} A_{S}^{\mathrm{X}} \ln A_{S}^{\mathrm{X}}\right) \\
= & -\sum_{S \in\left(A^{\mathrm{X}}-A\right)^{\mathrm{FS}}}\left(A_{S}^{\mathrm{X}}-A_{S}\right) \ln A_{S}-\sum_{S \in\left(A-A^{\mathrm{X}}\right)^{\mathrm{FS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln A_{S}^{\mathrm{X}} \\
< & 0
\end{aligned}
$$

In this case, the distribution distribution $E$ is aligned against the sample histogram $A$.

The examples above are of aligned distribution histograms that are either aligned with the sample histogram or aligned against the sample histogram. Another case is where the distribution histogram is orthogonally aligned to the sample histogram. In this case the distribution histogram alignment is non-zero, $E \neq E^{\mathrm{X}}$, and the sample histogram alignment is non-zero, $A \neq A^{\mathrm{X}}$, but the mis-alignment is zero,

$$
\sum_{S \in A^{\mathrm{xS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln E_{S}=0
$$

If the size of the distribution histogram is much larger than the size of the sample histogram, $z_{E} \gg z$, and such that each distribution histogram count is greater than the corresponding count of both the sample and independent sample, $E>A$ and $E>A^{\mathrm{X}}$, then there is a approximate condition for orthogonal alignment. First approximate the mis-alignment as an alignment
delta

$$
\begin{aligned}
& \sum_{S \in A^{\mathrm{xS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln E_{S} \\
& \quad=\sum_{S \in A^{\mathrm{xS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln E_{S}-\sum_{S \in A^{\mathrm{xS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln E_{S}^{\mathrm{X}} \\
& \approx \sum_{S \in E^{\mathrm{S}}}\left(E+A-A^{\mathrm{x}}\right)_{S} \ln E_{S}-\sum_{S \in E^{\mathrm{xS}}}\left(E^{\mathrm{X}}+A-A^{\mathrm{X}}\right)_{S} \ln E_{S}^{\mathrm{X}}-\operatorname{algn}(E) \\
& \approx \sum_{S \in E^{\mathrm{S}}}\left(E+A-A^{\mathrm{x}}\right)_{S} \ln E_{S}-\sum_{S \in E^{\mathrm{xS}}}\left(E+A-A^{\mathrm{X}}\right)_{S}^{\mathrm{X}} \ln E_{S}^{\mathrm{X}}-\operatorname{algn}(E) \\
& \approx \sum_{S \in E^{\mathrm{S}}}\left(E+A-A^{\mathrm{x}}\right)_{S} \ln \left(E+A-A^{\mathrm{x}}\right)_{S}- \\
& \approx \sum_{S \in E^{\mathrm{xS}}}\left(E+A-A^{\mathrm{X}}\right)_{S}^{\mathrm{X}} \ln \left(E+A-A^{\mathrm{x}}\right)_{S}^{\mathrm{X}}-\operatorname{algn}(E) \\
& \approx \operatorname{algn}\left(E+A-A^{\mathrm{X}}\right)-\operatorname{algn}(E)
\end{aligned}
$$

The perturbed distribution histogram, $E+A-A^{\mathrm{X}}$, is the distribution histogram, $E$, plus the delta, $\left(A^{\mathrm{X}}, A\right)$. The approximate condition for orthogonal alignment is thus algn $\left(E+A-A^{\mathrm{X}}\right) \approx \operatorname{algn}(E)$. A symmetrical argument yields a similar approximate condition $\operatorname{algn}\left(E+A^{\mathrm{X}}-A\right) \approx \operatorname{algn}(E)$. Together the condition is $\operatorname{algn}\left(E+A-A^{\mathrm{X}}\right)-\operatorname{algn}\left(E+A^{\mathrm{X}}-A\right) \approx 0$. The appropriate degree of approximation can be guaged by calculating the alignment delta of the perturbed distribution histogram relative to itself after scaling

$$
\operatorname{algn}\left(E+Z_{z / z_{E}} * E-Z_{z / z_{E}} * E^{\mathrm{X}}\right)-\operatorname{algn}\left(E+Z_{z / z_{E}} * E^{\mathrm{X}}-Z_{z / z_{E}} * E\right)
$$

where $Z_{q}=\operatorname{scalar}(q)$.
The constraints on $E$ to make the perturbed distribution histogram alignment delta, $\operatorname{algn}\left(E+A-A^{\mathrm{X}}\right)-\operatorname{algn}\left(E+A^{\mathrm{X}}-A\right)$, a reasonable limit on the orthogonal alignment condition, are similar to those that make multinomial distributions approximations to historical distributions. That is, that the generalised multinomial probability distribution approximates to the stuffed historical probability distribution, $\hat{Q}_{\mathrm{m}, U}(E, z) \approx \hat{Q}_{\mathrm{h}, U}(E, z)$, where $z \ll \operatorname{minr}(E)$, $E \in \mathcal{A}_{\mathrm{i}}$ and $E^{\mathrm{F}}=E^{\mathrm{C}}$.

### 4.12 Alignment of partially independent

A histogram $A$ of variables $V=\operatorname{vars}(A)$ is said to be partially independent in a partition of the variables $P \in \mathrm{~B}(V)$ if

$$
A=Z_{A} * \prod_{K \in P} \frac{A}{Z_{A}} \% K
$$

where $Z_{A}=\operatorname{scalar}(\operatorname{size}(A))$. Conjecture that the alignment of the histogram equals the sum of the alignments of the reductions

$$
\operatorname{algn}(A)=\sum_{K \in P} \operatorname{algn}(A \% K)
$$

The components of the partition are said to be independent of eachother. So, for example, given $K, J \in P$ then algn $\left(A *\left\{K^{\mathrm{CS}\{ \} \mathrm{T}}, J^{\mathrm{CS}\{ \} \mathrm{T}}\right\}^{\mathrm{T}}\right)=0$.

A histogram may be contracted by removing the largest subset of independent variables. Let $\{J\}=\operatorname{mind}(\{(K,|K|): K \subseteq V, A=A \% K *$ $\left.\left.\prod_{w \in V \backslash K}\left(A / Z_{A}\right) \%\{w\}\right\}\right)$, then $\operatorname{algn}(A)=\operatorname{algn}(A \% J)$. Note that there is exactly one contraction. If the histogram is independent, $A=A^{\mathrm{X}}$, then it contracts to a scalar, $A \% \emptyset$.

### 4.13 Alignment of axial reductions

Let non-scalar non-singleton trimmed histogram $A=\operatorname{trim}(A)$ have variables $V=\operatorname{vars}(A)$. Let $P_{A}$ be a non-unary partition of the trimmed histogram, $P_{A} \in \mathrm{~B}(A)$ and $\left|P_{A}\right|>1$. Let $P_{V}$ be a partition of the variables, $P_{V} \in$ $\mathrm{B}(V)$, of the same cardinality, $\left|P_{V}\right|=\left|P_{A}\right|$. Consider the total bijection $Q \in P_{A}: \leftrightarrow: P_{V}$. If the map, $Q$, is (i) such that there exists a pivot state $X=\bigcup\left\{(A * C \%(V \backslash K))^{\mathrm{S}}:(C, K) \in Q\right\} \in \operatorname{cartesian}(U)(V)$ for implied system $U=\operatorname{implied}(A)$, and (ii) such that all of the sliced reductions are diagonalised, $\forall(C, K) \in Q$ (diagonal $(A * C \% K))$, then for all selections $M \in P_{A}: \leftrightarrow V$ of $Q, \forall C \in P_{A}\left(M_{C} \in Q_{C}\right)$, there exists a reduced histogram

$$
B_{M}=\sum_{(C, w) \in M}(A * C \%\{w\}) *(X \%(\operatorname{ran}(M) \backslash\{w\}))
$$

which is axial, axial $\left(B_{M}\right)$. Conjecture that for all such selections, $M$, of such maps, $Q$, the alignment of the histogram equals the alignment of the axial reduction plus the sum of the alignments of the sliced diagonalised reductions

$$
\operatorname{algn}(A)=\operatorname{algn}\left(B_{M}\right)+\sum_{(C, K) \in Q} \operatorname{algn}(A * C \% K)
$$

The sliced diagonalised reductions, $\{A * C \% K:(C, K) \in Q\}$, are said to be axially independent of eachother and axially independent of the axial reduced histogram, $B_{M}$, because the alignments sum together similarly to the alignments of a partially independent histogram, see section 'Alignment of partially independent' above. The pivot state, $X$, need not be effective, only that it is a member of the cartesian set of states, $X \in V^{\mathrm{CS}}$. If $X \notin A^{\mathrm{S}}$ then the axial is missing the pivot.

### 4.14 Alignment and conditional probability

Consider the complete integral congruent support sample histogram $A \in$ $\mathcal{A}_{U, \mathrm{i}, V, z}$ drawn with replacement from distribution histogram $E \in \mathcal{A}_{U, V, z_{E}}$. In the case where the distribution histogram $E$ is as effective as the independent, $E^{\mathrm{F}} \geq A^{\mathrm{XF}}$, then the generalised multinomial probability of the sample histogram, $\hat{Q}_{\mathrm{m}, U}(E, z)(A)$, may be decomposed into (i) the iso-independents multinomial probability and (ii) iso-independent conditional dependent multinomial probability
$\hat{Q}_{\mathrm{m}, U}(E, z)(A)=\sum_{B \in Y_{U, 1,1, z, z}^{1}\left(A^{\mathrm{X}}\right)} \hat{Q}_{\mathrm{m}, U}(E, z)(B) \times \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in Y_{U, i, V, z},\left(A^{\mathrm{X}}\right)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}$
where the generalised multinomial probability distribution $\hat{Q}_{\mathrm{m}, U}(E, z) \in\left(\mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow\right.$ $\left.\mathrm{Q}_{\geq 0}\right) \cap \mathcal{P}$ is defined

$$
\hat{Q}_{\mathrm{m}, U}(E, z):=\left\{\left(A, \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}}\left(\frac{E_{S}}{z_{E}}\right)^{A_{S}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
$$

and the integral iso-independent function, $Y_{U, \mathrm{i}, V, z} \in \mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathcal{A}_{U, V, z}$, is defined

$$
Y_{U, \mathrm{i}, V, z}=\left\{\left(B, B^{\mathrm{X}}\right): B \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\} \subset Y_{U, V, z} \subset \text { independent }
$$

Compare the conditional dependent to the relative dependent. In the case of the relative dependent the generalised multinomial probability is decomposed into (i) the independent multinomial probability and (ii) relative dependent multinomial probability

$$
\hat{Q}_{\mathrm{m}, U}(E, z)(A)=\hat{Q}_{\mathrm{m}, U}(E, z)\left(A^{\mathrm{x}}\right) \times \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\hat{Q}_{\mathrm{m}, U}(E, z)\left(A^{\mathrm{x}}\right)}
$$

Unlike in the relative dependent case, where the independent histogram must be integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, in the conditional dependent case there is no need for the independent histogram to be integral because the integral iso-independents, $Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right) \subseteq \mathcal{A}_{U, \mathrm{i}, V, z}$, is non-empty regardless.

Defined in terms of the generalised multinomial probability, the generalised iso-independent conditional multinomial probability distribution, $\hat{Q}_{\mathrm{m}, \mathrm{y}, U}$, is

$$
\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z)=\text { normalise }\left(\left\{\left(A, \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in Y_{U,, i,, z}^{-1}\left(A^{\mathrm{x}}\right)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right)
$$

So

$$
\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z)(A)=\frac{1}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)\right|} \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}
$$

and the generalised multinomial probability may be decomposed

$$
\hat{Q}_{\mathrm{m}, U}(E, z)(A)=\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} \hat{Q}_{\mathrm{m}, U}(E, z)(B) \times\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)\right| \hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z)(A)
$$

The cardinality of the components of the partition of $\mathcal{A}_{U, \mathrm{i}, V, z}$ is the normalisation factor,

$$
\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)\right|=\prod_{w \in V} \frac{\left(z+\left|U_{w}\right|-1\right)!}{z!\left(\left|U_{w}\right|-1\right)!}
$$

The relative dependent multinomial probability equals the iso-independent conditional dependent multinomial probability if the iso-independents set is a singleton containing the independent, for example if the histogram is monovariate, $|V|=1$. In this case, however, the sample must be independent, $Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)=\left\{A^{\mathrm{X}}\right\} \Longrightarrow A=A^{\mathrm{X}}$, and therefore the probability is 1 ,

$$
\frac{\hat{Q}_{\mathrm{m}, U}(E, z)\left(A^{\mathrm{X}}\right)}{\sum_{B \in\left\{A^{\mathrm{x}}\right\}} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}=\frac{\hat{Q}_{\mathrm{m}, U}(E, z)\left(A^{\mathrm{X}}\right)}{\hat{Q}_{\mathrm{m}, U}(E, z)\left(A^{\mathrm{X}}\right)}=1
$$

and the generalised iso-independent conditional multinomial probability does not depend on $A^{\mathrm{X}}$

$$
\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z)\left(A^{\mathrm{x}}\right)=\frac{1}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)\right|}
$$

The iso-independent conditional dependent multinomial probability is greater than 0 and less than or equal to 1

$$
0<\frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)} \leq 1
$$

because

$$
0<\hat{Q}_{\mathrm{m}, U}(E, z)(A) \leq \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \hat{Q}_{\mathrm{m}, U}(E, z)(B) \leq 1
$$

The iso-independent conditional dependent multinomial probability only equals 1 if the sample is independent

$$
\frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}=1 \Longrightarrow A=A^{\mathrm{X}}
$$

because a non-independent sample has more than one integral iso-independents, $A \neq A^{\mathrm{X}} \Longrightarrow\left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|>1$.

In some cases the relative probability may be greater than one,

$$
\exists E, A \in \mathcal{A}\left(\frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\hat{Q}_{\mathrm{m}, U}(E, z)\left(A^{\mathrm{x}}\right)}>1\right)
$$

and hence relative probability is not strictly speaking a probability per se. In the conditional dependent case, however, the conditional probability is always between zero and one, yielding a probability function,

$$
\left\{\left(C, \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(C)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}\right): C \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right\} \in \mathcal{P}
$$

Therefore conditional probability is a probability proper.

The iso-independent conditional dependent multinomial probability may be generalised to a probability density. Instead of drawing an integral sample histogram from the finite integral congruent support, $\mathcal{A}_{U, \mathrm{i}, V, z}$, the sample histogram is drawn from the infinite complete congruent histograms, $A \in \mathcal{A}_{U, V, z}$. The iso-independent conditional dependent multinomial probability density given the infinite iso-independents is

$$
\frac{\operatorname{mpdf}(U)(E, z)(A)}{\int_{B \in Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \operatorname{mpdf}(U)(E, z)(B) d B}
$$

which is defined if the distribution histogram $E$ is as effective as the independent sample, $E^{\mathrm{F}} \geq A^{\mathrm{XF}}$.

The iso-independent conditional dependent multinomial probability density is greater than 0 and less than or equal to 1

$$
0<\frac{\operatorname{mpdf}(U)(E, z)(A)}{\int_{B \in Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \operatorname{mpdf}(U)(E, z)(B) d B} \leq 1
$$

because

$$
0<\operatorname{mpdf}(U)(E, z)(A) \leq \int_{B \in Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \operatorname{mpdf}(U)(E, z)(B) d B \leq 1
$$

The iso-independent conditional dependent multinomial probability tends to the iso-independent conditional dependent multinomial probability density as the size increases
$\lim _{k \rightarrow \infty} \frac{\hat{Q}_{\mathrm{m}, U}(E, k z)\left(Z_{k} * A\right)}{\sum_{B \in Y_{U, i, V, k z}^{-1}\left(Z_{k} * A^{\mathrm{X}}\right)} \hat{Q}_{\mathrm{m}, U}(E, k z)(B)}=\frac{\operatorname{mpdf}(U)(E, z)(A)}{\int_{B \in Y_{U, V, z}^{-1}\left(A^{\mathrm{x}}\right)} \operatorname{mpdf}(U)(E, z)(B) d B}$
where $Z_{k}=\operatorname{scalar}(k)$. This is because (i) either the finite integral isoindependents becomes a larger subset of the iso-independents as the size increases, $Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right) \subset Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, or (ii) both are singletons, $Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)=$ $Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)=\left\{A^{\mathrm{X}}\right\}$.

Consider the case where the distribution histogram is independent, $E=$ $E^{\mathrm{X}}$, as well as sufficiently effective, $E^{\mathrm{XF}} \geq A^{\mathrm{XF}}$. The negative logarithm independently-distributed iso-independent conditional dependent multinomial probability is

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}: E^{\mathrm{XF}} \geq A^{\mathrm{XF}}\right) \\
= & -\ln \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B) \\
= & -\ln \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}}\left(\frac{E_{S}^{\mathrm{X}}}{z_{E}}\right)^{A_{S}}+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{z!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!} \prod_{S \in B^{\mathrm{S}}}\left(\frac{E_{S}^{\mathrm{X}}}{z_{E}}\right)^{B_{S}} \\
= & \sum_{S \in A^{\mathrm{S}}} \ln A_{S}!+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{1}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}
\end{aligned}
$$

because

$$
\begin{aligned}
& \forall B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right) \\
& \qquad\left(\sum_{S \in B^{\mathrm{S}}} B_{S} \ln E_{S}^{\mathrm{X}}=\sum_{S \in B^{\mathrm{xS}}} B_{S}^{\mathrm{X}} \ln E_{S}^{\mathrm{X}}=\sum_{S \in A^{\mathrm{xS}}} A_{S}^{\mathrm{X}} \ln E_{S}^{\mathrm{X}}=\sum_{S \in A^{\mathrm{S}}} A_{S} \ln E_{S}^{\mathrm{X}}\right)
\end{aligned}
$$

As in the case of the negative logarithm independently-distributed relative dependent multinomial probability density of the sample, which is the alignment,

$$
\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!-\sum_{S \in A^{\mathrm{XS}}} \ln \Gamma_{!} A_{S}^{\mathrm{X}}=\operatorname{alignment}(A)
$$

the negative logarithm independently-distributed iso-independent conditional dependent multinomial probability,

$$
\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{1}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}
$$

does not depend on the distribution histogram, $E$, so long as the distribution histogram is sufficiently effective, $E^{\mathrm{F}} \geq A^{\mathrm{XF}}$, and independent, $E=E^{\mathrm{X}}$.

Let integral congruent delta $(D, I) \in \mathcal{A}_{\mathrm{i}} \times \mathcal{A}_{\mathrm{i}}$ be such that its perturbation, $A-D+I$, is iso-independence conserving, $A-D+I \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, so that ( $A-$ $D+I)^{\mathrm{X}}=A^{\mathrm{X}}$. The change in negative logarithm independently-distributed iso-independent conditional dependent multinomial probability because of the application of delta, $(D, I)$, is

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A-D+I)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left((A-D+I)^{\mathrm{x}}\right)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}\right)- \\
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}\right) \\
= & \left(\sum_{S \in(A-D+I)^{\mathrm{S}}} \ln (A-D+I)_{S}!+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left((A-D+I)^{\mathrm{x}}\right)} \frac{1}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}\right)- \\
= & \left(\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!+\ln \sum_{B \in Y_{U, i, V, z}^{1}\left(A^{\mathrm{x}}\right)} \overline{1} \sum_{S \in(A-D+I)^{\mathrm{S}}} \ln (A-D+I)_{S}!-\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!\right.
\end{aligned}
$$

This difference equals the difference in alignments, $\operatorname{algn}(A-D+I)-\operatorname{algn}(A)$, because the independent perturbation, $(A-D+I)^{\mathrm{X}}$, and the independent sam$p l e, A^{\mathrm{X}}$, are equal.

The idealisation of a histogram given an effective transform, $A * T * T^{\dagger A}$, is in the iso-independents, $A * T * T^{\dagger A} \in Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, because the independent of the idealisation equals the independent histogram, $\left(A * T * T^{\dagger A}\right)^{\mathrm{X}}=A^{\mathrm{X}}$. In the case where the idealisation is integral, $A * T * T^{\dagger} A \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, there is a corresponding iso-independence conserving delta, $A * T * T^{\dagger A}=A-D+I$. The change in negative logarithm independently-distributed iso-independent conditional dependent multinomial probability because of the integral idealisation of the sample histogram is

$$
\left.\begin{array}{rl} 
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)\left(A * T * T^{\dagger A}\right)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(\left(A * T * T^{\dagger A}\right)^{\mathrm{X}}\right)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}\right)- \\
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}\right) \\
= & \left(\sum_{S \in\left(A * T * T^{\dagger A}\right)^{\mathrm{S}}} \ln \left(A * T * T^{\dagger A}\right)_{S}!+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(\left(A * T * T^{\dagger A}\right)^{\mathrm{X}}\right)} \frac{1}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}\right)- \\
= & \left(\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{1}{\sum_{S \in\left(A * T * T^{\dagger A}\right)^{\mathrm{S}}}}\right) \\
\sum_{S \in B^{\mathrm{S}}} B_{S}!
\end{array}\right),
$$

This difference equals the difference in alignments, $\operatorname{algn}\left(A * T * T^{\dagger A}\right)-\operatorname{algn}(A)$, because the independent idealisation, $\left(A * T * T^{\dagger A}\right)^{\mathrm{X}}$, and the independent sample, $A^{\mathrm{X}}$, are equal.

In the case where the independent histogram is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, then the independent histogram is in the iso-independents, $A^{\mathrm{X}} \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, and the negative logarithm independently-distributed iso-independent conditional dependent multinomial probability can be rearranged in terms of the alignment,

$$
\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{1}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}=\operatorname{algn}(A)+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{\prod_{S \in A^{\mathrm{xs}}} A_{S}^{\mathrm{X}}!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}
$$

The minimum alignment conjecture, defined above in 'Minimum alignment', states that the alignment is conjectured to be always greater than or equal
to zero where the independent is integral, $\forall B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)(\operatorname{algn}(B) \geq 0)$, and hence

$$
\forall B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)\left(\frac{\prod_{S \in A^{\mathrm{xS}}} A_{S}^{\mathrm{X}}!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!} \leq 1\right)
$$

and so

$$
0 \leq \ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{\prod_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}}!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!} \leq \ln \left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|
$$

and so
$\operatorname{algn}(A) \leq \sum_{S \in A^{\mathrm{S}}} \ln A_{S}!+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{1}{\prod_{S \in B^{\mathrm{S}}} B_{S}!} \leq \operatorname{algn}(A)+\ln \left|Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|$
The negative logarithm independently-distributed iso-independent conditional dependent multinomial probability where the independent is integral is such that

$$
\begin{aligned}
& \operatorname{algn}(A) \\
\leq & \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}: E^{\mathrm{XF}} \geq A^{\mathrm{XF}}, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right) \\
\leq & \operatorname{algn}(A)+\ln \left|Y_{U, \mathrm{i}, V, z}\left(A^{\mathrm{X}}\right)\right|
\end{aligned}
$$

The negative logarithm independently-distributed iso-independent conditional dependent multinomial probability where the independent is integral equals the alignment only if the sample histogram is independent and the isoindependents is a singleton,

$$
\sum_{S \in A^{\mathrm{XS}}} \ln A_{S}^{\mathrm{X}}!+\ln \sum_{B \in\left\{A^{\mathrm{X}}\right\}} \frac{1}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}=\operatorname{algn}\left(A^{\mathrm{X}}\right)=0
$$

Therefore the alignment is always an underestimate of the negative logarithm independently-distributed iso-independent conditional dependent multinomial probability where the independent is integral and the sample is nonindependent

$$
A \neq A^{\mathrm{X}} \Longrightarrow \operatorname{algn}(A)<\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{1}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}
$$

The cardinality of the integral iso-independents must be less than or equal to the cardinality of the integral congruent support,

$$
\left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right| \leq\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right|=\frac{(z+v-1)!}{z!(v-1)!}
$$

where $v=\left|V^{\mathrm{C}}\right|$. Thus $\ln \left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|<\bar{v} \ln z$ if $z>v$. So

$$
\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{1}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}<\operatorname{algn}(A)+\bar{v} \ln z
$$

Compare this to maximum alignment, alignmentMaximum $(U)(V, z)$, which for large size, $z \gg v$, approximates to $z(n-1) \ln d$ for a regular histogram of dimension $n=|V|$ and valency $\{d\}=\left\{\left|U_{w}\right|: w \in V\right\}$. Therefore, in some cases the difference between the alignment and the negative logarithm independently-distributed iso-independent conditional dependent multinomial probability is less than the alignment, $\ln \left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|<\bar{v} \ln z<$ alignment $(A)$. That is, in some cases

$$
\operatorname{algn}(A) \leq \sum_{S \in A^{\mathrm{S}}} \ln A_{S}!+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{1}{\prod_{S \in B^{\mathrm{S}}} B_{S}!} \leq 2 \times \operatorname{algn}(A)
$$

In the case where the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathfrak{i}}$, the negative logarithm independently-distributed relative dependent multinomial probability, which is the alignment, can be expressed in terms of multinomial coefficients

$$
\operatorname{alignment}(A)=\ln \left(\frac{z!}{\prod_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}!}}\right)-\ln \left(\frac{z!}{\prod_{S \in A^{S}} A_{S}!}\right)
$$

In all cases, the negative logarithm independently-distributed iso-independent conditional dependent multinomial probability can be expressed in terms of multinomial coefficients

$$
\begin{aligned}
& \sum_{S \in A^{\mathrm{S}}} \ln A_{S}!+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{1}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}= \\
& \quad \ln \left(\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{z!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}\right)-\ln \left(\frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!}\right)
\end{aligned}
$$

In the case where the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, the negative logarithm independently-distributed iso-independent conditional dependent multi-
nomial probability,

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}: E^{\mathrm{XF}} \geq A^{\mathrm{XF}}, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right) \\
= & \left(\operatorname{algn}(A)+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{\prod_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}}!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}\right) \in \ln \mathbf{Q}_{>0}
\end{aligned}
$$

may be abbreviated to the alignment-bounded iso-independent space.
The difference between the alignment-bounded iso-independent space and the alignment is the alignment-bounded iso-independent error

$$
\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{\prod_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}}!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}
$$

The numerator in the alignment-bounded iso-transform error expression is derived from the independent term of the alignment, $\sum_{S \in A^{\mathrm{xS}}} \ln A_{S}^{\mathrm{X}}$ !, which varies against the entropy of the independent histogram, entropy $\left(A^{\mathrm{X}}\right)$. In the case of uniform independent histogram of size $z$ and volume $v$ where $z / v \in \mathbf{N}_{>0}$, the independent term is $v \ln (z / v)!\approx z \ln (z / v)$. So the alignmentbounded iso-transform error with respect to the numerator varies with the size, $z$, and varies against the logarithm of the volume, $\ln v$. The independent histogram, $A^{\mathrm{X}}$, tends to be more uniform at higher alignments.

The alignment-bounded iso-independent error varies with the cardinality of the integral iso-independents, $\left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|$. As shown above, the average cardinality of the integral iso-independents is

$$
\frac{\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right|}{\left|\operatorname{ran}\left(Y_{U, i, V, z}\right)\right|}=\frac{(z+v-1)!}{z!(v-1)!} / \prod_{w \in V} \frac{\left(z+\left|U_{w}\right|-1\right)!}{z!\left(\left|U_{w}\right|-1\right)!}
$$

The average cardinality of the integral iso-independents varies with both size, $z$, and volume, $v$. Hence the error varies with both size, $z$, and volume, $v$.

In the case where the size is greater than the volume, $z>v$, the logarithm of the average cardinality is less than $\bar{v} \ln z$. In this case the negative contribution to the variation between the error and the volume from the numerator, $\ln v$, is outweighed by the positive contribution from the summation, $\bar{v}$. Hence, in the case where $z>v$, the error varies with both size, $z$,
and volume, $v$.
For a given volume, $v$, the average cardinality of the integral iso-independents varies with the entropy of the valencies, entropy $\left(\left\{\left(w,\left|U_{w}\right|\right): w \in V\right\}\right)$. Hence the error also varies with valency entropy. Thus the error tends to increase with dimension, $n=|V|$. Regular histograms tend to have higher error than irregular.

It is conjectured above that the cardinality of the integral iso-independents corresponding to $A^{\mathrm{X}}$ varies with the entropy of the independent, $A^{\mathrm{X}}$,

$$
\ln \left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right| \sim z \times \operatorname{entropy}\left(A^{\mathrm{X}}\right)
$$

Therefore the alignment-bounded iso-independent error also varies with the entropy of the independent, entropy $\left(A^{\mathrm{X}}\right)$.

The ratio of the alignment-bounded iso-independent error to the alignment is

$$
\left(\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{\prod_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}!}}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}\right) / \operatorname{algn}(A)
$$

where the histogram is not independent, $A \neq A^{\mathrm{X}} \Longrightarrow \operatorname{algn}(A)>0$.
As the alignment increases to maximum alignment, alignmentMaximum $(U)(V, z) \approx$ $z \ln v$ where $z \gg v$, the ratio decreases, $\bar{v} \ln z / z \ln v$.

On the other hand, as noted above, the alignment approximates to the difference in entropy between the independent and the sample histogram, $\operatorname{algn}(A) \approx z \times \operatorname{entropy}\left(A^{\mathrm{X}}\right)-z \times$ entropy $(A)$. Hence increases in alignment imply increases in the entropy of the independent to some degree. So there is a tendency to increase the ratio of the alignment-bounded iso-independent error to the alignment at higher alignments due to the independent entropy which partly counteracts the tendency to decrease the ratio at higher alignments due to the size.

In the case where the alignment is approximately equal to the expected alignment, it is conjectured above ('Minimum alignment') that expected alignment varies as the volume for constant size greater than the volume

$$
\operatorname{expected}\left(\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)\right)\left(\left\{(A, \operatorname{algn}(A)): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right) \sim v
$$

So in the case of expected alignment the alignment-bounded iso-independent error tends to be greater than the alignment and the ratio is greater than one, $\bar{v} \ln z / v$.

The change in alignment-bounded iso-independent space because of the application of iso-independence conserving delta, $A-D+I \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, is equal to the change in alignment

$$
\begin{aligned}
& \left(\operatorname{algn}(A-D+I)+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left((A-D+I)^{\mathrm{x}}\right)} \frac{\prod_{S \in(A-D+I)^{\mathrm{xs}}}(A-D+I)_{S}^{\mathrm{X}}!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}\right)- \\
& \left(\operatorname{algn}(A)+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{\prod_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}!}}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}\right) \\
= & \operatorname{algn}(A-D+I)-\operatorname{algn}(A)
\end{aligned}
$$

A special case is the integral idealisation, $A * T * T^{\dagger A} \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, where the change in alignment-bounded iso-independent space because of the integral idealisation of the sample histogram is

$$
\begin{aligned}
& \left(\operatorname{algn}\left(A * T * T^{\dagger A}\right)+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(\left(A * T * T^{\dagger A}\right)^{\mathrm{x}}\right)} \frac{\prod_{S \in\left(A * T * T^{\dagger A}\right)^{\mathrm{xS}}}\left(A * T * T^{\dagger A}\right)_{S}^{\mathrm{X}}!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}\right)- \\
& \left(\operatorname{algn}(A)+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{\prod_{S \in A^{\mathrm{xs}}} A_{S}^{\mathrm{X}!}}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}\right) \\
= & \operatorname{algn}\left(A * T * T^{\dagger A}\right)-\operatorname{algn}(A)
\end{aligned}
$$

Similarly, consider the integral idealisations of two transforms $T_{1}$ and $T_{2}$, where $A * T_{1} * T_{1}^{\dagger A}, A * T_{2} * T_{2}^{\dagger A} \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$. In this case the change in alignment-bounded iso-independent space between the two integral idealisations of the sample histogram is

$$
\operatorname{algn}\left(A * T_{2} * T_{2}^{\dagger A}\right)-\operatorname{algn}\left(A * T_{1} * T_{1}^{\dagger A}\right)
$$

### 4.15 Transform alignment

Let the set $\mathcal{O}_{U, z} \subset \mathcal{A}_{U} \times \mathcal{T}_{U, \mathrm{f}, 1}$ be the set of pairs of (i) histograms of nonzero size $z>0$ such that the independent histogram is completely effective
and (ii) one functional transforms having underlying variables equal to the histogram variables

$$
\begin{aligned}
& \mathcal{O}_{U, z}= \\
& \quad\left\{(A, T): A \in \mathcal{A}_{U}, \operatorname{size}(A)=z, A^{\mathrm{XF}}=A^{\mathrm{C}}, T \in \mathcal{T}_{U, \mathrm{f}, 1}, \operatorname{und}(T)=\operatorname{vars}(A)\right\}
\end{aligned}
$$

So $\forall A \in \operatorname{dom}\left(\mathcal{O}_{U, z}\right)(\operatorname{size}(A)=z), \forall A \in \operatorname{dom}\left(\mathcal{O}_{U, z}\right)\left(A^{\mathrm{XF}}=A^{\mathrm{C}}\right)$ and $\forall(A, T) \in \mathcal{O}_{U, z}(\operatorname{und}(T)=\operatorname{vars}(A))$. For any given $A \in \operatorname{dom}\left(\mathcal{O}_{U, z}\right)$ of variables $V=\operatorname{vars}(A)$ the set $\left\{T:(B, T) \in \mathcal{O}_{U, z}, B=A\right\}$ is a superset of the finite substrate transforms set in $V, \mathcal{T}_{U, V} \subset \operatorname{ran}\left(\operatorname{filter}\left(\{A\}, \mathcal{O}_{U, z}\right)\right)$.

Let $(A, T) \in \mathcal{O}_{U, z}$. The application of the transform $T$ to its corresponding histogram $A$ is called the derived histogram $A * T$. In this context, $A$ is called the underlying histogram. The application to create the derived histogram is size conserving, $\forall(A, T) \in \mathcal{O}_{U, z}(\operatorname{size}(A * T)=z)$. If the transform is not right total, $\left|T^{-1}\right|<\left|W^{\mathrm{C}}\right|$, then the derived histogram is always incompletely effective, $(X \% W)^{\mathrm{F}}<W^{\mathrm{C}} \Longrightarrow(A * T)^{\mathrm{F}}<(A * T)^{\mathrm{C}}$, where $(X, W)=T$. If the transform is right total, then the volume of the derived histogram must be less than or equal to that of the underlying, $(X \% W)^{\mathrm{F}}=W^{\mathrm{C}} \Longrightarrow\left|V^{\mathrm{C}}\right| \geq\left|W^{\mathrm{C}}\right|$ and so $\left|A^{\mathrm{C}}\right| \geq\left|(A * T)^{\mathrm{C}}\right|$, where $(X, W)=T$ and $V=\operatorname{und}(T)$.

The idealisation and the neutralisation are both size conserving, $\forall(A, T) \in$ $\mathcal{O}_{U, z}\left(\operatorname{size}\left(A * T * T^{\dagger A}\right)=z\right)$ and $\forall(A, T) \in \mathcal{O}_{U, z}\left(\operatorname{size}\left(A * T * T^{\odot A^{\mathrm{x}}}\right)=z\right)$. The idealisation and the neutralisation are both at least as effective as the underlying, $\left(A * T * T^{\dagger A}\right)^{\mathrm{F}} \geq A^{\mathrm{F}}$ and $\left(A * T * T^{\odot A^{\mathrm{X}}}\right)^{\mathrm{F}} \geq A^{\mathrm{F}}$. A surrealisation is size-conserving if the derived histogram is as effective as the abstract histogram, $\forall(A, T) \in \mathcal{O}_{U, z}\left((A * T)^{\mathrm{F}}=(A * T)^{\mathrm{XF}} \Longrightarrow \operatorname{size}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)=z\right)$. Otherwise the size of the surrealisation is less than the size of the histogram, $\forall(A, T) \in \mathcal{O}_{U, z}\left((A * T)^{\mathrm{F}}<(A * T)^{\mathrm{XF}} \Longrightarrow \operatorname{size}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)<z\right)$. A contentisation is size-conserving if the derived histogram is as effective as the formal histogram, $\forall(A, T) \in \mathcal{O}_{U, z}\left((A * T)^{\mathrm{F}} \geq\left(A^{\mathrm{X}} * T\right)^{\mathrm{F}} \Longrightarrow \operatorname{size}\left(A^{\mathrm{X}} * T * T^{\odot A}\right)=\right.$ $z)$. Otherwise the size of the contentisation is less than the size of the histogram, $\forall(A, T) \in \mathcal{O}_{U, z}\left((A * T)^{\mathrm{F}}<\left(A^{\mathrm{X}} * T\right)^{\mathrm{F}} \Longrightarrow \operatorname{size}\left(A^{\mathrm{X}} * T * T^{\odot A}\right)<z\right)$. The surrealisation and the contentisation are no more effective than the underlying, $\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)^{\mathrm{F}} \leq A^{\mathrm{F}}$ and $\left(A^{\mathrm{X}} * T * T^{\odot A}\right)^{\mathrm{F}} \leq A^{\mathrm{F}}$.

The alignment of the derived histogram is called the derived alignment,

$$
\operatorname{algn}(A * T)
$$

where $(A, T) \in \mathcal{O}_{U, z}$ and algn $=$ alignment.

The alignment of the underlying histogram is called the underlying alignment,

$$
\operatorname{algn}(A)
$$

The formal alignment is the derived alignment of the independent histogram,

$$
\operatorname{algn}\left(A^{\mathrm{X}} * T\right)
$$

The derived alignment relative to the formal alignment is called the content alignment

$$
\operatorname{algn}(A * T)-\operatorname{algn}\left(A^{\mathrm{x}} * T\right)
$$

The idealisation alignment is

$$
\operatorname{algn}\left(A * T * T^{\dagger A}\right)
$$

The surrealisation alignment is

$$
\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)
$$

The midisation pseudo-alignment is the histogram alignment less the surrealisation alignment less the idealisation alignment

$$
\operatorname{algn}(A)-\operatorname{algn}\left((A * T)^{\mathrm{x}} * T^{\odot A}\right)-\operatorname{algn}\left(A * T * T^{\dagger A}\right)
$$

The derived variables of a transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ are non-overlapping if there exists an equivalent transform of a fud $F \in \mathcal{F}_{U, 1}$ which is non-overlapping, $\exists F \in \mathcal{F}_{U, 1}\left(\left(F^{\mathrm{T}}=T\right) \wedge \neg \operatorname{overlap}(F)\right)$. There exists histogram-transform pairs $(A, T) \in \mathcal{O}_{U, z}$ for which the transform, $T$, is non-overlapping, $\exists(A, T) \in$ $\mathcal{O}_{U, z}(\neg \operatorname{overlap}(T))$.

Consider the histogram-transform pair $(A, T) \in \mathcal{O}_{U, z}$. The transform $T$ is effectively non-overlapping with respect to histogram $A$ if there exists an equivalent fud $F \in \mathcal{F}_{U, 1}$ which is non-overlapping in the application to the effective histogram, $\exists F \in \mathcal{F}_{U, 1}\left(\left(A^{\mathrm{F}} * F^{\mathrm{T}}=A^{\mathrm{F}} * T\right) \wedge \neg \operatorname{overlap}(F)\right)$. A transform $T$ that is overlapping, but is effectively non-overlapping with respect to histogram A, must be effectively overlapping with respect to the independent underlying $A^{\mathrm{X}}$ because the independent underlying is completely effective $A^{\mathrm{XF}}=A^{\mathrm{C}}$.

Define the degree of overlap of $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ as $\operatorname{algn}\left(V_{z}^{\mathrm{C}} * T\right)$ relative to size $z$ where $V=\operatorname{und}(T)$ and the scaled cartesian is $V_{z}^{\mathrm{C}}=\operatorname{resize}\left(z, V^{\mathrm{C}}\right)$. Define $\operatorname{alignmentOverlap}(U) \in \mathcal{T}_{U, f, 1} \times \mathbf{Q}_{>0} \rightarrow \mathbf{R}$ as

$$
\operatorname{alignmentOverlap}(U)(T, z):=\operatorname{algn}\left(V_{z}^{\mathrm{C}} * T\right)
$$

If a transform $T$ is non-overlapping its application to a complete uniform histogram leaves the derived variables independent of each other, and so the derived alignment is zero and the degree of overlap is zero, $\neg \operatorname{overlap}(T) \Longrightarrow$ $V^{\mathrm{C}} * T=\left(V^{\mathrm{C}} * T\right)^{\mathrm{X}}$ and hence alignmentOverlap $(U)(T, z)=0$.

Derived variables $x, y \in W$ are said to be tautological if their partitions are equal, partition $((X \%(V \cup\{x\}),\{x\}))=\operatorname{partition}((X \%(V \cup\{y\}),\{y\}))$, where $(X, W)=T$ and $V=\operatorname{und}(T)$. A transform is tautologically overlapped if all of its derived variables are tautological. A tautology is always overlapped, $\forall T \in \mathcal{T}_{\mathrm{f}} \cap \mathcal{T}_{\mathrm{U}}$ (tautology $(T) \Longrightarrow$ overlap $(T)$ ). A tautologically overlapped transform has a high degree of overlap, algn $\left(V_{z}^{\mathrm{C}} * T\right)$, because $V^{\mathrm{C}} * T$ is regular and fully diagonalised in the underlying cartesian, diagonalFull $(U)\left(V^{\mathrm{C}} * T\right)$. None of the transforms in the substrate transforms set, $\mathcal{T}_{U, V}$, contain tautologically derived variables because each derived variable corresponds to a different partition, $\forall(X, W) \in \mathcal{T}_{U, V}(\mid\{\operatorname{partition}((X \%(V \cup\{w\}),\{w\})): w \in$ $W\}|=|W|)$. Thus none are tautologically overlapped $\forall T \in \mathcal{T}_{U, V}(\neg \operatorname{tautology}(T))$.

There is a case of a tautologically overlapping transform that has maximum degree of overlap, algnOver $(U)(T, z)=\operatorname{algnMax}(U)(W, z)$ where $T \in \mathcal{T}_{U, \mathrm{f}, 1}$, $W=\operatorname{der}(T)$, algnOver $=$ alignmentOverlap, algnMax $=$ alignmentMaximum, and $T$ is such that tautology $(T)$. This is the case where the derived variables are each frames of the same underlying variable $v$. For example, let $V=\{v\}$, and $\forall w \in W\left(U_{w}=U_{v}\right)$ and $\operatorname{his}(T)=\{\{(v, u)\} \cup\{(w, u): w \in W\}:$ $\left.u \in U_{v}\right\}^{\mathrm{U}}$. All the derived variables are tautologically aligned. The degree of overlap of $T$ is equal to maximum alignment, $\operatorname{algn}\left(\operatorname{resize}\left(z,\{v\}^{\mathrm{C}}\right) * T\right)=$ $\operatorname{algnMax}(U)(W, z)$. This example is of a literal frame where the values are shared, $U_{w}=U_{v}$, but non-literal frames are also tautologically aligned. The non-literal frame transforms can be constructed using bijective maps, $\forall w \in$ $W \exists M_{w} \in U_{v} \leftrightarrow U_{w}\left(\left|M_{w}\right|=\left|U_{v}\right|\right)$ and $\operatorname{his}(T)=\left\{\{(v, u)\} \cup\left\{\left(w, M_{w}(u)\right):\right.\right.$ $\left.w \in W\}: u \in U_{v}\right\}^{U}$.

Another case of tautologically overlapping transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ that has maximum degree of overlap is such that each of the tautologically aligned derived variables enumerates the cartesian underlying states and are therefore self-partitions. For example, $\forall w \in W\left(U_{w}=\left\{\{S\}: S \in V^{\mathrm{CS}}\right\}\right)$ and $\operatorname{his}(T)=\left\{S \cup\{(w,\{S\}): w \in W\}: S \in V^{\mathrm{CS}}\right\}^{\mathrm{U}}$ where $W=\operatorname{der}(T)$ and $V=\operatorname{und}(T)$. The degree of overlap of $T$ is equal to maximum alignment, algnOver $(U)(T, z)=\operatorname{algnMax}(U)(W, z)$. This approximately scales the underlying maximum alignment $(m-1) n /(n-1) \times \operatorname{algnMax}(U)(V, z)$ where $m=|W|$ and $n=|V|$ and the underlying histogram is regular,
$\operatorname{algnMax}(U)(V, z) \approx z(n-1) \ln d$, where $d$ is the regular valency, $\left|V^{\mathrm{CS}}\right|=d^{n}$.
Consider the histogram-transform pair $(A, T)$ where $A \in \mathcal{A}_{U}, T \in \mathcal{T}_{U, \mathrm{f}, 1}$, $\operatorname{und}(T)=\operatorname{vars}(A)$ and the $T$ is tautologically aligned, algnOver $(U)(T, z)=$ $\operatorname{algnMax}(U)(W, z)$. If the derived alignment is less than maximum alignment, $\operatorname{algn}(A * T)<\operatorname{algnMax}(U)(W, z)$, then the content alignment may be negative, $\operatorname{algn}\left(A^{\mathrm{X}} * T\right)>\operatorname{algn}(A * T) . A^{\mathrm{X}}$ is more uniform than $A$ in the sense that the entropy of $A^{\mathrm{X}}$ is approximately greater than or equal to the entropy of $A$, entropy $\left(A^{\mathrm{X}}\right) \geq$ entropy $(A)$, if the minimum alignment conjecture is true. Hence the diagonalised formal histogram, diagonal $\left(A^{\mathrm{X}} * T\right)$, is sometimes more uniform along the diagonal than the derived histogram, $\operatorname{entropy}\left(A^{\mathrm{X}} * T \%\{w\}\right) \geq \operatorname{entropy}(A * T \%\{w\})$ where $w \in W$. Therefore the formal alignment $\operatorname{algn}\left(A^{\mathrm{X}} * T\right)$ may be closer to maximum alignment $\operatorname{algnMax}(U)(W, z)$ than the derived alignment $\operatorname{algn}(A * T)$.

There exist histogram-transform pairs, $(A, T) \in \mathcal{O}_{U, z}$, such that the derived alignment equals the underlying alignment, $\operatorname{algn}(A * T)=\operatorname{algn}(A)$. An example is the value full functional transform $T$ for which the derived histogram is a non-literal reframe of the underlying histogram. That is, let $M \in(V \leftrightarrow W) \rightarrow(\mathcal{U} \leftrightarrow \mathcal{U})$, such that $\operatorname{dom}(M) \in V \cdot W$ and $\forall(v, w) \in$ $\operatorname{dom}(M)\left(M_{v, w} \in U_{v} \cdot U_{w}\right)$ and $\operatorname{his}(T)=\left\{S \cup\left\{\left(w, M_{v, w}(u)\right):(v, u) \in S, w=\right.\right.$ $\left.\operatorname{dom}(M)(v)\}: S \in V^{\mathrm{CS}}\right\}^{\mathrm{U}}$, where $V=\operatorname{und}(T)$ and $W=\operatorname{der}(T)$. For example, the self non-overlapping substrate self-cartesian value full functional transform, $T=\left\{\{v\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: v \in V\right\}^{\mathrm{T}}$. The content alignment of the nonoverlapping transform also equals the alignment of the underlying histogram, $\operatorname{algn}(A * T)-\operatorname{algn}\left(A^{\mathrm{X}} * T\right)=\operatorname{algn}(A)$ because $\operatorname{algn}\left(A^{\mathrm{X}} * T\right)=\operatorname{algn}\left(A^{\mathrm{X}}\right)=0$.

A derived histogram can be independent even though the underlying histogram is not, $\exists(A, T) \in \mathcal{O}_{U, z}\left(\left(A * T=(A * T)^{\mathrm{X}}\right) \wedge\left(A \neq A^{\mathrm{X}}\right)\right)$. This implies that the derived alignment is sometimes less than the underlying alignment, $\exists(A, T) \in \mathcal{O}_{U, z}(\operatorname{algn}(A * T)<\operatorname{algn}(A))$. Examples of independent derived histograms include singletons, mono-variate and effectively mono-valent. If the transform is a unary partition transform, $\mid$ inverse $(T) \mid=1$, for example $T=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$, then the derived histogram is necessarily a singleton. Transforms having one derived variable, $|\operatorname{der}(T)|=1$, imply a mono-variate derived histogram.

A transform that is non-overlapping, $\neg$ overlap $(T)$, and such that the derived variables partition the underlying variables of a partially independent underlying histogram, must be independent, $\operatorname{algn}(A * T)=0$. The independent
underlying histogram $A^{\mathrm{X}}$ is a partially independent histogram by definition and so it follows that for non-overlapping transforms the formal histogram is independent, $\neg \operatorname{overlap}(T) \Longrightarrow A^{\mathrm{X}} * T \equiv\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, hence formal alignment is zero, $\neg \operatorname{overlap}(T) \Longrightarrow \operatorname{algn}\left(A^{\mathrm{X}} * T\right)=0$.

If a transform is non-overlapping, $\neg \operatorname{overlap}(T)$, then it has an equivalent fud, $F^{\mathrm{T}}=T$, such that the transforms have a single derived variable, $\forall R \in F(|\operatorname{der}(R)|=1)$, and the underlying of the transforms partition the underlying variables $V$, $\{\operatorname{und}(\operatorname{depends}(F,\{w\})): w \in \operatorname{der}(T)\} \in \mathrm{B}(\operatorname{und}(T))$. Therefore the derived dimension must be less than or equal to the underlying dimension, $\forall T \in \mathcal{T}_{U, V}(\neg \operatorname{overlap}(T) \Longrightarrow|W| \leq|V|)$ where $V=\operatorname{und}(T)$ and $W=\operatorname{der}(T)$. Each of the transforms is one functional, $F \subset \mathcal{T}_{U, \mathrm{f}, 1}$, and each is right total because the derived variables are partition variables and hence the transform $T$ must be right total, $\forall T \in \mathcal{T}_{U, V}\left(\neg \operatorname{overlap}(T) \Longrightarrow(X \% W)^{\mathrm{F}}=\right.$ $\left.W^{\mathrm{C}}\right)$ where $(X, W)=T$. Therefore the derived volume must be less than or equal to the underlying volume, $\forall T \in \mathcal{T}_{U, V}\left(\neg \operatorname{overlap}(T) \Longrightarrow\left|W^{\mathrm{C}}\right| \leq\left|V^{\mathrm{C}}\right|\right)$.

If a histogram $A \in \operatorname{dom}\left(\mathcal{O}_{U, z}\right)$ is irregular, $\left|\left\{\left|U_{v}\right|: v \in V\right\}\right|>1$ where $V=\operatorname{vars}(A)$, then it must be less than maximally aligned, $\operatorname{algn}(A)<$ $\operatorname{algnMax}(U)(V, z)$. The independent histogram $A^{\mathrm{X}}$ is constrained to be completely effective, $A^{\mathrm{XF}}=A^{\mathrm{C}}$ and so $A$ cannot be diagonalised.

The alignment of a derived histogram may be less than the alignment of the underlying histogram even when neither is independent, $\exists(A, T) \in \mathcal{O}_{U, z}(((A *$ $\left.\left.T) \neq(A * T)^{\mathrm{X}}\right) \wedge\left(A \neq A^{\mathrm{X}}\right) \wedge \operatorname{algn}(A * T)<\operatorname{algn}(A)\right)$. This can be shown to be true by first showing that if a transform is non-overlapping, then the maximum alignment of the derived histogram must be less than or equal to the maximum underlying alignment, $\neg \operatorname{overlap}(T) \Longrightarrow \operatorname{algnMax}(U)(W, z) \leq$ $\operatorname{algnMax}(U)(V, z)$ where $V=\operatorname{und}(T)$ and $W=\operatorname{der}(T)$. The derived volume must be less than or equal to the underlying volume $\left|W^{\mathrm{C}}\right| \leq\left|V^{\mathrm{C}}\right|$. If an underlying histogram is maximally aligned, $\operatorname{algn}(A)=\operatorname{algnMax}(U)(V, z)$, then it must be regular because the independent histogram $A^{\mathrm{X}}$ is constrained to be completely effective, $A \in \operatorname{dom}\left(\mathcal{O}_{U, z}\right)$. The largest maximum derived alignment occurs when the derived histogram is regular. Let $d_{V}$ be the underlying valency such that $d_{V}^{|V|}=\left|V^{\mathrm{C}}\right|$. Let $d_{W}$ be the derived valency such that $d_{W}^{|W|}=$ $\left|W^{\mathrm{C}}\right|$. Approximate the maximal alignments, algnMax $(U)(V, z) \approx z(|V|-$ 1) $\ln d_{V}$ and $\operatorname{algnMax}(U)(W, z) \approx z(|W|-1) \ln d_{W}$. Then $\left|W^{\mathrm{C}}\right| \leq\left|V^{\mathrm{C}}\right| \Longrightarrow$ $d_{W}^{|W|} \leq d_{V}^{|V|} \Longrightarrow|W| \ln d_{W} \leq|V| \ln d_{V}$. But $|W| \leq|V|$ hence $(|W|-$ 1) $\ln d_{W} \leq(|V|-1) \ln d_{V} \Longrightarrow \operatorname{algnMax}(U)(W, z) \leq \operatorname{algnMax}(U)(V, z)$. If
both $A$ and $A * T$ are maximally aligned and $\left|W^{\mathrm{C}}\right|<\left|V^{\mathrm{C}}\right|$ then $\operatorname{algn}(A * T)<$ $\operatorname{algn}(A)$.

If the transform is not right total, the derived histogram is pluri-variate and each of the reductions of the derived histogram is complete, then the derived histogram must be aligned, $\left((X \% W)^{\mathrm{F}}<W^{\mathrm{C}}\right) \wedge(|W|>1) \wedge(\forall w \in$ $W\left(((A * T) \%\{w\})^{\mathrm{F}}=\{w\}^{\mathrm{C}}\right) \Longrightarrow \operatorname{algn}(A * T)>0$, where $(X, W)=T$. This is the case even if the underlying histogram is independent, $\left((X \% W)^{\mathrm{F}}<\right.$ $\left.W^{\mathrm{C}}\right) \wedge(|W|>1) \wedge\left(\forall w \in W\left(\left(\left(A^{\mathrm{X}} * T\right) \%\{w\}\right)^{\mathrm{F}}=\{w\}^{\mathrm{C}}\right) \Longrightarrow \operatorname{algn}\left(A^{\mathrm{X}} * T\right)>\right.$ 0 .

The derived alignment, $\operatorname{algn}(A * T)$, of a histogram-transform pair $(A, T) \in$ $\mathcal{O}_{U, z}$ constructed from a partition of the variables $Y \in \mathrm{~B}(V)$, where $V=$ $\operatorname{und}(T)=\operatorname{vars}(A)$, such that the derived variables map to components and the values enumerate the cartesian states of the components, $\forall w \in$ $W \exists K \in Y\left(\left|U_{w}\right|=\left|K^{\mathrm{C}}\right|\right)$ where $W=\operatorname{der}(T)$, is less than or equal to the underlying alignment, $\operatorname{algn}(A * T) \leq \operatorname{algn}(A)$. For example, $\forall Y \in$ $\mathrm{B}(V)\left(\operatorname{algn}\left(A *\left\{K^{\mathrm{CS}\{ \}}: K \in Y\right\}^{\mathrm{T}}\right) \leq \operatorname{algn}(A)\right)$.

This may be shown for the partition of the variables $Y=\{K, V \backslash K\}$ and transform $T=\left\{K^{\mathrm{CS}\{ \}},(V \backslash K)^{\mathrm{CS}\{ \}}\right\}^{\mathrm{T}}$. The entropy of the partially independent histogram corresponding to the independent term of the alignment is such that

$$
\begin{aligned}
\sum_{S \in W^{\mathrm{xS}}} \ln \Gamma_{!}(A * T)_{S}^{\mathrm{X}} & =\sum_{S \in V^{\mathrm{xS}}} \ln \Gamma_{!}\left(\frac{1}{Z_{A}} *(A \% K) *(A \%(V \backslash K))\right)_{S} \\
& \geq \sum_{S \in V^{\mathrm{xS}}} \ln \Gamma_{!}\left(\frac{1}{Z_{A}} *(A \% K) *(A \%(V \backslash K))^{\mathrm{x}}\right)_{S} \\
& \geq \sum_{S \in V^{\mathrm{xS}}} \ln \Gamma_{!} A_{S}^{\mathrm{X}}
\end{aligned}
$$

The dependent term of the alignment is unchanged

$$
\sum_{S \in W^{\mathrm{xS}}} \ln \Gamma_{!}(A * T)_{S}=\sum_{S \in V^{\mathrm{xS}}} \ln \Gamma_{!} A_{S}
$$

Hence the upper bound of the underlying alignment,

$$
\operatorname{algn}(A * T) \leq \operatorname{algn}(A)
$$

Similarly, the derived alignment function and the parent partition relation are monotonic,

$$
\begin{aligned}
& \forall Y_{1}, Y_{2} \in \mathrm{~B}(V)\left(\operatorname{parent}\left(Y_{1}, Y_{2}\right) \Longrightarrow\right. \\
& \left.\quad \operatorname{algn}\left(A *\left\{K^{\mathrm{CS}\{ \}}: K \in Y_{1}\right\}^{\mathrm{T}}\right) \leq \operatorname{algn}\left(A *\left\{K^{\mathrm{CS}\{ \}}: K \in Y_{2}\right\}^{\mathrm{T}}\right)\right)
\end{aligned}
$$

The derived alignment, $\operatorname{algn}(A * T)$, and the derived alignment valencydensity, $\operatorname{algn}(A * T) /$ capacityValency $(U)\left((A * T)^{\mathrm{FS}}\right)=\operatorname{algn}(A * T) / w^{1 / m}$, where derived variables $W=\operatorname{der}(T)$, derived dimension $m=|W|=|Y|$, volume $w=\left|W^{\mathrm{C}}\right|=\left|V^{\mathrm{C}}\right|$, and the valency capacity is defined in section 'Capacity and Alignment density', above, are therefore also monotonic. For example, $\forall Y \in \mathrm{~B}(V) \diamond T=\left\{K^{\mathrm{CS}\{ \}}: K \in Y\right\}^{\mathrm{T}} \diamond W=\operatorname{der}(T)(\operatorname{algn}(A *$ $\left.T) /\left|W^{\mathrm{C}}\right|^{1 /|W|} \leq \operatorname{algn}(A) /\left|V^{\mathrm{C}}\right|^{1 /|V|}\right)$. This is because for any derived dimension, $m$, the valency capacity is constant

$$
\left(\prod_{K \in Y}\left|K^{\mathrm{C}}\right|\right)^{1 / m}=\left|V^{\mathrm{C}}\right|^{1 / m}=w^{1 / m}
$$

and the valency capacity of a parent partition of the variables is greater than that of the child partition where the volume is greater than one, $\left|V^{\mathrm{C}}\right|>1$,

$$
\forall Y_{1}, Y_{2} \in \mathrm{~B}(V)\left(\operatorname{parent}\left(Y_{1}, Y_{2}\right) \Longrightarrow\left|V^{\mathrm{C}}\right|^{1 /\left|Y_{1}\right|}>\left|V^{\mathrm{C}}\right|^{1 /\left|Y_{2}\right|}\right)
$$

Conjecture that the alignments of the abstract converse actions, which depend on the derived histogram, $A * T$, and the abstract histogram, $(A * T)^{\mathrm{X}}$, are constrained to be less than or equal to the alignment of the histogram, in the case where the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathfrak{i}}$, given the minimum alignment conjecture. Conjecture that the idealisation alignment is always less than or equal to the alignment of the histogram, where the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$,

$$
\forall(A, T) \in \mathcal{O}_{U, z}\left(A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}} \Longrightarrow \operatorname{algn}\left(A * T * T^{\dagger A}\right) \leq \operatorname{algn}(A)\right)
$$

The non-idealisation alignment is defined as the difference, $\operatorname{algn}(A)-\operatorname{algn}(A *$ $\left.T * T^{\dagger A}\right)$.

Conjecture that the surrealisation alignment is always less than or equal to the alignment of the histogram, where the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$,

$$
\forall(A, T) \in \mathcal{O}_{U, z}\left(A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}} \Longrightarrow \operatorname{algn}\left((A * T)^{\mathrm{x}} * T^{\odot A}\right) \leq \operatorname{algn}(A)\right)
$$

This is the case whether the surrealisation is effective or not, $(A * T)^{\mathrm{F}} \leq$ $(A * T)^{\mathrm{XF}}$. If it is ineffective, $(A * T)^{\mathrm{F}}<(A * T)^{\mathrm{XF}}$, then the size of the
surrealisation is less, $\operatorname{size}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)<z$, and the alignment is correspondingly less. The non-surrealisation alignment is defined as the difference, $\operatorname{algn}(A)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)$.

If the abstract converse actions are integral then the alignments must be positive, given the minimum alignment conjecture

$$
\forall(A, T) \in \mathcal{O}_{U, z}\left(A * T * T^{\dagger A} \in \mathcal{A}_{\mathrm{i}} \Longrightarrow 0 \leq \operatorname{algn}\left(A * T * T^{\dagger A}\right)\right)
$$

and

$$
\forall(A, T) \in \mathcal{O}_{U, z}\left((A * T)^{\mathrm{X}} * T^{\odot A} \in \mathcal{A}_{\mathrm{i}} \Longrightarrow 0 \leq \operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)\right)
$$

Consider the histogram-transform pair $(A, T) \in \mathcal{O}_{U, z}$ where the derived histogram is as effective as the formal histogram, $(A * T)^{\mathrm{F}} \geq\left(A^{\mathrm{X}} * T\right)^{\mathrm{F}}$, so that the contentisation is size-conserving, $\operatorname{size}\left(A^{\mathrm{X}} * T * T^{\odot A}\right)=\operatorname{size}(A)$.

In section 'Likely histograms', above, it is conjectured that the midisation entropy varies as the entropy of the histogram less the entropies of the liftisation and the surrealisation,

$$
\begin{aligned}
\operatorname{entropy}\left(A^{\mathrm{M}(T)}\right) \sim \operatorname{entropy}(A) & -\operatorname{entropy}\left(A^{\mathrm{K}(T)}\right) \\
& -\operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)
\end{aligned}
$$

and that insofar as the idealisation entropy approximates to the liftisation entropy, entropy $\left(A * T * T^{\dagger A}\right) \approx \operatorname{entropy}\left(A^{\mathrm{K}(T)}\right)$, the midisation entropy varies as the histogram entropy less the entropies of the idealisation and the surrealisation,

$$
\begin{aligned}
\operatorname{entropy}\left(A^{\mathrm{M}(T)}\right) \sim \operatorname{entropy}(A) & -\operatorname{entropy}\left(A * T * T^{\dagger A}\right) \\
& -\operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)
\end{aligned}
$$

Alignment is approximately equal to the scaled difference between the independent entropy and the histogram entropy,

$$
\operatorname{algn}(A) \approx z \times \operatorname{entropy}\left(A^{\mathrm{X}}\right)-z \times \operatorname{entropy}(A)
$$

where $z=\operatorname{size}(A)$. So, insofar as the midisation independent entropy approximates to the independent entropy, entropy $\left(A^{\mathrm{M}(T) \mathrm{X}}\right) \approx \operatorname{entropy}\left(A^{\mathrm{X}}\right)$, and the surrealisation independent entropy approximates to the independent entropy, entropy $\left(\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)^{\mathrm{X}}\right) \approx \operatorname{entropy}\left(A^{\mathrm{X}}\right)$, the midisation alignment varies
as the histogram alignment less the alignments of the idealisation and the surrealisation,

$$
\operatorname{algn}\left(A^{\mathrm{M}(T)}\right) \sim \operatorname{algn}(A)-\operatorname{algn}\left(A * T * T^{\dagger A}\right)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)
$$

The computable right hand side is called the midisation pseudo-alignment to distinguish it from the usually incomputable midisation alignment.

The midisation pseudo-alignment is not necessarily positive, but it is always greater than or equal to the greater of $-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)$ and $-\operatorname{algn}\left(A * T * T^{\dagger A}\right)$, because $\operatorname{algn}(A)-\operatorname{algn}\left(A * T * T^{\dagger A}\right) \geq 0$ and $\operatorname{algn}(A)-$ $\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right) \geq 0$. If the abstract converse actions are integral, $A * T * T^{\dagger A} \in \mathcal{A}_{\mathrm{i}}$ and $(A * T)^{\mathrm{X}} * T^{\odot A} \in \mathcal{A}_{\mathrm{i}}$, then midisation pseudo-alignment must be less than or equal to the histogram alignment, $\operatorname{algn}(A)$.

If the transform is a unary partition transform $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, \mathrm{f}, 1}$ then the idealisation equals the independent, $A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger A} \equiv A^{\mathrm{X}}$, and the surrealisation equals the histogram, $\left(A * T_{\mathrm{u}}\right)^{\mathrm{X}} * T_{\mathrm{u}}^{\odot A} \equiv A$, so the midisation pseudo-alignment is zero, $\operatorname{algn}(A)-\operatorname{algn}\left(\left(A * T_{\mathrm{u}}\right)^{\mathrm{X}} * T_{\mathrm{u}}^{\odot A}\right)-\operatorname{algn}\left(A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger A}\right)=0$.

If the transform is a full functional transform, for example a value full functional transform $T_{\mathrm{s}}=\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in V\right\}^{\mathrm{T}}$, then the idealisation equals the histogram, $A * T_{\mathrm{s}} * T_{\mathrm{s}}^{\dagger A} \equiv A$, and the surrealisation equals the independent if the histogram is as effective as the independent, $A^{\mathrm{F}}=A^{\mathrm{XF}} \Longrightarrow$ $\left(A * T_{\mathrm{s}}\right)^{\mathrm{X}} * T_{\mathrm{s}}^{\odot A} \equiv A^{\mathrm{X}}$, so the midisation pseudo-alignment is zero, $\operatorname{algn}(A)-$ $\operatorname{algn}\left(\left(A * T_{\mathrm{s}}\right)^{\mathrm{X}} * T_{\mathrm{s}}^{\odot A}\right)-\operatorname{algn}\left(A * T_{\mathrm{s}} * T_{\mathrm{s}}^{\dagger A}\right)=0$.

The midisation alignment may also be expressed in terms of the contentisation alignment. In section 'Likely histograms', above, it is conjectured that the midisation entropy varies as the difference between the entropies of the contentisation and the surrealisation less the entropy of the independent,

$$
\begin{aligned}
\operatorname{entropy}\left(A^{\mathrm{M}(T)}\right) \sim \operatorname{entropy}\left(A^{\mathrm{X}} * T * T^{\odot A}\right) & -\operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right) \\
& -\operatorname{entropy}\left(A^{\mathrm{X}}\right)
\end{aligned}
$$

Insofar as the contentisation independent entropy approximates to the independent entropy, entropy $\left(\left(A^{\mathrm{X}} * T * T^{\odot A}\right)^{\mathrm{X}}\right) \approx \operatorname{entropy}\left(A^{\mathrm{X}}\right)$, the midisation alignment varies as the difference between the alignments of the contentisation and the surrealisation,

$$
\operatorname{algn}\left(A^{\mathrm{M}(T)}\right) \sim \operatorname{algn}\left(A^{\mathrm{X}} * T * T^{\odot A}\right)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)
$$

As shown in section 'Likely histograms', above, if the histogram, $A$, is a given, and the formal is constrained to be independent, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, so that the contentisation equals the doubly-independent formal independent converse action, $A^{\mathrm{X}} * T * T^{\odot A}=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}} * T^{\odot A}$, then as the midisation entropy, entropy $\left(A^{\mathrm{M}(T)}\right)$, is minimised the contentisation entropy decreases to equal the surrealisation entropy, and formal tends to equal the abstract, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$. Similarly, as the midisation alignment, $\operatorname{algn}\left(A^{\mathrm{M}(T)}\right)$, is maximised the contentisation alignment increases to equal the surrealisation alignment, and so midisation alignment maximisation also tends to formalabstract equivalence, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$.

The discussion of midisation entropy in 'Likely histograms', above, goes on to conjecture that there exists a mid substrate transform $T_{\mathrm{m}} \in \mathcal{T}_{U, V}$ which is neither self nor unary, $T_{\mathrm{m}} \notin\left\{T_{\mathrm{s}}, T_{\mathrm{u}}\right\}$, where the formal is independent and the midisation entropy is minimised,

$$
T_{\mathrm{m}} \in \operatorname{mind}\left(\left\{\left(T, \operatorname{entropy}\left(A^{\mathrm{M}(T)}\right)\right): T \in \mathcal{T}_{U, V}, A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right\}\right)
$$

At the mid transform the formal tends to the abstract, $A^{\mathrm{X}} * T_{\mathrm{m}} \approx\left(A * T_{\mathrm{m}}\right)^{\mathrm{X}}$, and the mid component size cardinality relative entropy is small,

$$
\text { entropyRelative }\left(A * T_{\mathrm{m}}, V^{\mathrm{C}} * T_{\mathrm{m}}\right) \approx 0
$$

Conjecture that an approximation to the mid transform may also be obtained by a maximisation of the midisation pseudo-alignment,

$$
\begin{aligned}
& T_{\mathrm{m}} \in \operatorname{maxd}\left(\left\{\left(T, \operatorname{algn}(A)-\operatorname{algn}\left(A * T * T^{\dagger A}\right)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)\right):\right.\right. \\
& T\left.\left.\in \mathcal{T}_{U, V}, A^{\mathrm{x}} * T=\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}\right\}\right)
\end{aligned}
$$

The discussion in 'Likely histograms' then goes on to show that subsequent minimisation of the idealisation entropy, where the mid idealisation is integral, $A * T_{\mathrm{m}} * T_{\mathrm{m}}^{\dagger A} \in \mathcal{A}_{\mathrm{i}}$, tends to increase the mid component size cardinality relative entropy,

$$
\text { entropyRelative }\left(A * T_{\mathrm{m}}, V^{\mathrm{C}} * T_{\mathrm{m}}\right) \sim-\operatorname{entropy}\left(A * T_{\mathrm{m}} * T_{\mathrm{m}}^{\dagger A}\right)
$$

Conjecture, therefore, that subsequent maximisation of the idealisation alignment also tends to increase the relative entropy,

$$
\text { entropyRelative }\left(A * T_{\mathrm{m}}, V^{\mathrm{C}} * T_{\mathrm{m}}\right) \sim \operatorname{algn}\left(A * T_{\mathrm{m}} * T_{\mathrm{m}}^{\dagger A}\right)
$$

Consider the histogram-transform pair $(A, T) \in \mathcal{O}_{U, z}$ where the derived histogram is as effective as the formal histogram, $(A * T)^{\mathrm{F}} \geq\left(A^{\mathrm{X}} * T\right)^{\mathrm{F}}$, so that the contentisation is size-conserving, $\operatorname{size}\left(A^{\mathrm{X}} * T * T^{\odot A}\right)=\operatorname{size}(A)$. The idealisation histogram, $A * T * T^{\dagger A}$, can be defined as the summation of its independent components

$$
A * T * T^{\dagger A} \equiv \sum\left((A * C)^{\mathrm{x}}:(R, C) \in T^{-1}\right)
$$

where $T^{-1}$. Hence conjecture that the non-idealisation alignment, $\operatorname{algn}(A)-$ $\operatorname{algn}\left(A * T * T^{\dagger A}\right)$, varies as the sum of the alignments of the components

$$
\operatorname{algn}(A)-\operatorname{algn}\left(A * T * T^{\dagger A}\right) \sim \sum\left(\operatorname{algn}(A * C):(R, C) \in T^{-1}\right)
$$

So, the non-idealisation alignment varies as the sum of the alignments of the derivedly re-sized components

$$
\begin{aligned}
& \operatorname{algn}(A)-\operatorname{algn}\left(A * T * T^{\dagger A}\right) \sim \\
& \quad \sum\left(\operatorname{algn}\left(Z_{D_{R} / D_{R}} * A * C\right):(R, C) \in T^{-1}, D_{R}>0\right)
\end{aligned}
$$

where $D=A * T$ and $Z_{x}=\operatorname{scalar}(x)$. Similarly, the surrealisation alignment, $\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)$, varies as the sum of the alignments of the abstractly re-sized components

$$
\begin{aligned}
& \operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right) \sim \\
& \quad \sum\left(\operatorname{algn}\left(Z_{D_{R}^{\mathrm{X}} / D_{R}} * A * C\right):(R, C) \in T^{-1}, D_{R}>0\right)
\end{aligned}
$$

Therefore the midisation pseudo-alignment, $\operatorname{algn}(A)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)-$ $\operatorname{algn}\left(A * T * T^{\dagger A}\right)$, varies as the difference

$$
\begin{aligned}
& \operatorname{algn}(A)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)-\operatorname{algn}\left(A * T * T^{\dagger A}\right) \sim \\
& \quad \sum\left(\operatorname{algn}\left(Z_{D_{R} / D_{R}} * A * C\right)-\operatorname{algn}\left(Z_{D_{R}^{\mathrm{X}} / D_{R}} * A * C\right):(R, C) \in T^{-1}, D_{R}>0\right)
\end{aligned}
$$

Stated roughly in terms of the most effective states of a highly diagonalised derived histogram, the midisation pseudo-alignment increases as on-diagonal component alignments, algn $(A * C)$ where $(R, C) \in T^{-1}$ and $R \in((A * T)-$ $\left.(A * T)^{\mathrm{X}}\right)^{\mathrm{FS}}$, exceed off-diagonal abstractly re-sized component alignments, $\operatorname{algn}\left(Z_{D_{R}^{\mathrm{x}} / D_{R}} * A * C\right)$ where $(R, C) \in T^{-1}$ and $R \in\left((A * T)^{\mathrm{X}}-(A * T)\right)^{\mathrm{FS}}$. Conjecture that the midisation pseudo-alignment (i) increases with the derived alignment, increasing the difference between the on-diagonal and offdiagonal component sizes, but (ii) decreases with the length of the diagonal, because long diagonals decrease the component sizes. That is,
$\operatorname{algn}(A)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)-\operatorname{algn}\left(A * T * T^{\dagger A}\right) \sim \operatorname{algn}(A * T) / w^{1 / m}$
where $m=|W|, w=\left|W^{\mathrm{C}}\right|$ and $W=\operatorname{der}(T)$. Here the length of the diagonal, $w^{1 / m}$, is approximated to the geometric average of the valencies of the derived variables, $w^{1 / m}=\left(\prod_{u \in W}\left|U_{u}\right|\right)^{1 / m}$. In other words, the midisation pseudoalignment varies with the derived alignment valency density,

$$
\begin{aligned}
\operatorname{algn}(A)-\operatorname{algn}\left((A * T)^{\mathrm{X}}\right. & \left.* T^{\odot A}\right)-\operatorname{algn}\left(A * T * T^{\dagger A}\right) \sim \\
& \operatorname{algn}(A * T) / \operatorname{capacityValency}(U)\left((A * T)^{\mathrm{FS}}\right)
\end{aligned}
$$

where valency capacity is defined in section 'Capacity and Alignment density', above, capacityValency $(U) \in$ capacities in system $U$ as

$$
\operatorname{capacityValency}(U)(Q):=x^{1 / p}
$$

where $x=\operatorname{volume}(U)(\operatorname{vars}(Q))$ and $p=|\operatorname{vars}(Q)|$.
Although the idealisation alignment, $\operatorname{algn}\left(A * T * T^{\dagger} A\right.$, varies with the derived alignment, algn $(A * T)$, this is less the case in the region of short diagonals. The idealisation alignment is a convex, positive-gradient function of derived histogram diagonal length. The convexity increases with derived alignment for given diagonal length because the on-diagonal components have greater size and the alignment of the components is a convex function of component size. That is, the alignment only scales linearly with size, $\operatorname{algn}(\operatorname{scalar}(k) * A) \approx k \times \operatorname{algn}(A)$, at high entropies and low alignments, as discussed in 'Scaled alignment', above. For example, the sum of the alignments of the components of a uniformly diagonalised regular derived histogram of valency 2 is expected to be greater than for valency 3 in the same underlying histogram, $\sum_{\left(\cdot, C_{1}\right) \in T_{1}^{-1}} \operatorname{algn}\left(A * C_{1}\right)>\sum_{\left(\cdot, C_{2}\right) \in T_{2}^{-1}} \operatorname{algn}\left(A * C_{2}\right)$ where $\left|\left(A * T_{1}\right)^{\mathrm{F}}\right|=2$ and $\left|\left(A * T_{2}\right)^{\mathrm{F}}\right|=3$. So the effect of rendering the compenents independent, when the independent converse, $T^{\dagger A}$, is applied, is greater in the idealisation at shorter valencies.

The surrealisation alignment, algn $\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)$, varies against the derived alignment, $\operatorname{algn}(A * T)$, because the application of the actual converse, $T^{\odot A}$, to the derived, $A * T$, is the constant underlying histogram, $A * T * T^{\odot A}=A$. The surrealisation alignment is a convex, negative-gradient function of derived histogram diagonal length. The convexity increases with derived alignment for given diagonal length because ineffective off-diagonal components are still ineffective after abstract re-sizing, $\operatorname{size}(A * C)=0 \Longrightarrow$ $\operatorname{algn}\left(Z_{D_{R}^{\mathrm{x}} / D_{R}} * A * C\right)=0$, where $(R, C) \in T^{-1}$ and $R \notin(A * T)^{\mathrm{FS}}$.

Thus the midisation pseudo-alignment, $\operatorname{algn}(A)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)-$
$\operatorname{algn}\left(A * T * T^{\dagger A}\right)$, which depends on the alignments of histograms in the underlying variables, varies with the derived alignment valency density, $\operatorname{algn}(A *$ $T) / w^{1 / m}$, which depends only on the geometry and alignment of the derived histogram in the derived variables.

Consider the example of a histogram-transform pair $(A, T) \in \mathcal{O}_{U, z+y}$, where the histogram is a regular cardinal histogram, $A \in \mathcal{A}_{c}$, of dimension $n$ and valency $d$ that consists of a diagonal histogram of size $z$ plus a cartesian histogram of size $y$,

$$
\begin{aligned}
A= & \{(S, z / d): S \in\{\{(x, u): x \in\{1 \ldots n\}\}: u \in\{1 \ldots d\}\}\}+ \\
& \left\{\left(S, y / d^{n}\right): S \in \prod\{\{(x, u): u \in\{1 \ldots d\}\}: x \in\{1 \ldots n\}\}\right\}
\end{aligned}
$$

and the transform, $T$, has a derived variable for every underlying variable having derived values which roll up adjacent $d / c$ underlying values, where $c$ is the derived valency,

$$
\begin{aligned}
T= & (\{(S \cup\{(x+n,(u / c)+1):(x, u) \in S\}, 1): \\
& \left.\left.S \in \prod\{\{(x, u): u \in\{1 \ldots d\}\}: x \in\{1 \ldots n\}\}\right\},\{n+1 \ldots n+n\}\right)
\end{aligned}
$$

where $(/) \in \mathbf{N} \times \mathbf{N}_{>0} \rightarrow \mathbf{N}$.
Let $q_{0}=y, q_{1}=z+y, q_{\mathrm{c}}=c^{n-1} z+y, q_{\mathrm{d}}=d^{n-1} z+y$, and $r=d / c$. The histogram alignment is

$$
\operatorname{algn}(A)=d \ln \frac{q_{\mathrm{d}}}{d^{n}}!+\left(d^{n}-d\right) \ln \frac{q_{0}}{d^{n}}!-d^{n} \ln \frac{q_{1}}{d^{n}}!
$$

The derived alignment is

$$
\operatorname{algn}(A * T)=c \ln \frac{q_{\mathrm{c}}}{c^{n}}!+\left(c^{n}-c\right) \ln \frac{q_{0}}{c^{n}}!-c^{n} \ln \frac{q_{1}}{c^{n}}!
$$

The formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, so the formal alignment is zero

$$
\operatorname{algn}\left(A^{\mathrm{X}} * T\right)=0
$$

The neutralisation equals the idealisation, $A * T * T^{\odot} A^{\mathrm{x}}=A * T * T^{\dagger}{ }^{\text {. }}$. The idealisation alignment is

$$
\begin{aligned}
\operatorname{algn}\left(A * T * T^{\dagger A}\right) & =r^{n} c \ln \frac{q_{\mathrm{c}}}{d^{n}}!+r^{n}\left(c^{n}-c\right) \ln \frac{q_{0}}{d^{n}}!-d^{n} \ln \frac{q_{1}}{r^{n} c^{n}}! \\
& =r^{n} c \ln \frac{q_{\mathrm{c}}}{r^{n} c^{n}}!+r^{n}\left(c^{n}-c\right) \ln \frac{q_{0}}{r^{n} c^{n}}!-r^{n} c^{n} \ln \frac{q_{1}}{r^{n} c^{n}}!
\end{aligned}
$$

Each of the terms of the expression for the derived alignment, $\operatorname{algn}(A * T)$, has a corresponding term in the expression for the idealisation alignment, $\operatorname{algn}\left(A * T * T^{\dagger A}\right)$, scaled by $r^{n}$ and such that the argument to the factorial is inversely scaled by $r^{n}$. Thus the idealisation alignment is approximately less than the derived alignment, $\operatorname{algn}\left(A * T * T^{\dagger A}\right) \approx \operatorname{algn}(A * T)$, and $\operatorname{algn}\left(A * T * T^{\dagger A}\right) \leq \operatorname{algn}(A * T)$.

When $c=1$ both the derived alignment and the idealisation alignment are zero, $c=1 \Longrightarrow \operatorname{algn}(A * T)=\operatorname{algn}\left(A * T * T^{\dagger A}\right)=0$. This is the case, for example, if the transform is a unary partition transform $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$. When $c=d$ both the derived alignment and the idealisation alignment equal the histogram alignment, $c=d \Longrightarrow \operatorname{algn}(A * T)=\operatorname{algn}\left(A * T * T^{\dagger A}\right)=\operatorname{algn}(A)$. This is the case, for example, if the transform is a value full functional transform $T_{\mathrm{s}}=\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in V\right\}^{\mathrm{T}}$. The partial derivative of the idealisation alignment with respect to $c$ is positive where $1 \leq c \leq d$,

$$
\frac{\partial}{\partial c}\left(\frac{d^{n}}{c^{n-1}} \ln \frac{q_{\mathrm{c}}}{d^{n}}!-\frac{1}{c^{n-1}} \ln \frac{q_{0}}{d^{n}}!\right) \geq 0
$$

The contentisation equals the surrealisation, $A^{\mathrm{X}} * T * T^{\odot A}=(A * T)^{\mathrm{X}} * T^{\odot A}$. The surrealisation alignment is

$$
\operatorname{algn}\left((A * T)^{\mathrm{x}} * T^{\odot A}\right)=d \ln \frac{q_{\mathrm{d}}}{d^{n}} \frac{q_{1}}{q_{\mathrm{c}}}!+\left(r^{n} c-d\right) \ln \frac{q_{0}}{d^{n}} \frac{q_{1}}{q_{\mathrm{c}}}!-r^{n} c \ln \frac{q_{1}}{d^{n}}!
$$

When $c=1$ the surrealisation alignment equals the histogram alignment, $c=1 \Longrightarrow \operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)=\operatorname{algn}(A)$. When $c=d$ the surrealisation alignment is zero, $c=d \Longrightarrow \operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)=0$. The partial derivative of the surrealisation alignment with respect to $c$ is negative where $1<c<d$,

$$
\frac{\partial}{\partial c}\left(d \ln \frac{q_{\mathrm{d}}}{d^{n}} \frac{q_{1}}{q_{\mathrm{c}}}!+\left(\frac{d^{n}}{c^{n-1}}-d\right) \ln \frac{q_{0}}{d^{n}} \frac{q_{1}}{q_{\mathrm{c}}}!-\frac{d^{n}}{c^{n-1}} \ln \frac{q_{1}}{d^{n}}!\right) \leq 0
$$

The midisation pseudo-alignment is

$$
\begin{gathered}
\operatorname{algn}(A)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)-\operatorname{algn}\left(A * T * T^{\dagger A}\right)= \\
\left(d \ln \frac{q_{\mathrm{d}}}{d^{n}}!+\left(r^{n} c-d\right) \ln \frac{q_{0}}{d^{n}}!+r^{n} c \ln \frac{q_{1}}{d^{n}}!\right)- \\
\left(d \ln \frac{q_{\mathrm{d}}}{d^{n}} \frac{q_{1}}{q_{\mathrm{c}}}!+\left(r^{n} c-d\right) \ln \frac{q_{0}}{d^{n}} \frac{q_{1}}{q_{\mathrm{c}}}!+r^{n} c \ln \frac{q_{\mathrm{c}}}{d^{n}}!\right)
\end{gathered}
$$

When $c=1$ or $c=d$ the midisation pseudo-alignment is zero, $(c=1) \wedge$ $(c=d) \Longrightarrow \operatorname{algn}(A)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)-\operatorname{algn}\left(A * T * T^{\dagger A}\right)=0$.

Elsewhere the midisation pseudo-alignment is greater than zero, $1<c<$ $d \Longrightarrow \operatorname{algn}(A)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)-\operatorname{algn}\left(A * T * T^{\dagger A}\right)>0$, therefore the midisation pseudo-alignment as a function of $c$ contains a maximum away from the boundaries.

Having shown that the midisation pseudo-alignment varies with derived alignment valency density

$$
\operatorname{algn}(A)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)-\operatorname{algn}\left(A * T * T^{\dagger A}\right) \sim \operatorname{algn}(A * T) / w^{1 / m}
$$

conjecture that the approximation to the mid transform obtained by a maximisation of the midisation pseudo-alignment, where the formal is independent,

$$
\begin{aligned}
& T_{\mathrm{m}} \in \operatorname{maxd}\left(\left\{\left(T, \operatorname{algn}(A)-\operatorname{algn}\left(A * T * T^{\dagger A}\right)-\operatorname{algn}\left((A * T)^{\mathrm{x}} * T^{\odot A}\right)\right):\right.\right. \\
& T\left.\left.\in \mathcal{T}_{U, V}, A^{\mathrm{x}} * T=\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}\right\}\right)
\end{aligned}
$$

also has high derived alignment, $\operatorname{algn}\left(A * T_{\mathrm{m}}\right)$, and hence low derived entropy, entropy $\left(A * T_{\mathrm{m}}\right)$. Although the mid derived entropy decreases, the mid derived relative entropy is small, entropyRelative $\left(A * T_{\mathrm{m}}, V^{\mathrm{C}} * T_{\mathrm{m}}\right) \approx 0$, because the formal tends to the abstract, $A^{\mathrm{X}} * T_{\mathrm{m}} \approx\left(A * T_{\mathrm{m}}\right)^{\mathrm{X}}$. That is, while a maximisation of the midisation pseudo-alignment, where the formal is independent, tends to decrease the derived entropy, the relative entropy also tends to decrease. A subsequent maximisation of the mid integral idealisation alignment, $\operatorname{algn}\left(A * T_{\mathrm{m}} * T_{\mathrm{m}}^{\dagger A}\right)$, which tends to lengthen derived diagonals towards full functional, is necessary to recover the relative entropy.

Given a histogram-transform pair $(A, T) \in \mathcal{O}_{U, z}$, having variables $V=$ $\operatorname{vars}(A)$, size $z=\operatorname{size}(A)$ and volume $v=\left|V^{\mathrm{C}}\right|$, it is conjectured in section 'Likely histograms', above, that the maximum likelihood estimate for the integral iso-deriveds is the naturalisation, $A * T * T^{\dagger}$,

$$
\begin{aligned}
& \left\{A * T * T^{\dagger}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The corresponding dependent analogue is the derived-dependent, $A^{\mathrm{D}(T)} \in$ $\mathcal{A}_{U, V, z}$, defined

$$
\left\{A^{\mathrm{D}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in D_{U, \mathbf{i}, T, z}^{-1}(A * T)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

The naturalisation-distributed-relative multinomial space is
spaceRelative $\left(A * T * T^{\dagger}\right)(A):=-\ln \frac{\operatorname{mpdf}(U)\left(A * T * T^{\dagger}, z\right)(A)}{\operatorname{mpdf}(U)\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right)}$
where the distribution-relative multinomial space is defined, in section 'Likely histograms', above, as

$$
\text { spaceRelative }(E)(A):=-\ln \frac{\operatorname{mpdf}(U)(E, z)(A)}{\operatorname{mpdf}(U)(E, z)(E)}
$$

The naturalisation is computable, so a rational approximation to the naturalisation distributed-relative multinomial space is computable.

In the case where both the histogram and naturalisation are integral, $A, A *$ $T * T^{\dagger} \in \mathcal{A}_{\mathrm{i}}$, the naturalisation-distributed-relative multinomial space is

$$
\operatorname{spaceRelative}\left(A * T * T^{\dagger}\right)(A):=-\ln \frac{Q_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)(A)}{Q_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right)}
$$

The naturalisation-distributed-relative multinomial space of the naturalisation is zero,

$$
\operatorname{spaceRelative}\left(A * T * T^{\dagger}\right)\left(A * T * T^{\dagger}\right)=0
$$

In the case where the histogram and naturalisation are integral, $A, A * T * T^{\dagger} \in$ $\mathcal{A}_{\mathrm{i}}$, the naturalisation-distributed-relative multinomial space is conjectured to be greater than or equal to zero, and less than or equal to the naturalisation-distributed-relative multinomial space of the derived-dependent,

$$
0 \leq \operatorname{spaceRelative}\left(A * T * T^{\dagger}\right)(A) \leq \operatorname{spaceRelative}\left(A * T * T^{\dagger}\right)\left(A^{\mathrm{D}(T)}\right)
$$

This is consistent with the entropies,

$$
\operatorname{entropy}\left(A * T * T^{\dagger}\right) \geq \operatorname{entropy}(A) \geq \operatorname{entropy}\left(A^{\mathrm{D}(T)}\right)
$$

In the case where the transform is full functional, $T=T_{\mathrm{f}}$, the naturalisation equals the histogram, $A * T_{\mathrm{f}} * T_{\mathrm{f}}^{\dagger}=A$, and so the naturalisation-distributedrelative multinomial space equals zero,

$$
\operatorname{spaceRelative}\left(A * T_{\mathrm{f}} * T_{\mathrm{f}}^{\dagger}\right)(A)=0
$$

At the other extreme where the transform is unary, $T=T_{\mathrm{u}}$, the naturalisation equals the scaled normalised cartesian, $A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger}=\operatorname{scalar}(z / v) * V^{\mathrm{C}}$, and so the naturalisation-distributed-relative multinomial space simplifies to

$$
\text { spaceRelative }\left(A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger}\right)(A)=\sum_{S \in A^{\mathrm{s}}} \ln \Gamma_{!} A_{S}-v \ln \Gamma_{!}(z / v)
$$

The naturalisation-derived is equal to the derived, $\left(A * T * T^{\dagger}\right) * T=A * T$, so the naturalisation-derived alignment equals the derived alignment,

$$
\operatorname{algn}\left(\left(A * T * T^{\dagger}\right) * T\right)=\operatorname{algn}(A * T)
$$

Of the integral iso-deriveds, only the naturalisation has zero naturalisation-distributed-relative multinomial space,
$\forall B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)\left(B \neq A * T * T^{\dagger} \Longrightarrow \operatorname{spaceRelative}\left(A * T * T^{\dagger}\right)(B)>0\right)$
Insofar as the naturalisation is approximately equal to the independent, $A *$ $T * T^{\dagger} \approx A^{\mathrm{X}}$, then the naturalisation-distributed-relative multinomial space approximates to

$$
\begin{aligned}
\operatorname{spaceRelative}\left(A * T * T^{\dagger}\right)(A) & \approx \sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}-\sum_{S \in A^{\mathrm{xS}}} \ln \Gamma_{!}\left(A * T * T^{\dagger}\right)_{S} \\
& \approx z \times \operatorname{entropy}\left(A * T * T^{\dagger}\right)-z \times \operatorname{entropy}(A)
\end{aligned}
$$

The difference is the mis-naturalisation-distributed-relative multinomial space,

$$
\sum_{S \in A^{\mathrm{xS}}}\left(A_{S}-\left(A * T * T^{\dagger}\right)_{S}\right) \ln \left(A * T * T^{\dagger}\right)_{S}
$$

The degree to which the integral iso-derived is aligned-like is the iso independence,

$$
\frac{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T) \cap Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T) \cup Y_{U, \mathbf{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}
$$

As the iso-independence of an iso-set increases, the independent analogue tends to the independent. In this case the naturalisation, $A * T * T^{\dagger}$, tends to the independent, $A^{\mathrm{X}}$, and so the relative space, spaceRelative $\left(A * T * T^{\dagger}\right)(A)$, tends to the alignment, $\operatorname{algn}(A)$. That is, as the integral iso-deriveds becomes more aligned-like, the relative space becomes less dependent on the transform, $T$.

The iso-set is law-like, so in the case where the dependent analogue is in the iso-set, $A^{\mathrm{D}(T)} \in D_{U, T, z}^{-1}(A * T)$, the dependent derived equals the derived, $A^{\mathrm{D}(T)} * T=A * T$, and the difference in relative space between the histogram and the dependent must be in the relative spaces of the components,

$$
\begin{aligned}
& A^{\mathrm{D}(T)} \in D_{U, T, z}^{-1}(A * T) \Longrightarrow \\
& \quad \sum_{(\cdot, C) \in T^{-1}} \operatorname{spaceRelative}\left(A * T * T^{\dagger} * C\right)(A * C) \\
& \leq \sum_{(\cdot, C) \in T^{-1}} \operatorname{spaceRelative}\left(A * T * T^{\dagger} * C\right)\left(A^{\mathrm{D}(T)} * C\right)
\end{aligned}
$$

and so

$$
\begin{aligned}
& A^{\mathrm{D}(T)} \in D_{U, T, z}^{-1}(A * T) \Longrightarrow \\
& \quad \sum_{(\cdot, C) \in T^{-1}} \sum_{S \in C^{\mathrm{S}}} \ln \Gamma_{!} A_{S} \leq \sum_{(\cdot, C) \in T^{-1}} \sum_{S \in C^{\mathrm{S}}} \ln \Gamma_{!} A_{S}^{\mathrm{D}(T)}
\end{aligned}
$$

or

$$
A^{\mathrm{D}(T)} \in D_{U, T, z}^{-1}(A * T) \Longrightarrow \sum_{S \in V^{\mathrm{CS}}} \ln \Gamma_{!} A_{S} \leq \sum_{S \in V^{\mathrm{CS}}} \ln \Gamma_{!} A_{S}^{\mathrm{D}(T)}
$$

In 'Iso-sets', above, the cardinality of the set of integral iso-deriveds is the product of the weak compositions of the components,

$$
\left|D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right|=\prod_{(R, C) \in T^{-1}} \frac{\left((A * T)_{R}+|C|-1\right)!}{(A * T)_{R}!(|C|-1)!}
$$

It is shown in 'Integral iso-sets and entropy', above, that the integral isoderiveds log-cardinality varies against the size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
& \ln \left|D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right| \sim \\
& \quad-\left((z+v) \times \operatorname{entropy}\left(A * T+V^{\mathrm{C}} * T\right)\right. \\
& \left.\quad-z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)\right)
\end{aligned}
$$

In the domain where the size is less than or equal to the volume, $z \leq v$, the integral iso-deriveds log-cardinality varies against the size scaled component size cardinality relative entropy,

$$
\ln \left|D_{U, i, T, z}^{-1}(A * T)\right| \sim-z \times \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)
$$

In the domain where the size is greater than the volume, $z>v$, the integral iso-deriveds log-cardinality varies against the volume scaled component cardinality size relative entropy,

$$
\ln \left|D_{U, i, T, z}^{-1}(A * T)\right| \sim-v \times \operatorname{entropyRelative}\left(V^{\mathrm{C}} * T, A * T\right)
$$

The relative entropy is the cross entropy minus the component entropy, so in the case where the size is less than or equal to the volume, $z \leq v$, the iso-derived log-cardinality varies against the component size cardinality cross entropy and varies with the derived entropy or component size entropy,

$$
\ln \left|D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right| \sim-z \times \operatorname{entropyCross}\left(A * T, V^{\mathrm{C}} * T\right)
$$

and

$$
\ln \left|D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right| \sim z \times \operatorname{entropy}(A * T)
$$

Given a histogram-transform pair $(A, T) \in \mathcal{O}_{U, z}$, it is conjectured above that the maximum likelihood estimate for the integral iso-idealisations is the idealisation, $A * T * T^{\dagger A}$,

$$
\begin{aligned}
& \left\{A * T * T^{\dagger A}\right\}= \\
& \quad \quad \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isoi}(U)(T, A)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

where $\operatorname{isoi}(U)(T, A):=Y_{U, \mathrm{i}, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)$.
The corresponding dependent analogue is the idealisation-dependent, $A^{\dagger(T)} \in$ $\mathcal{A}_{U, V, z}$, defined

$$
\begin{aligned}
& \left\{A^{\dagger(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isoi}(U)(T, A)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The idealisation-distributed-relative multinomial space is
spaceRelative $\left(A * T * T^{\dagger A}\right)(A):=-\ln \frac{\operatorname{mpdf}(U)\left(A * T * T^{\dagger A}, z\right)(A)}{\operatorname{mpdf}(U)\left(A * T * T^{\dagger A}, z\right)\left(A * T * T^{\dagger A}\right)}$
The idealisation is computable, so a rational approximation to the idealisation-distributed-relative multinomial space is computable.

In the case where both the histogram and idealisation are integral, $A, A *$ $T * T^{\dagger A} \in \mathcal{A}_{\mathrm{i}}$, the idealisation-distributed-relative multinomial space is
spaceRelative $\left(A * T * T^{\dagger A}\right)(A):=-\ln \frac{Q_{\mathrm{m}, U}\left(A * T * T^{\dagger A}, z\right)(A)}{Q_{\mathrm{m}, U}\left(A * T * T^{\dagger A}, z\right)\left(A * T * T^{\dagger A}\right)}$
The idealisation-distributed-relative multinomial space of the idealisation is zero,

$$
\text { spaceRelative }\left(A * T * T^{\dagger A}\right)\left(A * T * T^{\dagger A}\right)=0
$$

In the case where the histogram and idealisation are integral, $A, A * T * T^{\dagger A} \in$ $\mathcal{A}_{\mathrm{i}}$, the idealisation-distributed-relative multinomial space is conjectured to be greater than or equal to zero, and less than or equal to the idealisation-distributed-relative multinomial space of the idealisation-dependent, $0 \leq \operatorname{spaceRelative}\left(A * T * T^{\dagger A}\right)(A) \leq \operatorname{spaceRelative}\left(A * T * T^{\dagger A}\right)\left(A^{\dagger(T)}\right)$

This is consistent with the entropies,

$$
\operatorname{entropy}\left(A * T * T^{\dagger A}\right) \geq \operatorname{entropy}(A) \geq \operatorname{entropy}\left(A^{\dagger(T)}\right)
$$

In the case where the transform is full functional, $T=T_{\mathrm{f}}$, the idealisation equals the histogram, $A * T_{\mathrm{f}} * T_{\mathrm{f}}^{\dagger A}=A$, and so the idealisation equals zero,

$$
\operatorname{spaceRelative}\left(A * T_{\mathrm{f}} * T_{\mathrm{f}}^{\dagger A}\right)(A)=0
$$

At the other extreme where the transform is unary, $T=T_{\mathrm{u}}$, the idealisation equals the independent, $A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger A}=A^{\mathrm{X}}$, and so the idealisation-distributedrelative multinomial space equals the alignment

$$
\operatorname{spaceRelative}\left(A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger A}\right)(A)=\operatorname{algn}(A)
$$

Conjecture that the relative space of the histogram with respect to the idealisation is less than or equal to that with respect to the independent,

$$
\operatorname{spaceRelative}\left(A * T * T^{\dagger A}\right)(A) \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}}\right)(A)=\operatorname{algn}(A)
$$

and similarly for the idealisation-dependent
spaceRelative $\left(A * T * T^{\dagger A}\right)\left(A^{\dagger(T)}\right) \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}}\right)\left(A^{\dagger(T)}\right)=\operatorname{algn}\left(A^{\dagger(T)}\right)$
because the idealisation entropy is less than or equal to the independent entropy, entropy $\left(A * T * T^{\dagger A}\right) \leq \operatorname{entropy}\left(A^{\mathrm{X}}\right)$.

The idealisation-derived is equal to the derived, $\left(A * T * T^{\dagger A}\right) * T=A * T$, so the idealisation-derived alignment equals the derived alignment,

$$
\operatorname{algn}\left(\left(A * T * T^{\dagger A}\right) * T\right)=\operatorname{algn}(A * T)
$$

Of the integral iso-idealisations, only the idealisation has zero idealisation-distributed-relative multinomial space,

$$
\begin{aligned}
& \forall B \in Y_{U, \mathrm{i}, T, \mathrm{t}, z}^{-1}\left(A * T * T^{\dagger A}\right) \\
& \qquad\left(B \neq A * T * T^{\dagger A} \Longrightarrow \operatorname{spaceRelative}\left(A * T * T^{\dagger A}\right)(B)>0\right)
\end{aligned}
$$

Insofar as the transform approximates to unary, $T \approx T_{\mathrm{u}}$, the idealisation approximates to the independent, $A * T * T^{\dagger A} \approx A^{\mathrm{X}}$, and the idealisation-distributed-relative multinomial space approximates to

$$
\begin{aligned}
\operatorname{spaceRelative}\left(A * T * T^{\dagger A}\right)(A) & \approx \sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}-\sum_{S \in A^{\mathrm{XS}}} \ln \Gamma_{!}\left(A * T * T^{\dagger A}\right)_{S} \\
& \approx z \times \operatorname{entropy}\left(A * T * T^{\dagger A}\right)-z \times \operatorname{entropy}(A)
\end{aligned}
$$

The difference is the mis-idealisation-distributed-relative multinomial space,

$$
\sum_{S \in A^{\mathrm{XS}}}\left(A_{S}-\left(A * T * T^{\dagger A}\right)_{S}\right) \ln \left(A * T * T^{\dagger A}\right)_{S}
$$

The iso-idealisations is a subset of the iso-independents, $Y_{U, T, \dagger, z}^{-1}\left(A * T * T^{\dagger A}\right) \subseteq$ $Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, so the iso-independence is the fraction of their integral cardinalities,

$$
\frac{\left|Y_{U, i, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)\right|}{\left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}
$$

In some cases the iso-independence of the iso-idealisations is greater than or equal to the iso-independence of the iso-derived,

$$
\frac{\left|Y_{U, i, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)\right|}{\left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|} \geq \frac{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T) \cap Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T) \cup Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}
$$

As the iso-independence increases, the transform becomes more unary, the idealisation, $A * T * T^{\dagger A}$, tends to the independent, $A^{\mathrm{X}}$, and the relative space, spaceRelative $\left(A * T * T^{\dagger A}\right)(A)$, tends to the alignment, $\operatorname{algn}(A)$.

The iso-set is law-like, so in the case where the dependent analogue is in the iso-set, $A^{\dagger(T)} \in D_{U, T, z}^{-1}(A * T)$, the dependent derived equals the derived, $A^{\dagger(T)} * T=A * T$, and the difference in relative space between the histogram and the dependent must be in the relative spaces of the components,

$$
\begin{aligned}
A^{\dagger(T)} & \in D_{U, T, z}^{-1}(A * T) \Longrightarrow \\
& \quad \sum_{(\cdot, C) \in T^{-1}} \operatorname{spaceRelative}\left(A * T * T^{\dagger A} * C\right)(A * C) \\
& \leq \sum_{(\cdot, C) \in T^{-1}} \operatorname{spaceRelative}\left(A * T * T^{\dagger A} * C\right)\left(A^{\dagger(T)} * C\right)
\end{aligned}
$$

So, in the case of the idealisation-dependent, the component alignments must be greater than or equal to the component alignments of the histogram,

$$
\begin{aligned}
& A^{\dagger(T)} \in D_{U, T, z}^{-1}(A * T) \Longrightarrow \\
& \quad \sum_{(\cdot, C) \in T^{-1}} \operatorname{algn}(A * C) \leq \sum_{(\cdot, C) \in T^{-1}} \operatorname{algn}\left(A^{\dagger(T)} * C\right)
\end{aligned}
$$

The iso-derivedence, or degree of law-likeness, of the iso-idealisations is

$$
\frac{\left|Y_{U, i, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)\right|}{\left|D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right|} \leq 1
$$

As the iso-derivedence increases, the difference between the relative spaces of the dependents, spaceRelative $\left(A * T * T^{\dagger}\right)\left(A^{\mathrm{D}(T)}\right)-\operatorname{spaceRelative}(A * T *$ $\left.T^{\dagger A}\right)\left(A^{\dagger(T)}\right)$, decreases.

Given a histogram-transform pair $(A, T) \in \mathcal{O}_{U, z}$, it is conjectured in section 'Likely histograms', above, that the maximum likelihood estimate for the integral iso-abstracts is the naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$,

$$
\begin{aligned}
& \left\{(A * T)^{\mathrm{x}} * T^{\dagger}\right\}= \\
& \quad \quad \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The corresponding dependent analogue is the abstract-dependent, $A^{\mathrm{W}(T)} \in$ $\mathcal{A}_{U, V, z}$, defined

$$
\begin{aligned}
& \left\{A^{\mathrm{W}(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The naturalised abstract distributed relative multinomial space is

$$
\begin{aligned}
& \text { spaceRelative }\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)(A):= \\
& \\
& \quad-\ln \frac{\operatorname{mpdf}(U)\left((A * T)^{\mathrm{x}} * T^{\dagger}, z\right)(A)}{\operatorname{mpdf}(U)\left((A * T)^{\mathrm{X}} * T^{\dagger}, z\right)\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)}
\end{aligned}
$$

The naturalised abstract is computable, so a rational approximation to the naturalised abstract distributed relative multinomial space is computable.

In the case where both the histogram and naturalised abstract are integral, $A,(A * T)^{\mathrm{X}} * T^{\dagger} \in \mathcal{A}_{\mathfrak{i}}$, the naturalised abstract distributed relative multinomial space is

$$
\begin{aligned}
& \text { spaceRelative }\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)(A):= \\
& \\
& \quad-\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}} * T^{\dagger}, z\right)(A)}{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}} * T^{\dagger}, z\right)\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)}
\end{aligned}
$$

The naturalised abstract distributed relative multinomial space of the naturalised abstract is zero,

$$
\text { spaceRelative }\left((A * T)^{\mathrm{x}} * T^{\dagger}\right)\left((A * T)^{\mathrm{x}} * T^{\dagger}\right)=0
$$

In the case where the histogram and naturalised abstract are integral, $A,(A *$ $T)^{\mathrm{X}} * T^{\dagger} \in \mathcal{A}_{\mathrm{i}}$, the naturalised abstract distributed relative multinomial space is conjectured to be greater than or equal to zero, and less than or equal to the naturalised abstract distributed relative multinomial space of the abstractdependent,
$0 \leq \operatorname{spaceRelative}\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)(A) \leq \operatorname{spaceRelative}\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)\left(A^{\mathrm{W}(T)}\right)$

This is consistent with the entropies,

$$
\operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\dagger}\right) \geq \operatorname{entropy}(A) \geq \operatorname{entropy}\left(A^{\mathrm{W}(T)}\right)
$$

In the case where the transform is full functional, $T=T_{\mathrm{f}}$, the naturalised abstract equals the independent, $\left(A * T_{\mathrm{f}}\right)^{\mathrm{X}} * T_{\mathrm{f}}^{\dagger}=A^{\mathrm{X}}$, and so the naturalised abstract distributed relative multinomial space equals the aligment,

$$
\text { spaceRelative }\left(\left(A * T_{\mathrm{f}}\right)^{\mathrm{X}} * T_{\mathrm{f}}^{\dagger}\right)(A)=\operatorname{algn}(A)
$$

At the other extreme where the transform is unary, $T=T_{\mathrm{u}}$, the naturalised abstract equals the scaled normalised cartesian, $\left(A * T_{\mathrm{u}}\right)^{\mathrm{X}} * T_{\mathrm{u}}^{\dagger}=\operatorname{scalar}(z / v) *$ $V^{\mathrm{C}}$, and so the naturalised abstract distributed relative multinomial space simplifies to

$$
\text { spaceRelative }\left(\left(A * T_{\mathrm{u}}\right)^{\mathrm{X}} * T_{\mathrm{u}}^{\dagger}\right)(A)=\sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}-v \ln \Gamma_{!}(z / v)
$$

Of the integral iso-abstracts, only the naturalised abstract has zero naturalised abstract distributed relative multinomial space,

$$
\begin{aligned}
& \forall B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \\
& \quad\left(B \neq(A * T)^{\mathrm{x}} * T^{\dagger} \Longrightarrow \text { spaceRelative }\left((A * T)^{\mathrm{x}} * T^{\dagger}\right)(B)>0\right)
\end{aligned}
$$

Insofar as the naturalised abstract is approximately equal to the independent, $(A * T)^{\mathrm{X}} * T^{\dagger} \approx A^{\mathrm{X}}$, then the naturalised abstract distributed relative multinomial space approximates to

$$
\begin{aligned}
\text { spaceRelative }\left((A * T)^{\mathrm{X}} * T^{\dagger}\right) & (A) \\
& \approx \sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}-\sum_{S \in A^{\mathrm{xS}}} \ln \Gamma_{!}\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)_{S} \\
& \approx z \times \operatorname{entropy}\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)-z \times \operatorname{entropy}(A)
\end{aligned}
$$

The difference is the mis-naturalised abstract distributed relative multinomial space,

$$
\sum_{S \in A^{\mathrm{xS}}}\left(A_{S}-\left((A * T)^{\mathrm{x}} * T^{\dagger}\right)_{S}\right) \ln \left((A * T)^{\mathrm{x}} * T^{\dagger}\right)_{S}
$$

The degree to which the set of integral iso-abstracts is aligned-like is the iso-independence,

$$
\frac{\left|Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \cap Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|}
$$

As the iso-independence increases, the naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$, tends to the independent, $A^{\mathrm{X}}$, and the relative space, spaceRelative $\left((A * T)^{\mathrm{X}} *\right.$ $\left.T^{\dagger}\right)(A)$, tends to the alignment, algn $(A)$. That is, as the integral iso-abstracts becomes more aligned-like, the relative space becomes less dependent on the transform, $T$.

The independent analogue is the naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$. The derived alignment of the independent analogue is zero, algn $\left((A * T)^{\mathrm{X}} * T^{\dagger} * T\right)=$ $\operatorname{algn}\left((A * T)^{\mathrm{X}}\right)=0$. The set of iso-abstracts is entity-like so the derived, $A * T$, and the dependent derived, $A^{\mathrm{W}(T)} * T$, are not necessarily equal to each other and nor are they necessarily equal to the abstract, $(A * T)^{\mathrm{X}}$. Conjecture that the relation between the relative spaces,

$$
\begin{aligned}
0 & =\operatorname{spaceRelative}\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)\left((A * T)^{\mathrm{X}} * T^{\dagger}\right) \\
& \leq \operatorname{spaceRelative}\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)(A) \\
& \leq \operatorname{spaceRelative}\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)\left(A^{\mathrm{W}(T)}\right)
\end{aligned}
$$

can be lifted,

$$
\begin{aligned}
0 & =\text { spaceRelative }\left((A * T)^{\mathrm{X}}\right)\left((A * T)^{\mathrm{X}}\right) \\
& \leq \text { spaceRelative }\left((A * T)^{\mathrm{X}}\right)(A * T) \\
& \leq \text { spaceRelative }\left((A * T)^{\mathrm{X}}\right)\left(A^{\mathrm{W}(T)} * T\right)
\end{aligned}
$$

and so conjecture that the dependent analogue derived alignment is greater than or equal to the derived alignment which in turn is greater than or equal to the independent analogue derived alignment,

$$
0=\operatorname{algn}\left((A * T)^{\mathrm{x}}\right) \leq \operatorname{algn}(A * T) \leq \operatorname{algn}\left(A^{\mathrm{W}(T)} * T\right)
$$

The iso-derivedence of the iso-abstracts equals the iso-abstractence of the iso-deriveds,

$$
\frac{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}{\left|Y_{U, \mathbf{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
$$

As the iso-derivedence and iso-abstractence increases, the difference between the relative spaces of the dependents, spaceRelative $\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)\left(A^{\mathrm{W}(T)}\right)-$ spaceRelative $\left(A * T * T^{\dagger}\right)\left(A^{\mathrm{D}(T)}\right)$, decreases.

In 'Iso-sets', above, in the case where the derived is independent, $A *$ $T=(A * T)^{\mathrm{X}}$, the cardinality of the set of integral iso-abstracts equals the
cardinality of the set of integral iso-deriveds,

$$
\begin{aligned}
\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right| & =\left|D_{U, \mathrm{i}, T, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right| \\
& =\prod_{(R, C) \in T^{-1}} \frac{\left((A * T)_{R}^{\mathrm{X}}+|C|-1\right)!}{(A * T)_{R}^{\mathrm{X}}!(|C|-1)!}
\end{aligned}
$$

and so in this case the integral iso-abstracts log-cardinality is approximately proportional to the negative abstract size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
& \ln \left|Y_{U, 1, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right| \\
& \begin{array}{l}
\approx(z+v) \ln (z+v)-z \ln z-v \ln v \\
\quad-\left((z+v) \times \operatorname{entropy}\left((A * T)^{\mathrm{X}}+V^{\mathrm{C}} * T\right)\right. \\
\left.\quad-z \times \operatorname{entropy}\left((A * T)^{\mathrm{X}}\right)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)\right)
\end{array}
\end{aligned}
$$

In the case where the size is less than or equal to the volume, $z \leq v$, the log iso-abstract cardinality varies against the size scaled component size cardinality relative abstract entropy,

$$
\ln \left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right| \sim-z \times \text { entropyRelative }\left((A * T)^{\mathrm{X}}, V^{\mathrm{C}} * T\right)
$$

and where the size is greater than the volume, $z>v$, the log iso-abstract cardinality varies against the volume scaled component cardinality size relative abstract entropy,

$$
\ln \left|Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right| \sim-v \times \text { entropyRelative }\left(V^{\mathrm{C}} * T,(A * T)^{\mathrm{X}}\right)
$$

The relative entropy is the cross entropy minus the component entropy, so in the case where the size is less than or equal to the volume, $z \leq v$, the log iso-abstract cardinality varies against the component size cardinality cross abstract entropy and varies with the abstract entropy,

$$
\ln \left|Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right| \sim-z \times \text { entropyCross }\left((A * T)^{\mathrm{X}}, V^{\mathrm{C}} * T\right)
$$

and

$$
\ln \left|Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right| \sim z \times \operatorname{entropy}\left((\hat{A} * T)^{\mathrm{X}}\right)
$$

In this case where the size is less than or equal to the volume, $z \leq v$, the log iso-derivedence of the iso-abstracts varies with the difference between the
derived entropy and the abstract entropy, and so varies against the derived alignment,

$$
\begin{aligned}
\ln \frac{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|} & \sim z \times \operatorname{entropy}(A * T)-z \times \operatorname{entropy}\left((\hat{A} * T)^{\mathrm{X}}\right) \\
& \approx-\operatorname{spaceRelative}\left((A * T)^{\mathrm{X}}\right)(A * T) \\
& =-\operatorname{algn}(A * T)
\end{aligned}
$$

That is, the fraction of the entity-like histograms that are also law-like decreases as the derived alignment increases. In the case where the derived is independent, the derived alignment is minimised, $A * T=(A * T)^{\mathrm{X}} \Longrightarrow$ $\operatorname{algn}(A * T)$, and the iso-derivedence is maximised,

$$
\frac{\left|D_{U, \mathrm{i}, T, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}=1
$$

Given a histogram-transform pair $(A, T) \in \mathcal{O}_{U, z}$, the transform-independent, $A^{\mathrm{X}(T)} \in \mathcal{A}_{U, V, z}$, is defined in section 'Likely histograms', above, as
$\left\{A^{\mathrm{X}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)$
where the integral iso-transform-independents is abbreviated

$$
\begin{aligned}
\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A) & =Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{x}}\right)\right) \\
& =\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{x}} * T=A^{\mathrm{x}} * T,(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}\right\}
\end{aligned}
$$

The corresponding dependent analogue is the transform-dependent, $A^{\mathrm{Y}(T)} \in$ $\mathcal{A}_{U, V, z}$, defined

$$
\left\{A^{\mathrm{Y}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

The transform-independent-distributed-relative multinomial space is

$$
\operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)(A):=-\ln \frac{\operatorname{mpdf}(U)\left(A^{\mathrm{X}(T)}, z\right)(A)}{\operatorname{mpdf}(U)\left(A^{\mathrm{X}(T)}, z\right)\left(A^{\mathrm{X}(T)}\right)}
$$

The transform-independent is sometimes not computable, so the transform-independent-distributed-relative multinomial space is sometimes not computable.

In the case where both the histogram and transform-independent are integral, $A, A^{\mathrm{X}(T)} \in \mathcal{A}_{\mathbf{i}}$, the transform-independent-distributed-relative multinomial space is

$$
\operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)(A):=-\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)(A)}{Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)\left(A^{\mathrm{X}(T)}\right)}
$$

The transform-independent-distributed-relative multinomial space of the transform independent is zero,

$$
\operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)\left(A^{\mathrm{X}(T)}\right)=0
$$

In the case where the histogram is integral, $A \in \mathcal{A}_{\mathbf{i}}$, and the transformindependent is an integral iso-transform-independent, $A^{\mathrm{X}(T)} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)$, the transform-independent-distributed-relative multinomial space is conjectured to be greater than or equal to zero and less than or equal to the transform-independent-distributed-relative multinomial space of the transformdependent,

$$
0 \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)(A) \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)\left(A^{\mathrm{Y}(T)}\right)
$$

This is consistent with the entropies,

$$
\operatorname{entropy}\left(A^{\mathrm{X}(T)}\right) \geq \operatorname{entropy}(A) \geq \operatorname{entropy}\left(A^{\mathrm{Y}(T)}\right)
$$

In the case where the transform is full functional, $T=T_{\mathrm{f}}$, where $T_{\mathrm{f}}=$ $\left\{\{w\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: w \in V\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V}$, the transform-independent equals the independent, $A^{\mathrm{X}\left(T_{\mathrm{f}}\right)}=A^{\mathrm{X}}$, and so the transform-independent-distributed-relative multinomial space equals the alignment,

$$
\operatorname{spaceRelative(A^{\mathrm {X}(T_{\mathrm {f}})})(A)} \begin{aligned}
& =\operatorname{algn}(A) \\
& =\sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}-\sum_{S \in A^{\mathrm{XS}}} \ln \Gamma_{!} A_{S}^{\mathrm{X}}
\end{aligned}
$$

At the other extreme where the transform is unary, $T=T_{\mathrm{u}}$, where $T_{\mathrm{u}}=$ $\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V}$, the transform-independent equals the scaled normalised cartesian, $A^{\mathrm{X}\left(T_{u}\right)}=\operatorname{scalar}(z / v) * V^{\mathrm{C}}$, and so the transform-independent-distributed-relative multinomial space simplifies to

$$
\operatorname{spaceRelative}\left(A^{\mathrm{X}\left(T_{\mathrm{u}}\right)}\right)(A)=\sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}-v \ln \Gamma_{!}(z / v)
$$

Conjecture that if the transform-independent is an integral iso-transformindependent, $A^{\mathrm{X}(T)} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)$, the relative space of the histogram with
respect to the transform-independent is greater than or equal to that with respect to the independent,

$$
\operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)(A) \geq \operatorname{spaceRelative}\left(A^{\mathrm{X}}\right)(A)=\operatorname{algn}(A)
$$

and similarly for the transform-dependent

$$
\operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)\left(A^{\mathrm{Y}(T)}\right) \geq \operatorname{spaceRelative}\left(A^{\mathrm{X}}\right)\left(A^{\mathrm{Y}(T)}\right)=\operatorname{algn}\left(A^{\mathrm{Y}(T)}\right)
$$

because the transform-independent entropy is greater than or equal to the independent entropy, entropy $\left(A^{\mathrm{X}(T)}\right) \geq \operatorname{entropy}\left(A^{\mathrm{X}}\right)$.

Of the integral iso-independents, only the independent has zero alignment,

$$
\forall B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\left(B \neq A^{\mathrm{X}} \Longrightarrow \operatorname{algn}(B)>0\right)
$$

Similarly, of the integral iso-transform-independents, only the transformindependent has zero transform-independent-distributed-relative multinomial space,
$\forall B \in Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\left(B \neq A^{\mathrm{X}(T)} \Longrightarrow \operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)(B)>0\right)$
where the transform-independent is an integral iso-transform-independent, $A^{\mathrm{X}(T)} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)$.

Insofar as the transform approximates to full functional, $T \approx T_{\mathrm{f}}$, the transformindependent approximates to the independent, $A^{\mathrm{X}(T)} \approx A^{\mathrm{X}}$, and the transform-independent-distributed-relative multinomial space approximates to

$$
\begin{aligned}
\operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)(A) & \approx \sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}-\sum_{S \in A^{\mathrm{XS}}} \ln \Gamma_{!} A_{S}^{\mathrm{X}(T)} \\
& \approx z \times \operatorname{entropy}\left(A^{\mathrm{X}(T)}\right)-z \times \operatorname{entropy}(A)
\end{aligned}
$$

The difference is the mis-transform-independent-distributed-relative multinomial space,

$$
\sum_{S \in A^{\mathrm{XS}}}\left(A_{S}-A_{S}^{\mathrm{X}(T)}\right) \ln A_{S}^{\mathrm{X}(T)}
$$

The degree to which the set of integral iso-transform-independents is alignedlike is the iso-independence,

$$
\frac{\left|Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|}{\left|Y_{U, \mathbf{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|}
$$

As the iso-independence increases, the transform-independent, $A^{\mathrm{X}(T)}$, tends to the independent, $A^{\mathrm{X}}$, and the relative space, spaceRelative $\left(A^{\mathrm{X}(T)}\right)(A)$, tends to the alignment, $\operatorname{algn}(A)$. That is, as the integral iso-transformindependents becomes more aligned-like, the relative space becomes less dependent on the transform, $T$.

The set of iso-transform-independents may be more law-like then the set of iso-abstracts, depending on the iso-derivedence, but is still entity-like. So the derived, $A * T$, and the dependent derived, $A^{\mathrm{Y}(T)} * T$, are not necessarily equal to each other and nor are they necessarily equal to the abstract, $(A * T)^{\mathrm{X}}$. The set of iso-transform-independents is the intersection of the set of iso-formals and the set of iso-abstracts. The independent analogue of the iso-abstracts is the naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$, which has zero derived alignment, $\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\dagger} * T\right)=\operatorname{algn}\left((A * T)^{\mathrm{X}}\right)=0$. So the derived alignment of the independent analogue of the iso-transform-independents, $\operatorname{algn}\left(A^{\mathrm{X}(T)} * T\right)$, is conjectured to be less than or equal to the derived alignment, $\operatorname{algn}(A * T)$, which in turn is conjectured to be less than or equal to the dependent analogue derived alignment, $\operatorname{algn}\left(A^{\mathrm{Y}(T)} * T\right)$. The relation between the relative spaces,

$$
\begin{aligned}
0 & =\operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)\left(A^{\mathrm{X}(T)}\right) \\
& \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)(A) \\
& \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)\left(A^{\mathrm{Y}(T)}\right)
\end{aligned}
$$

can be lifted,

$$
\begin{aligned}
0 & =\operatorname{spaceRelative}\left(A^{\mathrm{X}(T)} * T\right)\left(A^{\mathrm{X}(T)} * T\right) \\
& \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}(T)} * T\right)(A * T) \\
& \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}(T)} * T\right)\left(A^{\mathrm{Y}(T)} * T\right)
\end{aligned}
$$

so conjecture that

$$
\operatorname{algn}\left(A^{\mathrm{X}(T)} * T\right) \leq \operatorname{algn}(A * T) \leq \operatorname{algn}\left(A^{\mathrm{Y}(T)} * T\right)
$$

Similarly, the independent analogue of the iso-formals is the naturalised formal, $A^{\mathrm{X}} * T * T^{\dagger}$, which is formal, $A^{\mathrm{X}} * T * T^{\dagger} * T=A^{\mathrm{X}} * T$, and so the derived alignment is equal to the formal alignment, $\operatorname{algn}\left(A^{\mathrm{X}} * T * T^{\dagger} * T\right)=$ $\operatorname{algn}\left(A^{\mathrm{X}} * T\right)$. Conjecture that the formal alignment of the naturalised formal is greater than or equal to its derived alignment, $\operatorname{algn}\left(\left(A^{\mathrm{X}} * T * T^{\dagger}\right)^{\mathrm{X}} * T\right) \geq$ $\operatorname{algn}\left(A^{\mathrm{X}} * T * T^{\dagger} * T\right)$. So conjecture that the formal alignment of the naturalised formal is greater than or equal to the formal alignment of the histogram, $\operatorname{algn}\left(\left(A^{\mathrm{X}} * T * T^{\dagger}\right)^{\mathrm{X}} * T\right) \geq \operatorname{algn}\left(A^{\mathrm{X}} * T\right)$. The transform-dependent, is
near the histogram, $A^{\mathrm{Y}(T)} \sim A$, only in as much as it is far from the transformindependent, $A^{\mathrm{Y}(T)} \nsim A^{\mathrm{X}(T)}$, so conjecture that the formal alignment of the independent analogue of the iso-transform-independents, $\operatorname{algn}\left(A^{\mathrm{X}(T) \mathrm{X}} * T\right)$, is greater than or equal to the formal alignment, $\operatorname{algn}\left(A^{\mathrm{X}} * T\right)$, which in turn is greater than or equal to the dependent analogue formal alignment, $\operatorname{algn}\left(A^{\mathrm{Y}(T) \mathrm{X}} * T\right)$,

$$
\operatorname{algn}\left(A^{\mathrm{X}(T) \mathrm{X}} * T\right) \geq \operatorname{algn}\left(A^{\mathrm{X}} * T\right) \geq \operatorname{algn}\left(A^{\mathrm{Y}(T) \mathrm{X}} * T\right)
$$

That is, the dependent analogue derived alignment is greater than or equal to the derived alignment, $\operatorname{algn}\left(A^{\mathrm{Y}(T)} * T\right) \geq \operatorname{algn}(A * T)$, but the dependent analogue formal alignment is less than or equal to the formal alignment, $\operatorname{algn}\left(A^{\mathrm{Y}(T) \mathrm{X}} * T\right) \leq \operatorname{algn}\left(A^{\mathrm{X}} * T\right)$.

The iso-abstractence of the iso-transform-independents is

$$
\frac{\left|Y_{U,, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|} \leq 1
$$

As the iso-abstractence increases, the iso-transform-independents becomes more entity-like and the difference between the relative spaces of the dependents, spaceRelative $\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)\left(A^{\mathrm{W}(T)}\right)-\operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)\left(A^{\mathrm{Y}(T)}\right)$, decreases.

The iso-derivedence of the iso-transform-independents is

$$
\frac{\left|Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cap D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}{\left|Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cup D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}
$$

As the iso-derivedence increases, the iso-transform-independents becomes more law-like and the difference between the relative spaces of the dependents, spaceRelative $\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)\left(A^{\mathrm{Y}(T)}\right)-$ spaceRelative $\left(A * T * T^{\dagger}\right)\left(A^{\mathrm{D}(T)}\right)$, decreases, in the case where the formal equals the abstract, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$.

Given a histogram-transform pair $(A, T) \in \mathcal{O}_{U, z}$, the partition-independent, $A^{\mathrm{P}(T)} \in \mathcal{A}_{U, V, z}$, is defined in section 'Likely histograms', above, as

$$
\left\{A^{\mathrm{P}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isop}(U)(T, A)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

where the integral iso-partition-independents is abbreviated

$$
\operatorname{isop}(U)(T, A):=Y_{U, \mathrm{i}, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}\right) \cap Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)
$$

and the iso-partition-independents is such that

$$
\begin{aligned}
& Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \\
& \quad=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z},\left(B^{\mathrm{X}} * T\right)^{\mathrm{x}}=\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}},(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}\right\}
\end{aligned}
$$

The corresponding dependent analogue is the partition-dependent, $A^{\mathrm{R}(T)} \in$ $\mathcal{A}_{U, V, z}$, defined

$$
\left\{A^{\mathrm{R}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isop}(U)(T, A)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

The iso-partition-independents is intermediate between the iso-transformindependents and the iso-abstracts,

$$
\begin{aligned}
& Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \cap Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \\
\subseteq & Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \cap Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \\
\subseteq & Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)
\end{aligned}
$$

All three iso-sets are subsets of the iso-abstracts, $Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$. The iso-formal-independents, $Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right)$, is a superset of the iso-formals, $Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)$. So the properties of the likely histograms of the iso-partitionindependents are also intermediate between the likely histograms of the iso-transform-independents and the likely histograms of the iso-abstracts.

The partition-independent-distributed-relative multinomial space is

$$
\text { spaceRelative }\left(A^{\mathrm{P}(T)}\right)(A):=-\ln \frac{\operatorname{mpdf}(U)\left(A^{\mathrm{P}(T)}, z\right)(A)}{\operatorname{mpdf}(U)\left(A^{\mathrm{P}(T)}, z\right)\left(A^{\mathrm{P}(T)}\right)}
$$

The partition-independent-distributed-relative multinomial space of the partition independent is zero,

$$
\operatorname{spaceRelative}\left(A^{\mathrm{P}(T)}\right)\left(A^{\mathrm{P}(T)}\right)=0
$$

In the case where the histogram is integral, $A \in \mathcal{A}_{\mathrm{i}}$, and the partitionindependent is an integral iso-partition-independent, $A^{\mathrm{P}(T)} \in \operatorname{isop}(U)(T, A)$, the partition-independent-distributed-relative multinomial space is conjectured to be greater than or equal to zero and less than or equal to the partition-independent-distributed-relative multinomial space of the partition-dependent,

$$
0 \leq \operatorname{spaceRelative}\left(A^{\mathrm{P}(T)}\right)(A) \leq \operatorname{spaceRelative}\left(A^{\mathrm{P}(T)}\right)\left(A^{\mathrm{R}(T)}\right)
$$

This is consistent with the entropies,

$$
\operatorname{entropy}\left(A^{\mathrm{P}(T)}\right) \geq \operatorname{entropy}(A) \geq \operatorname{entropy}\left(A^{\mathrm{R}(T)}\right)
$$

In the case where the transform is full functional, $T=T_{\mathrm{f}}$, where $T_{\mathrm{f}}=$ $\left\{\{w\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: w \in V\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V}$, the partition-independent equals the independent, $A^{\mathrm{P}\left(T_{\mathrm{f}}\right)}=A^{\mathrm{X}}$, and so the partition-independent-distributed-relative multinomial space equals the alignment,

$$
\operatorname{spaceRelative}\left(A^{\mathrm{P}\left(T_{\mathrm{f}}\right)}\right)(A)=\operatorname{algn}(A) \quad 10 \sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}-\sum_{S \in A^{\mathrm{XS}}} \ln \Gamma_{!} A_{S}^{\mathrm{X}}
$$

At the other extreme where the transform is unary, $T=T_{\mathrm{u}}$, where $T_{\mathrm{u}}=$ $\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, V}$, the partition-independent equals the scaled normalised cartesian, $A^{\mathrm{P}\left(T_{\mathrm{u}}\right)}=\operatorname{scalar}(z / v) * V^{\mathrm{C}}$, and so the partition-independent-distributedrelative multinomial space simplifies to

$$
\operatorname{spaceRelative}\left(A^{\mathrm{P}\left(T_{\mathrm{u}}\right)}\right)(A)=\sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}-v \ln \Gamma_{!}(z / v)
$$

Conjecture that if the partition-independent is integral, $A^{\mathrm{P}(T)} \in \operatorname{isop}(U)(T, A)$, the relative space of the histogram with respect to the partition-independent is greater than or equal to that with respect to the independent,

$$
\operatorname{spaceRelative}\left(A^{\mathrm{P}(T)}\right)(A) \geq \operatorname{spaceRelative}\left(A^{\mathrm{X}}\right)(A)=\operatorname{algn}(A)
$$

and similarly for the partition-dependent

$$
\operatorname{spaceRelative}\left(A^{\mathrm{P}(T)}\right)\left(A^{\mathrm{R}(T)}\right) \geq \operatorname{spaceRelative}\left(A^{\mathrm{X}}\right)\left(A^{\mathrm{R}(T)}\right)=\operatorname{algn}\left(A^{\mathrm{R}(T)}\right)
$$

because the partition-independent entropy is greater than or equal to the $i n$ dependent entropy, entropy $\left(A^{\mathrm{P}(T)}\right) \geq \operatorname{entropy}\left(A^{\mathrm{X}}\right)$.

Of the integral iso-partition-independents, only the partition-independent has zero partition-independent-distributed-relative multinomial space,

$$
\forall B \in \operatorname{isop}(U)(T, A)\left(B \neq A^{\mathrm{P}(T)} \Longrightarrow \operatorname{spaceRelative}\left(A^{\mathrm{P}(T)}\right)(B)>0\right)
$$

where the partition-independent is integral, $A^{\mathrm{P}(T)} \in \operatorname{isop}(U)(T, A)$.

Insofar as the transform approximates to full functional, $T \approx T_{\mathrm{f}}$, the partitionindependent approximates to the independent, $A^{\mathrm{P}(T)} \approx A^{\mathrm{X}}$, and the partition-independent-distributed-relative multinomial space approximates to

$$
\begin{aligned}
\operatorname{spaceRelative}\left(A^{\mathrm{P}(T)}\right)(A) & \approx \sum_{S \in A^{\mathrm{S}}} \ln \Gamma_{!} A_{S}-\sum_{S \in A^{\mathrm{XS}}} \ln \Gamma_{!} A_{S}^{\mathrm{P}(T)} \\
& \approx z \times \operatorname{entropy}\left(A^{\mathrm{P}(T)}\right)-z \times \operatorname{entropy}(A)
\end{aligned}
$$

The difference is the mis-partition-independent-distributed-relative multinomial space,

$$
\sum_{S \in A^{\mathrm{XS}}}\left(A_{S}-A_{S}^{\mathrm{P}(T)}\right) \ln A_{S}^{\mathrm{P}(T)}
$$

Just as for the iso-abstracts and the iso-transform-independents, above, it is conjectured that, because the independent analogue of the iso-abstracts is the naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$, which has zero derived alignment, algn $((A *$ $\left.T)^{\mathrm{X}} * T^{\dagger} * T\right)=\operatorname{algn}\left((A * T)^{\mathrm{X}}\right)=0$, the derived alignment of the independent analogue of the iso-partition-independents, $\operatorname{algn}\left(A^{\mathrm{P}(T)} * T\right)$, is conjectured to be less than or equal to the derived alignment, $\operatorname{algn}(A * T)$, which in turn is conjectured to be less than or equal to the dependent analogue derived alignment, $\operatorname{algn}\left(A^{\mathrm{R}(T)} * T\right)$. So the relation between the relative spaces,

$$
\begin{aligned}
0 & =\text { spaceRelative }\left(A^{\mathrm{P}(T)}\right)\left(A^{\mathrm{P}(T)}\right) \\
& \leq \text { spaceRelative }\left(A^{\mathrm{P}(T)}\right)(A) \\
& \leq \text { spaceRelative }\left(A^{\mathrm{P}(T)}\right)\left(A^{\mathrm{R}(T)}\right)
\end{aligned}
$$

can be lifted to derived alignment, depending on the derived iso-independence,

$$
\operatorname{algn}\left(A^{\mathrm{P}(T)} * T\right) \leq \operatorname{algn}(A * T) \leq \operatorname{algn}\left(A^{\mathrm{R}(T)} * T\right)
$$

Although the properties of the likely histograms of the iso-partition independents with respect to derived alignment are similar to those of the likely histograms of both the iso-abstracts and the iso-transform-independents, because all three iso-sets are subsets of the iso-abstracts, the properties with respect to formal alignment are not similar. The set of iso-abstracts is conditional on neither the formal, $A^{\mathrm{X}} * T$, nor the formal independent, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, so the abstract dependent, $A^{\mathrm{W}(T)}$, is neutral with respect to the formal and the formal independent, and nothing can be said of its formal alignment, $\operatorname{algn}\left(A^{\mathrm{W}(T) \mathrm{X}} * T\right)$. Indeed in some cases the abstract dependent may be purely formal, $A^{\mathrm{W}(T)} * T=A^{\mathrm{W}(T) \mathrm{X}} * T \Longrightarrow \operatorname{algn}\left(A^{\mathrm{W}(T)} * T\right)=\operatorname{algn}\left(A^{\mathrm{W}(T) \mathrm{X}} * T\right)$. This contrasts with the set of iso-transform-independents which is conditional on the formal. It is conjectured above that the formal alignment of the independent analogue of the iso-transform-independents, $\operatorname{algn}\left(A^{\mathrm{X}(T) \mathrm{X}} * T\right)$, is greater
than or equal to the formal alignment, $\operatorname{algn}\left(A^{\mathrm{X}} * T\right)$, which in turn is greater than or equal to the dependent analogue formal alignment, $\operatorname{algn}\left(A^{\mathrm{Y}(T) \mathrm{X}} * T\right)$,

$$
\operatorname{algn}\left(A^{\mathrm{X}(T) \mathrm{X}} * T\right) \geq \operatorname{algn}\left(A^{\mathrm{X}} * T\right) \geq \operatorname{algn}\left(A^{\mathrm{Y}(T) \mathrm{X}} * T\right)
$$

Now consider the formal alignment of the likely histograms of the iso-partitionindependents. The independent analogue of the iso-partition-independents, $A^{\mathrm{P}(T)}$, is intermediate between (i) the independent analogue of the iso-formalindependents, which is the naturalised formal independent, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}} * T^{\dagger}$, and (ii) the independent analogue of the iso-abstracts, which is the naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$. Conjecture that the triply-independent formal alignment of the naturalised formal independent is less than or equal to the doubly-independent formal alignment of the naturalised abstract which in turn is less than or equal to the singly-independent formal alignment of the histogram,

$$
\operatorname{algn}\left(\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}} * T^{\dagger}\right)^{\mathrm{X}} * T\right) \leq \operatorname{algn}\left(\left((A * T)^{\mathrm{x}} * T^{\dagger}\right)^{\mathrm{X}} * T\right) \leq \operatorname{algn}\left(A^{\mathrm{X}} * T\right)
$$

So the formal alignment of the partition-independent is less than or equal to the formal alignment of the histogram,

$$
\operatorname{algn}\left(A^{\mathrm{P}(T) \mathrm{X}} * T\right) \leq \operatorname{algn}\left(A^{\mathrm{X}} * T\right)
$$

The partition-dependent varies against the partition-independent, $A^{\mathrm{R}(T)} \nsim$ $A^{\mathrm{P}(T)}$, so conjecture that

$$
\operatorname{algn}\left(A^{\mathrm{P}(T) \mathrm{X}} * T\right) \leq \operatorname{algn}\left(A^{\mathrm{X}} * T\right) \leq \operatorname{algn}\left(A^{\mathrm{R}(T) \mathrm{X}} * T\right)
$$

That is, the dependent analogue derived alignment is greater than or equal to the derived alignment, $\operatorname{algn}\left(A^{\mathrm{R}(T)} * T\right) \geq \operatorname{algn}(A * T)$, and the dependent analogue formal alignment is greater than or equal to the formal alignment, $\operatorname{algn}\left(A^{\mathrm{R}(T) \mathrm{X}} * T\right) \geq \operatorname{algn}\left(A^{\mathrm{X}} * T\right)$.

The direction of the formal alignment inequality is opposite to that of the likely histograms of the iso-transform-independents. So conjecture that the partition-dependent formal alignment is greater than or equal to the transformdependent formal alignment

$$
\operatorname{algn}\left(A^{\mathrm{R}(T) \mathrm{X}} * T\right) \geq \operatorname{algn}\left(A^{\mathrm{X}} * T\right) \geq \operatorname{algn}\left(A^{\mathrm{Y}(T) \mathrm{X}} * T\right)
$$

### 4.16 Rolled alignment

A roll, defined above, $R \in$ rolls $\subset \mathcal{S} \rightarrow \mathcal{S}$, in variables $V$ and system $U$, is a state valued function of state, $R \in V^{\mathrm{CS}} \rightarrow V^{\mathrm{CS}}$. The application
of a roll $R$ in variables $V$ to a histogram $A$ having the same variables is roll $\in$ rolls $\times \mathcal{A} \rightarrow \mathcal{A}$

$$
\operatorname{roll}(R, A):=\sum_{S \in A^{\mathrm{S}} \backslash \operatorname{dom}(R)}\left\{\left(S, A_{S}\right)\right\}+\sum_{S \in A^{\mathrm{S}} \cap \operatorname{dom}(R)}\left\{\left(R_{S}, A_{S}\right)\right\}
$$

Define $(*) \in \mathcal{A} \times$ rolls $\rightarrow \mathcal{A}$ as $A * R:=\operatorname{roll}(R, A)$. Define the identity roll $\operatorname{id}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow$ rolls as $\operatorname{id}(U)(V):=\left\{(S, S): S \in V^{\mathrm{CS}}\right\}$.

A roll $R \in$ rolls having variables $V$ can converted to a partition transform $P^{\mathrm{T}} \in \mathcal{T}_{U, V}$ on the partition $P \in \mathcal{R}_{U}$ of the cartesian states of the variables, $P \in \mathrm{~B}\left(V^{\mathrm{CS}}\right)$, implied by the functional inverse, $P=\operatorname{ran}$ (inverse $(R \circ$ $\operatorname{id}(U)(V))$ ). This transform has a single derived variable, $\left|\operatorname{der}\left(P^{\mathrm{T}}\right)\right|=1$, and therefore the derived histogram is independent, $A * P^{\mathrm{T}}=\left(A * P^{\mathrm{T}}\right)^{\mathrm{X}}$, when applied to some underlying histogram $A$ in variables $V$. Hence, the derived alignment is zero, alignment $\left(A * P^{\mathrm{T}}\right)=0$.

The transform of a roll is defined transform $(U) \in$ rolls $\rightarrow \mathcal{T}_{U, \mathrm{f}, 1}$ as

$$
\begin{aligned}
& \operatorname{transform}(U)(R):= \\
& \qquad\left\{P^{\mathrm{T}}: v \in V, P=\operatorname{ran}\left(\operatorname{inverse}\left(\left\{\left(S_{1}, S_{2} \%\{v\}\right):\left(S_{1}, S_{2}\right) \in R^{\prime}\right\}\right)\right)\right\}^{\mathrm{T}}
\end{aligned}
$$

where $V=\operatorname{vars}(R)$ and $R^{\prime}=R \circ \operatorname{id}(U)(V)$ is the given roll stuffed with the identity roll. Define $R^{\mathrm{T}}:=\operatorname{transform}(U)(R)$ where the system $U$ is implicit.

The alignment of the derived histogram in variables $W=\operatorname{der}\left(R^{\mathrm{T}}\right)$ is equal to the alignment in variables $V=\operatorname{vars}(R)=\operatorname{und}\left(R^{\mathrm{T}}\right)$ of the rolled histogram

$$
\operatorname{alignment}\left(A * R^{\mathrm{T}}\right)=\operatorname{alignment}(A * R)
$$

This is the case because (i) the sizes are equal, $\operatorname{size}\left(A * R^{\mathrm{T}}\right)=\operatorname{size}(A * R)$, (ii) there is a map between states, $V^{\mathrm{CS}} \leftrightarrow W^{\mathrm{CS}}$, such that the counts are equal, $\exists M \in V^{\mathrm{CS}} \leftrightarrow W^{\mathrm{CS}}\left(|M|=\left|W^{\mathrm{CS}}\right| \wedge\left(\forall(S, T) \in M\left((A * R)_{S}=\left(A * R^{\mathrm{T}}\right)_{T}\right)\right)\right)$ and hence

$$
\sum_{S \in V^{\mathrm{CS}}} \ln \Gamma_{!}(A * R)_{S}=\sum_{T \in W^{\mathrm{CS}}} \ln \Gamma_{!}\left(A * R^{\mathrm{T}}\right)_{T}
$$

(iii) there exists a surjective mapping between the variables, $V \rightarrow W$, such that the reductions are equal, $\exists N \in V \rightarrow W(\operatorname{dom}(N)=V \wedge \operatorname{ran}(N)=$ $W \wedge\left(\forall(v, w) \in N \exists Q \in\{v\}^{\mathrm{CS}} \leftrightarrow\{w\}^{\mathrm{CS}}\left(|Q|=\left|U_{w}\right| \wedge(\forall(S, T) \in Q \quad(((A *\right.\right.$ $\left.\left.\left.\left.R) \%\{v\})_{S}=\left(\left(A * R^{\mathrm{T}}\right) \%\{w\}\right)_{T}\right)\right)\right)\right)$ ), so

$$
\sum_{S \in V^{\mathrm{CS}}} \ln \Gamma_{!}(A * R)_{S}^{\mathrm{X}}=\sum_{T \in W^{\mathrm{CS}}} \ln \Gamma_{!}\left(A * R^{\mathrm{T}}\right)_{T}^{\mathrm{X}}
$$

A value roll, defined above, is equivalent to a special case of a roll $R \in$ $V^{\mathrm{CS}} \rightarrow V^{\mathrm{CS}}$ on variables $V$ in system $U$. Define the set of value rolls rollValues $(U) \subset \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{V}_{U} \times \mathcal{W}_{U} \times \mathcal{W}_{U}$ such that $\forall(V, v, s, t) \in \operatorname{rollValues}(U)(v \in$ $\left.V \wedge s, t \in U_{v}\right)$. Define $\operatorname{roll}(U) \in \operatorname{rollValues}(U) \rightarrow\left(\operatorname{rolls} \cap\left(\mathcal{S}_{U} \rightarrow \mathcal{S}_{U}\right)\right)$. Define $(V, v, s, t)^{\mathrm{R}}:=\operatorname{roll}(U)((V, v, s, t))$.

The independent of the application of a value roll $(V, v, s, t)$ to a histogram $A$ is equal to the application of a value roll to the independent histogram

$$
\left(A *(V, v, s, t)^{\mathrm{R}}\right)^{\mathrm{X}}=A^{\mathrm{X}} *(V, v, s, t)^{\mathrm{R}}
$$

Thus the application of a value roll to an independent histogram is also independent, $A^{\mathrm{X}} *(V, v, s, t)^{\mathrm{R}}=\left(A^{\mathrm{X}} *(V, v, s, t)^{\mathrm{R}}\right)^{\mathrm{X}}$. The alignment of the rolled independent is zero, alignment $\left(A^{\mathrm{X}} *(V, v, s, t)^{\mathrm{R}}\right)=0$.
$\mathcal{J}_{U, V}$ is defined above as the set of lists of value rolls in variables $V$ and system $U, \mathcal{J}_{U, V}=\{L: L \in \mathcal{L}(\operatorname{rollValues}(U)),(\forall(W, v, s, t) \in \operatorname{set}(L)(W=V))\}$. The list of value rolls $J \in \mathcal{J}_{U, V}$ can be converted into a list of rolls. Define $J^{\mathrm{R}}:=\operatorname{map}(\operatorname{roll}(U), J)$. Rolled independent histograms remain independent $A^{\mathrm{X}} * J^{\mathrm{R}}=\left(A^{\mathrm{X}} * J^{\mathrm{R}}\right)^{\mathrm{X}}$.

The transform of a list of value rolls $J \in \mathcal{J}_{U, V}$ is defined above, $\operatorname{transform}(U) \in$ $\mathcal{L}(\operatorname{rollValues}(U)) \rightarrow \mathcal{T}_{U, \mathrm{f}, 1}$. Define $J^{\mathrm{T}}:=\operatorname{transform}(U)(J)$. The value roll list transform equals the roll list transform, $J^{\mathrm{T}}=J^{\mathrm{RT}}$.

The derived alignment equals the alignment of the rolled histogram

$$
\operatorname{alignment}\left(A * J^{\mathrm{T}}\right)=\operatorname{alignment}\left(A * J^{\mathrm{RT}}\right)=\operatorname{alignment}\left(A * J^{\mathrm{R}}\right)
$$

The alignment of a rolled independent histogram is zero, alignment $\left(A^{\mathrm{X}} *\right.$ $\left.J^{\mathrm{T}}\right)=0$ because $A^{\mathrm{X}} * J^{\mathrm{T}}=\left(A^{\mathrm{X}} * J^{\mathrm{T}}\right)^{\mathrm{X}}$. The value roll list transform is nonoverlapping, $\neg \operatorname{overlap}\left(J^{\mathrm{T}}\right)$, so the degree of overlap is zero, $\operatorname{alignment}\left(V^{\mathrm{C}} *\right.$ $\left.J^{\mathrm{T}}\right)=0$.

### 4.17 Decomposition alignment

In section 'Decompositions', above, the nullable transform, $D^{\mathrm{T}}$, of a well behaved distinct decomposition $D \in \mathcal{D}_{\mathrm{w}, U}$ was defined such that the derived variables, $\operatorname{der}\left(D^{\mathrm{T}}\right)$, consist of the union of (i) the root frame variables, $\left\{\{w\}^{\mathrm{CS}\{ \}}: w \in W_{\mathrm{r}}\right\}$, of the derived variables $W_{\mathrm{r}}=\operatorname{der}\left(T_{\mathrm{r}}\right)$ of the root transform $\left\{\left(\left(\emptyset, T_{\mathrm{r}}\right), \cdot\right)\right\}=D$, and (ii) the nullable variables, $\operatorname{dom}($ nullables $(U)(D))$. The nullable transform derived variables, $\operatorname{der}\left(D^{\mathrm{T}}\right)$, originate in the transform
derived variables, $\operatorname{der}(G)$, where $G=\operatorname{transforms}(D)$. So originals $(U)(D) \in$ $\operatorname{der}\left(D^{\mathrm{T}}\right) \rightarrow \operatorname{der}(G)$. The derived alignment given histogram $A \in \mathcal{A}$, having $\operatorname{vars}(A) \supseteq \operatorname{und}(D)$, is $\operatorname{algn}\left(A * D^{\mathrm{T}}\right)$.

In some cases the derived alignment, $\operatorname{algn}\left(A * D^{\mathrm{T}}\right)$, may not be practicably computable. The derived volume, $\left|N^{\mathrm{C}}\right|$ where $N=\operatorname{der}\left(D^{\mathrm{T}}\right)$, may be larger than the underlying volume, $\left|V^{\mathrm{C}}\right|$ where $V=\operatorname{und}(D)$. Certainly the volume of the nullable transform derived variables may be greater than the volume of the transform derived variables, $\left|N^{\mathrm{C}}\right| \geq\left|W^{\mathrm{C}}\right|$ where $W=$ $\operatorname{der}(G)$. For example, the application to cartesian may not be completely effective, $\left(V^{\mathrm{C}} * D^{\mathrm{T}}\right)^{\mathrm{F}}<N^{\mathrm{C}}$, if (i) the root transform, $T_{\mathrm{r}}$, is overlapping, $\operatorname{overlap}\left(T_{\mathrm{r}}\right)$, or (ii) there is more than one path, $|\operatorname{path}(D)|>1$, and no transform symmetries, and hence overlapping contingently applied nullable variables, nullables $(U)(D) \neq \emptyset$. However, it is conjectured that, given certain conditions, there is a calculation of the content alignment, $\operatorname{algn}\left(A * D^{\mathrm{T}}\right)-$ $\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)$, that does not require the computation of the derived histogram, $A * D^{\mathrm{T}}$.

Let $D \in \mathcal{D}_{\mathrm{w}, U}$ be a well behaved decomposition having no variable symmetries, $\{(w,(S, T)):(S, T) \in \operatorname{elements}(D), w \in \operatorname{der}(T)\} \in \operatorname{der}(G) \rightarrow \operatorname{elements}(D)$, where $G=\operatorname{transforms}(D)$. First, consider the case where the transforms of the decomposition, $D$, are all contingently diagonalised with respect to histogram A,

$$
\forall(C, T) \in \operatorname{cont}(D)(\operatorname{diagonal}(A * C * T))
$$

where $\operatorname{cont}(D):=\operatorname{elements}($ contingents $(D))$. Conjecture that in the contingently diagonalised decomposition case the derived alignment, $\operatorname{algn}\left(A * D^{\mathrm{T}}\right)$, equals (i) the derived alignment of the skeletal contingent reduction plus (ii) the sum of the alignments of the diagonalised derived histograms of the decomposition transforms. Let the skeletal contingent reduction be $D^{\prime} \in$ $\operatorname{reductions}(A, D)$ which is such that $\operatorname{skeletal}\left(A * D^{\prime \mathrm{T}}\right)$. Then

$$
\operatorname{algn}\left(A * D^{\mathrm{T}}\right)=\operatorname{algn}\left(A * D^{\prime \mathrm{T}}\right)+\sum_{(C, T) \in \operatorname{cont}(D)} \operatorname{algn}(A * C * T)
$$

To show this, consider the fud $F$ of children transforms of a decomposition transform $T \in G$, where $G=\operatorname{transforms}(D), F=\operatorname{ran}(\operatorname{dom}(E))$ and $((\cdot, T), E) \in \operatorname{nodes}(D)$. Let $N=\{\operatorname{flip}(\operatorname{originals}(U)(D))(w): w \in \operatorname{der}(F)\}$ be the set of nullable variables of the nullable transform which correspond to the originating derived variables, because the originating map is bijective, originals $(U)(D) \in \operatorname{der}\left(D^{\mathrm{T}}\right) \leftrightarrow \operatorname{der}(G)$, where there are no variable symmetries. Then the reduced derived histogram of the nullable variables
corresponding to $F$ is $B=A * D^{\mathrm{T}} \% N$, and its alignment is $\operatorname{algn}(B)$. This histogram, $B$, has an axial reduction as defined in the section 'Alignment of axial reductions', above. Let $T^{\prime} \in \operatorname{transforms}\left(D^{\prime}\right)$ be the reduced transform in the contingently diagonalised decomposition, $D^{\prime}$, that corresponds to $T$ in the decomposition $D$. The corresponding skeletal contingent reduction derived histogram is $B^{\prime}=A * D^{\prime \mathrm{T}} \% N^{\prime}$ where $F^{\prime}=\operatorname{ran}\left(\operatorname{dom}\left(E^{\prime}\right)\right)$ and $\left(\left(\cdot, T^{\prime}\right), E^{\prime}\right) \in \operatorname{nodes}\left(D^{\prime}\right)$. $N^{\prime} \subseteq \operatorname{der}\left(D^{\prime \mathrm{T}}\right)$ is the set of nullable variables of $F^{\prime}$ corresponding to $N . B^{\prime}$ is an axial reduction of $B$. That is, there exists a pivot state, $N_{*} \in N^{\mathrm{CS}}$ where $N_{*} \subseteq$ nullables $(U)(D)$ and $\operatorname{dom}\left(N_{*}\right)=N$, such that the implied set of slices are diagonalised, $\forall(C, R) \in \operatorname{cont}(D)(R \in$ $F \Longrightarrow \operatorname{diagonal}(A * C * R)$ ). It is conjectured that the alignment of the histogram $B$ equals (i) the alignment of the axial reduction, $B^{\prime}$, plus (ii) the sum of the alignments of the sliced diagonalised reductions

$$
\operatorname{algn}(B)=\operatorname{algn}\left(B^{\prime}\right)+\sum(\operatorname{algn}(A * C * R):(C, R) \in \operatorname{cont}(D), R \in F)
$$

The contingent slice diagonalisations, $\{A * C * R:(C, R) \in \operatorname{cont}(D), R \in F\}$, are axially independent of eachother and axially independent of the axial reduction, $B^{\prime}$, although, of course, they do not have the same variables. That is, they are axially independent in the sense defined in the section 'Alignment of axial reductions', above, where the slices partition the underlying variables.

Then conjecture that the same separation of the alignment, $\operatorname{algn}(B)$, of the particular children transforms, $F$, of a decomposition transform $T$, into components of (i) axial alignment, algn( $B^{\prime}$ ), and (ii) sum diagonal alignments, $\sum(\operatorname{algn}(A * C * R):(C, R) \in \operatorname{cont}(D), R \in F)$, can be extended to the whole decomposition, $D$. That is, the derived alignment, $\operatorname{algn}\left(A * D^{\mathrm{T}}\right)$, may be separated into components of (i) the skeletal contingent reduction alignment, $\operatorname{algn}\left(A * D^{\prime T}\right)$, and (ii) sum diagonal alignments, $\sum(\operatorname{algn}(A * C * T):(C, T) \in$ cont $(D)$ ), including the root transform diagonalised alignment, $\operatorname{algn}\left(A * T_{\mathrm{r}}\right)$,

$$
\operatorname{algn}\left(A * D^{\mathrm{T}}\right)=\operatorname{algn}\left(A * D^{\prime \mathrm{T}}\right)+\sum_{(C, T) \in \operatorname{cont}(D)} \operatorname{algn}(A * C * T)
$$

The contingent slice diagonalisations, $\{A * C * T:(C, T) \in \operatorname{cont}(D)\}$, are axially independent of eachother and axially independent of the skeleton, $A * D^{\prime \mathrm{T}}$.

Second, if it so happens to be the case that contingently diagonalised decomposition, $D$, is also such that contingently the formal histogram is equivalent to the abstract histogram

$$
\forall(C, T) \in \operatorname{cont}(D)\left(A^{\mathrm{x}} * C * T \equiv(A * C * T)^{\mathrm{x}}\right)
$$

then the skeletal contingent reduction must also be such that contingently the formal histogram is equivalent to the abstract histogram

$$
\forall\left(C, T^{\prime}\right) \in \operatorname{cont}\left(D^{\prime}\right)\left(A^{\mathrm{x}} * C * T^{\prime} \equiv\left(A * C * T^{\prime}\right)^{\mathrm{x}}\right)
$$

but, because each of the reduced transforms is mono-derived-variate, $\forall T^{\prime} \in$ transforms $\left(D^{\prime}\right)\left(\left|\operatorname{der}\left(T^{\prime}\right)\right|=1\right)$ and so

$$
\forall\left(C, T^{\prime}\right) \in \operatorname{cont}\left(D^{\prime}\right)\left(A * C * T^{\prime} \equiv\left(A * C * T^{\prime}\right)^{\mathrm{X}}\right)
$$

the reduced transforms are contingently formal

$$
\forall\left(C, T^{\prime}\right) \in \operatorname{cont}\left(D^{\prime}\right)\left(A^{\mathrm{x}} * C * T^{\prime} \equiv A * C * T^{\prime}\right)
$$

so the skeletal derived is formal, $A * D^{\prime \mathrm{T}} \equiv A^{\mathrm{X}} * D^{\prime \mathrm{T}}$, and the content skeletal alignment is zero,

$$
\operatorname{algn}\left(A * D^{\prime \mathrm{T}}\right)-\operatorname{algn}\left(A^{\mathrm{X}} * D^{\prime \mathrm{T}}\right)=0
$$

Also, if contingently the formal histogram is equivalent to the abstract histogram, the contingent content alignment of each transform, $T$, with respect to the slice, $C$, equals the contingent derived alignment

$$
\begin{aligned}
\operatorname{algn}(A * C * T)-\operatorname{algn}\left(A^{\mathrm{x}} * C * T\right) & =\operatorname{algn}(A * C * T)-\operatorname{algn}\left((A * C * T)^{\mathrm{x}}\right) \\
& =\operatorname{algn}(A * C * T)
\end{aligned}
$$

Thus, given (i) contingent diagonalisation and (ii) contingent formal-abstract equivalence, the content alignment of the nullable transform of the decomposition equals the sum of the contingent derived alignments of the contingently diagonalised transforms,

$$
\begin{aligned}
\operatorname{algn}\left(A * D^{\mathrm{T}}\right)-\operatorname{algn}\left(A^{\mathrm{X}} *\right. & \left.D^{\mathrm{T}}\right) \\
& =\operatorname{algn}\left(A * D^{\prime \mathrm{T}}\right)-\operatorname{algn}\left(A^{\mathrm{x}} * D^{\prime \mathrm{T}}\right)+ \\
& =\sum_{(C, T) \in \operatorname{cont}(D)} \operatorname{algn}(A * C * T)-\operatorname{algn}\left(A^{\mathrm{x}} * C * T\right) \\
& \operatorname{algn}(A * C * T)
\end{aligned}
$$

Note that a condition that the transforms are separately non-overlapping, $\forall T \in G(\neg \operatorname{overlap}(T))$, is insufficient to imply contingent formal-abstract equivalence. A non-overlapping transform implies that $(A * C)^{\mathrm{X}} * T \equiv$ $\left((A * C)^{\mathrm{x}} * T\right)^{\mathrm{X}}$ but does not constrain $A^{\mathrm{x}} * C * T$ to be independent nor imply that it is equivalent to $(A * C * T)^{\mathrm{X}}$.

Define the summation alignment as alignmentSum $\in \mathcal{A} \times \mathcal{D} \rightarrow \mathbf{R}$ as

$$
\operatorname{alignmentSum}(A, D):=\sum_{(C, T) \in \operatorname{cont}(D)} \operatorname{algn}(A * C * T)
$$

Given (i) contingent diagonalisation and (ii) contingent formal-abstract equivalence, the content alignment of a well behaved decomposition having no variable symmetries equals the summation alignment

$$
\operatorname{algn}\left(A * D^{\mathrm{T}}\right)-\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)=\operatorname{alignmentSum}(A, D)
$$

In order to calculate the summation alignment, alignmentSum $(A, D)$, only the contingent alignments of the recursive contingents tree need be computed. The contingents tree, contingents $(D)$, does not depend on the nullable fud, nullable $(U)(D)$, so there is no need to compute any of the slice transforms or their dependents. Thus the possibly impracticable derived volume, $\left|N^{\mathrm{C}}\right|$, of the nullable transform, $D^{\mathrm{T}}$, need not be realised.

Let the set of summation aligned decompositions $\mathcal{D}_{\Sigma}(A) \subset \mathcal{D}_{\mathrm{w}, U}$ be the subset of well behaved distinct decompositions having no variable symmetries that are subject to these two constraints with respect to histogram $A$,

$$
\begin{aligned}
& \forall A \in \mathcal{A}_{U}\left(\mathcal{D}_{\Sigma}(A)=\right. \\
& \qquad D: D \in \mathcal{D}_{\mathrm{w}, U}, \operatorname{vars}(D) \subseteq \operatorname{vars}(A), \\
& \quad \quad \operatorname{isfunc}(\{(w,(C, T)):(C, T) \in \operatorname{cont}(D), w \in \operatorname{der}(T)\}), \\
& \quad \forall(C, T) \in \operatorname{cont}(D)(\operatorname{diagonal}(A * C * T)) \\
& \left.\left.\quad \forall(C, T) \in \operatorname{cont}(D)\left((A * C * T)^{\mathrm{X}} \equiv A^{\mathrm{X}} * C * T\right)\right\}\right)
\end{aligned}
$$

Summation aligned decompositions are such that the content alignment equals the summation alignment,

$$
\forall D \in \mathcal{D}_{\Sigma}(A)\left(\operatorname{algn}\left(A * D^{\mathrm{T}}\right)-\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)=\operatorname{algnSum}(A, D)\right)
$$

where algnSum $=$ alignmentSum.

Note that a summation aligned decomposition $D \in \mathcal{D}_{\Sigma}(A)$ could consist of mono-derived-variate transforms, $\forall T \in G(|\operatorname{der}(T)|=1)$. In this case, all of the derived histograms would be diagonalised regardless of the histogram $A$, and so the decomposition would already be contingently reduced, $D=$ $D^{\prime}$. The contingent derived alignments, however, would all be zero, and hence the content alignment would be zero, $\operatorname{algn}\left(A * D^{\mathrm{T}}\right)-\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)=$
$\operatorname{alignmentSum}(A, D)=0$. That is, the summation aligned decomposition would be formal with respect to $A, A * D^{\mathrm{T}} \equiv A^{\mathrm{X}} * D^{\mathrm{T}}$. Therefore, as well as the (i) contingent diagonalisation and (ii) contingent formal-abstract equivalence constraints, idealising summation aligned decompositions, defined below, are also constrained (iii) such that the contingent derived histograms are not independent,

$$
\forall(C, T) \in \operatorname{cont}(D)\left(\neg\left(A * C * T \equiv(A * C * T)^{\mathrm{X}}\right)\right)
$$

That is, the contingent derived histogram is not equivalent to the contingent abstract histogram. This constraint implies that an idealising summation aligned decomposition must be pluri-derived-variate everywhere, $\forall T \in$ $G(|\operatorname{der}(T)|>1)$.

In the case where the independent histogram is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, and given the minimum alignment conjecture, in section 'Minimum alignment' above, this implies that the contingent derived alignment of an idealising summation aligned decomposition is everywhere greater than zero,

$$
\forall(C, T) \in \operatorname{cont}(D)(\operatorname{algn}(A * C * T)>0)
$$

because $\left(A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right) \wedge\left(A^{\mathrm{X}} * C * T \equiv(A * C * T)^{\mathrm{X}}\right) \Longrightarrow(A * C * T)^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$.
Furthermore, because the slices are such that contingently the formal histogram is equivalent to the abstract histogram, $A^{\mathrm{X}} * C * T \equiv(A * C * T)^{\mathrm{x}}$, the non-independent constraint, $\neg\left(A * C * T \equiv(A * C * T)^{\mathrm{X}}\right)$, implies that the slice of the histogram, $A * C$, is not equivalent to the slice of the independent, $A^{\mathrm{X}} * C$,

$$
\neg\left(A * C * T \equiv A^{\mathrm{X}} * C * T\right) \Longrightarrow \neg\left(A * C \equiv A^{\mathrm{X}} * C\right)
$$

These three constraints allow an independent slice, $A * C \equiv(A * C)^{\mathrm{X}}$, to have derived alignment, algn $\left((A * C)^{\mathrm{X}} * T\right)>0$. That is, where (i) diagonal $((A *$ $\left.C)^{\mathrm{X}} * T\right)$, (ii) $\left((A * C)^{\mathrm{x}} * T\right)^{\mathrm{X}} \equiv A^{\mathrm{X}} * C * T$ and (iii) $\neg\left((A * C)^{\mathrm{X}} * T \equiv A^{\mathrm{X}} * C * T\right)$. Therefore, in order to exclude this case, add a fourth constraint (iv) that the formal slice is independent

$$
\forall(C, T) \in \operatorname{cont}(D)\left((A * C)^{\mathrm{x}} * T \equiv\left((A * C)^{\mathrm{x}} * T\right)^{\mathrm{X}}\right)
$$

Thus the derived alignment of an independent slice is zero, $\operatorname{algn}\left((A * C)^{\mathrm{X}} *\right.$ $T)=0$. This constraint holds in the case where the transform is nonoverlapping, $\neg \operatorname{overlap}(T)$. If the transform is non-overlapping then the formal slice must be independent, $\neg \operatorname{overlap}(T) \Longrightarrow(A * C)^{\mathrm{x}} * T \equiv$
$\left((A * C)^{\mathrm{X}} * T\right)^{\mathrm{X}}$. The non-overlapping constraint is stricter than necessary, but is such that any formal slice, $(A * C)^{\mathrm{X}} * T$, is independent regardless of the histogram, $A$, or slice, $A * C$.

Let the set of idealising summation aligned decompositions $\mathcal{D}_{\Sigma, \mathrm{k}}(A) \subset \mathcal{D}_{\Sigma}(A)$ be the subset of summation aligned decompositions that are subject to these two additional constraints with respect to histogram $A$ which has integral independent, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$,

$$
\begin{aligned}
& \forall A \in \mathcal{A}_{U} \cap \mathcal{A}_{\mathrm{xi}}\left(\mathcal{D}_{\Sigma, \mathrm{k}}(A)=\right. \\
& \qquad D: D \in \mathcal{D}_{\Sigma}(A), \\
& \quad \forall(C, T) \in \operatorname{cont}(D)\left(\neg\left(A * C * T \equiv(A * C * T)^{\mathrm{x}}\right)\right), \\
& \left.\left.\quad \forall(C, T) \in \operatorname{cont}(D)\left((A * C)^{\mathrm{x}} * T \equiv\left((A * C)^{\mathrm{x}} * T\right)^{\mathrm{x}}\right)\right\}\right)
\end{aligned}
$$

where $\mathcal{A}_{\mathrm{xi}}=\left\{A: A \in \mathcal{A}, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right\}$.
There are no idealising summation aligned decompositions of an independent substrate histogram, $\mathcal{D}_{\Sigma, \mathrm{k}}\left(A^{\mathrm{X}}\right)=\emptyset$, because the formal histogram is independent, $A^{\mathrm{X}} * T \equiv\left(A^{\mathrm{X}} * V^{\mathrm{C}}\right)^{\mathrm{X}} * T \equiv\left(\left(A^{\mathrm{X}} * V^{\mathrm{C}}\right)^{\mathrm{X}} * T\right)^{\mathrm{X}}$.

Idealising summation aligned decompositions are such that the content alignment is greater than zero,

$$
\forall D \in \mathcal{D}_{\Sigma, \mathrm{k}}(A)\left(\operatorname{algn}\left(A * D^{\mathrm{T}}\right)-\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)=\operatorname{algnSum}(A, D)>0\right)
$$

The length of the contingent diagonals is at least two because of the nonindependent constraint

$$
\forall D \in \mathcal{D}_{\Sigma, \mathrm{k}}(A) \forall(C, T) \in \operatorname{cont}(D)\left(\left|(A * C * T)^{\mathrm{F}}\right| \geq 2\right)
$$

Thus the slice sizes must also be at least two

$$
\forall D \in \mathcal{D}_{\Sigma, \mathrm{k}}(A) \forall(C, T) \in \operatorname{cont}(D)(\operatorname{size}(A * C) \geq 2)
$$

The length of the contingent diagonals is no greater than the slice size

$$
\forall D \in \mathcal{D}_{\Sigma, \mathrm{k}}(A) \forall(C, T) \in \operatorname{cont}(D)\left(\left|(A * C * T)^{\mathrm{F}}\right| \leq \operatorname{size}(A * C)\right)
$$

The length of the contingent diagonals is no greater than the underlying effective and hence the underlying volume

$$
\forall D \in \mathcal{D}_{\Sigma, \mathrm{k}}(A) \forall(C, T) \in \operatorname{cont}(D)\left(\left|(A * C * T)^{\mathrm{F}}\right| \leq\left|(A * C * T)^{\mathrm{C}}\right| \leq\left|A^{\mathrm{C}}\right|\right)
$$

The content alignment of the idealising summation aligned decomposition $D \in \mathcal{D}_{\Sigma, \mathrm{k}}(A)$ equals the summation of the derived alignments, $\operatorname{algn}\left(A * D^{\mathrm{T}}\right)-$ $\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)=\sum(\operatorname{algn}(A * C * T):(C, T) \in \operatorname{cont}(D))$, so the derived histograms of the slices are axially independent of eachother. Therefore the derived histogram of a slice, $A * C * T$, is axially independent from the derived histograms its ancestor slices. For example, consider $\left(\left(C_{1}, T_{1}\right),\left(C_{2}, T_{2}\right)\right) \in$ steps(contingents $(D)$ ). The parent transform $T_{1}$ has non-zero derived alignment when constrained to its own slice $A * C_{1}, \operatorname{algn}\left(A * C_{1} * T_{1}\right)>0$, but when constrained to its child slice, $A * C_{2} \subseteq A * C_{1}$, its derived alignment is zero, $\operatorname{algn}\left(A * C_{2} * T_{1}\right)=0$, because the derived histogram is an effective singleton, $\left|\left(A * C_{2} * T_{1}\right)^{\mathrm{F}}\right|=1$. That is, a slice $A * C$, where $C \in \operatorname{dom}(\operatorname{cont}(D))$, may be said to contain a derived alignment $R \in \operatorname{transforms}(D)$ if the derived histogram is aligned, $\operatorname{algn}(A * C * R)>0$. In this example, the parent slice, $A * C_{1}$, contains the parent derived alignment, $T_{1}$, because the derived histogram is a non-singleton diagonal, diagonal $\left(A * C_{1} * T_{1}\right)$ and $\left|\left(A * C_{1} * T_{1}\right)^{\mathrm{F}}\right|>1$, but the child slice, $A * C_{2}$, does not contain the parent derived alignment, $T_{1}$, because the derived histogram is singleton, $\left|\left(A * C_{2} * T_{1}\right)^{\mathrm{F}}\right|=1$. Conversely, the child slice, $A * C_{2}$, contains the child derived alignment, $T_{2}$, because the derived histogram is a non-singleton diagonal, diagonal $\left(A * C_{2} * T_{2}\right)$ and $\left|\left(A * C_{2} * T_{2}\right)^{\mathrm{F}}\right|>1$, and the parent slice, $A * C_{1}$, also contains the child derived alignment, $\operatorname{algn}\left(A * C_{1} * T_{2}\right)>0$, although not necessarily diagonalised. Thus a slice $A * C$ cannot contain any of the derived alignments of its ancestor slices, but contains all of the derived alignments of its descendant slices.

$$
\begin{aligned}
& \forall L \in \operatorname{paths}(\operatorname{contingents}(D)) \forall\left(i,\left(C_{i}, T_{i}\right)\right),\left(j,\left(C_{j}, T_{j}\right)\right) \in L \\
& \quad\left(i<j \Longrightarrow\left(\operatorname{algn}\left(A * C_{i} * T_{j}\right)>0\right) \wedge\left(\operatorname{algn}\left(A * C_{j} * T_{i}\right)=0\right)\right)
\end{aligned}
$$

A path of an idealising summation aligned decomposition may then be viewed as the cumulative removal of derived alignments as the index increases, or the cumulative addition of derived alignments as the index decreases.

Consider a slice $A * C$ that contains the derived alignment $T^{\prime}$ of another slice $A * C^{\prime}$, not necessarily a descendant slice, in an idealising summation aligned decomposition $D \in \mathcal{D}_{\Sigma, \mathrm{k}}(A)$. That is, $\operatorname{algn}\left(A * C * T^{\prime}\right)>0$, where $(C, T),\left(C^{\prime}, T^{\prime}\right) \in \operatorname{cont}(D)$. If it is the case that the derived alignment is diagonalised, diagonal $\left(A * C * T^{\prime}\right)$, then $T^{\prime}$ could be a transform symmetry of both slices, $A * C$ and $A * C^{\prime}$, in another idealising summation aligned decomposition $D^{\prime}$. That is, $\left(C, T^{\prime}\right),\left(C^{\prime}, T^{\prime}\right) \in \operatorname{cont}\left(D^{\prime}\right)$. However, it may be the case that the transform symmetry does not have higher alignment, $\operatorname{algn}\left(A * C * T^{\prime}\right)<\operatorname{algn}(A * C * T)$. So it may be the case that the decomposition with the transform symmetry, $D^{\prime}$, has lower alignment, $\operatorname{algnSum}\left(A, D^{\prime}\right)<\operatorname{algnSum}(A, D)$.

Let $D \in \mathcal{D}_{\Sigma, \mathrm{k}}(A)$ be an idealising summation aligned decomposition with respect to integral-independent histogram $A \in \mathcal{A}_{\text {xi }}$. The content alignment of each of the idealising summation aligned super-decompositions of $D$ is greater than that of $D$,

$$
\forall E \in \operatorname{desctrees}(A)(D)(\operatorname{algnSum}(A, E)>\operatorname{algnSum}(A, D))
$$

where desctrees $(A) \in \mathcal{D}_{\Sigma, \mathrm{k}}(A) \rightarrow \mathrm{P}\left(\mathcal{D}_{\Sigma, \mathrm{k}}(A)\right)$ is defined as desctrees $(A)(D):=$ $\left\{E: E \in \mathcal{D}_{\Sigma, \mathrm{k}}(A), D \in \operatorname{subtrees}(E), E \neq D\right\}$. The content alignments of immediate children idealising summation aligned super-decompositions of $D$, $\left\{E: E \in \mathcal{D}_{\Sigma, \mathrm{k}}(A), D \in \operatorname{subtrees}(E),|\operatorname{nodes}(D)|=|\operatorname{nodes}(E)|-1\right\}$, are greater than that of $D$, but less than the content alignments of their descendants,

$$
\forall E \in \operatorname{childtrees}(A)(D)(\operatorname{algnSum}(A, E)>\operatorname{algnSum}(A, D))
$$

and

$$
\begin{aligned}
& \forall E \in \operatorname{childtrees}(A)(D) \\
& \quad \forall F \in \operatorname{desctrees}(A)(E)(\operatorname{algnSum}(A, F)>\operatorname{algnSum}(A, E))
\end{aligned}
$$

where $\operatorname{childtrees}(A) \in \mathcal{D}_{\Sigma, \mathrm{k}}(A) \rightarrow \mathrm{P}\left(\mathcal{D}_{\Sigma, \mathrm{k}}(A)\right)$ is defined as childtrees $(A)(D):=$ $\{E: E \in \operatorname{desctrees}(A)(D),|\operatorname{nodes}(D)|=|\operatorname{nodes}(E)|-1\}$.

The non-idealisation alignment of a transform $T$ with respect to histogram $A$ is defined as the difference between the alignment of histogram and the alignment of the idealisation, $\operatorname{algn}(A)-\operatorname{algn}\left(A * T * T^{\dagger A}\right)$. The non-idealisation alignment is conjectured to be always positive in the case of integral independent, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$. The non-idealisation alignment of an idealising summation aligned decomposition $D$ with respect to $A$ is $\operatorname{algn}(A)-\operatorname{algn}\left(A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}\right)$. The non-idealisation alignment of an idealising summation aligned superdecomposition $E$ of $D$ is $\operatorname{algn}(A)-\operatorname{algn}\left(A * E^{\mathrm{T}} * E^{\mathrm{T} \dagger A}\right)$. Conjecture that the non-idealisation alignment of $E$ is less than the non-idealisation alignment of $D, \operatorname{algn}(A)-\operatorname{algn}\left(A * E^{\mathrm{T}} * E^{\mathrm{T} \dagger A}\right)<\operatorname{algn}(A)-\operatorname{algn}\left(A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}\right)$. Hence the idealisation alignment of $E$ is greater than the idealisation alignment of D,

$$
\forall E \in \operatorname{desctrees}(A)(D)\left(\operatorname{algn}\left(A * E^{\mathrm{T}} * E^{\mathrm{T} \dagger A}\right)>\operatorname{algn}\left(A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}\right)\right)
$$

Conjecture that the idealisation alignments of the immediate children are greater than that for $D$, but less than their descendants,

$$
\forall E \in \operatorname{childtrees}(A)(D)\left(\operatorname{algn}\left(A * E^{\mathrm{T}} * E^{\mathrm{T} \dagger A}\right)>\operatorname{algn}\left(A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}\right)\right)
$$

and

```
\(\forall E \in \operatorname{childtrees}(A)(D)\)
    \(\forall F \in \operatorname{desctrees}(A)(E)\left(\operatorname{algn}\left(A * F^{\mathrm{T}} * F^{\mathrm{T} \dagger A}\right)>\operatorname{algn}\left(A * E^{\mathrm{T}} * E^{\mathrm{T} \dagger A}\right)\right)\)
```

If an idealising summation aligned decomposition $D$ is ideal with respect to $A$, ideal $\left(A, D^{\mathrm{T}}\right)$, for example, if it is effectively sliced, $\forall C \in D^{\mathrm{TP}}\left(\left|\left(A * C^{\mathrm{U}}\right)^{\mathrm{F}}\right| \leq\right.$ $1) \Longrightarrow \operatorname{ideal}\left(A, D^{\mathrm{T}}\right)$, then there are no idealising summation aligned superdecompositions of $D$,

$$
\operatorname{ideal}\left(A, D^{\mathrm{T}}\right) \Longrightarrow \operatorname{desctrees}(A)(D)=\emptyset
$$

Thus, conjecture that the idealising summation aligned super-decompositions of $D$ are progressively more ideal as nodes are added.

Let $X \in \operatorname{trees}\left(\mathcal{D}_{\Sigma, \mathrm{k}}(A)\right)$ be a tree of idealising summation aligned decompositions of integral-independent histogram $A$ such that (i) the steps of the tree are immediate super-decompositions,

$$
\forall(D, E) \in \operatorname{steps}(X)(E \in \operatorname{childtrees}(A)(D))
$$

and (ii) the leaves of the tree are ideal,

$$
\left.\forall D \in \operatorname{leaves}(X) \text { (ideal }\left(A, D^{\mathrm{T}}\right)\right)
$$

The tree of idealising summation aligned decompositions, $X$, is said to be fully searched.

The content alignment increases along the paths of the tree, $\forall(D, E) \in$ $\operatorname{steps}(X)(\operatorname{algnSum}(A, E) \geq \operatorname{algnSum}(A, D))$. So the leaves of the tree, leaves $(X)$, have the maximum content alignment of their ancestors, $\forall L \in$ $\operatorname{paths}(X) \forall D \in \operatorname{set}(L)\left(\operatorname{algnSum}\left(A, L_{|L|}\right) \geq \operatorname{algnSum}(A, D)\right)$.

Conjecture that the idealisation alignment increases along the paths as the idealising summation aligned super-decompositions become progressively more ideal, $\forall(D, E) \in \operatorname{steps}(X)\left(\operatorname{algn}\left(A * E^{\mathrm{T}} * E^{\mathrm{T} \dagger A}\right) \geq \operatorname{algn}\left(A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}\right)\right)$. The idealisation alignment of the leaves equals the alignment of the histogram, $\forall D \in \operatorname{leaves}(X)\left(\operatorname{algn}\left(A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}\right)=\operatorname{algn}(A)\right)$.

The maximally aligned set of idealising summation aligned decompositions, $M=\operatorname{maxd}(\{(D, \operatorname{algnSum}(A, D)): D \in \operatorname{elements}(X)\})$, is a subset of the leaves, $M \subseteq$ leaves $(X)$, and so consists only of ideal decompositions, $\forall D \in$ $M\left(\operatorname{ideal}\left(A, D^{\mathrm{T}}\right)\right)$.

In section 'Likely histograms', it is conjectured that there exists an intermediate mid substrate transform $T_{\mathrm{m}} \in \mathcal{T}_{U_{A}, V_{A}}$ which is neither self nor unary, $T_{\mathrm{m}} \notin\left\{T_{\mathrm{s}}, T_{\mathrm{u}}\right\}$, where the formal is independent and the midisation entropy is minimised,

$$
T_{\mathrm{m}} \in \operatorname{mind}\left(\left\{\left(T, \operatorname{entropy}\left(A^{\mathrm{M}(T)}\right)\right): T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}}\right\}\right)
$$

At the mid transform the formal tends to the abstract, $A^{\mathrm{X}} * T_{\mathrm{m}} \approx\left(A * T_{\mathrm{m}}\right)^{\mathrm{X}}$, and the mid component size cardinality relative entropy is small,

$$
\text { entropyRelative }\left(A * T_{\mathrm{m}}, V_{A}^{\mathrm{C}} * T_{\mathrm{m}}\right) \approx 0
$$

Subsequent minimisation of the idealisation entropy, where the mid idealisation is integral, $A * T_{\mathrm{m}} * T_{\mathrm{m}}^{\dagger A} \in \mathcal{A}_{\mathrm{i}}$, tends to increase the mid component size cardinality relative entropy,

$$
\text { entropyRelative }\left(A * T_{\mathrm{m}}, V_{A}^{\mathrm{C}} * T_{\mathrm{m}}\right) \sim-\operatorname{entropy}\left(A * T_{\mathrm{m}} * T_{\mathrm{m}}^{\dagger A}\right)
$$

In section 'Transform alignment', it is conjectured that subsequent maximisation of the idealisation alignment also tends to increase the relative entropy,

$$
\text { entropyRelative }\left(A * T_{\mathrm{m}}, V_{A}^{\mathrm{C}} * T_{\mathrm{m}}\right) \sim \operatorname{algn}\left(A * T_{\mathrm{m}} * T_{\mathrm{m}}^{\dagger A}\right)
$$

The tree of idealising summation aligned decompositions, $X \in \operatorname{trees}\left(\mathcal{D}_{\Sigma, \mathrm{k}}(A)\right)$, is fully searched, so, given any path $L \in \operatorname{paths}(X)$, the last decomposition is ideal, $A * L_{l}^{\mathrm{T}} * L_{l}^{\mathrm{T} \dagger A}=A$, where $l=|L|$. Consider the case where (i) the root transform is the mid transform, $L_{1}=\left\{\left(\left(\emptyset, T_{\mathrm{m}}\right), \emptyset\right)\right\}$, and (ii) the idealisations along the path are all integral, $\forall i \in\{1 \ldots l\}\left(A * L_{i}^{\mathrm{T}} * L_{i}^{\mathrm{T} \dagger A} \in \mathcal{A}_{\mathrm{i}}\right)$. In this case the idealisation alignment increases along the path,

$$
\forall i \in\{2 \ldots l\}\left(\operatorname{algn}\left(A * L_{i}^{\mathrm{T}} * L_{i}^{\mathrm{T} \dagger A}\right)>\operatorname{algn}\left(A * L_{i-1}^{\mathrm{T}} * L_{i-1}^{\mathrm{T} \dagger A}\right)\right)
$$

and so the relative entropy also increases along the path,

$$
\begin{aligned}
& \forall i \in\{2 \ldots l\} \\
& \quad\left(\text { entropyRelative }\left(A * L_{i}^{\mathrm{T}}, V_{A}^{\mathrm{C}} * L_{i}^{\mathrm{T}}\right)>\operatorname{entropyRelative}\left(A * L_{i-1}^{\mathrm{T}}, V_{A}^{\mathrm{C}} * L_{i-1}^{\mathrm{T}}\right)\right)
\end{aligned}
$$

The first decomposition, $L_{1}$, which is a sub-decomposition of all subsequent, has the least relative entropy, entropyRelative $\left(A * L_{1}^{\mathrm{T}}, V_{A}^{\mathrm{C}} * L_{1}^{\mathrm{T}}\right) \approx 0$. The last decomposition, $L_{l}$, which is a super-decomposition of all previous, has the greatest relative entropy, entropyRelative $\left(A * L_{l}^{\mathrm{T}}, V_{A}^{\mathrm{C}} * L_{l}^{\mathrm{T}}\right)>0$.

That is, an idealising summation aligned decomposition $D$ that (i) is ideal,
$A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}=A$, and (ii) is rooted in the mid transform, $D=\left\{\left(\left(\emptyset, T_{\mathrm{m}}\right), \cdot\right)\right\}$, tends to increase relative entropy as the cardinality of decomposition nodes increases,

$$
\text { entropyRelative }\left(A * D^{\mathrm{T}}, V_{A}^{\mathrm{C}} * D^{\mathrm{T}}\right) \sim|\operatorname{nodes}(D)|
$$

In the case where each transform is the mid transform for the component,

$$
\begin{aligned}
\forall(C, T) \in \operatorname{cont}(D)(T \in \operatorname{mind} & \left(\left\{\left(T^{\prime}, \operatorname{entropy}\left((A * C)^{\mathrm{M}\left(T^{\prime}\right)}\right)\right):\right.\right. \\
T^{\prime} & \left.\left.\left.\in \mathcal{T}_{U_{A}, V_{A}},(A * C)^{\mathrm{x}} * T^{\prime}=\left((A * C)^{\mathrm{x}} * T^{\prime}\right)^{\mathrm{x}}\right\}\right)\right)
\end{aligned}
$$

then each non-leaf decomposition node $((\cdot, T), F) \in \operatorname{nodes}(D)$, where $F \neq \emptyset$, forms a child decomposition $E=\{((\emptyset, T), F)\}$ in slice $A * C$ which is rooted in the slice mid transform, $T$, so that the slice formal approximates to the slice abstract, $(A * C)^{\mathrm{X}} * T \approx(A * C * T)^{\mathrm{X}}$, but the child decomposition relative entropy, entropyRelative $\left(A * C * E^{\mathrm{T}}, V_{A}^{\mathrm{C}} * E^{\mathrm{T}}\right)$, is not necessarily small.

Conjecture that all idealising summation aligned decompositions can be fully searched,

$$
\begin{aligned}
& \forall A \in \mathcal{A}_{U} \cap \mathcal{A}_{\mathrm{xi}} \forall D \in \mathcal{D}_{\Sigma, \mathrm{k}}(A) \exists X \in \operatorname{trees}\left(\mathcal{D}_{\Sigma, \mathrm{k}}(A)\right) \\
& \quad(\operatorname{roots}(X)=\{D\} \wedge \\
& \quad \forall(E, F) \in \operatorname{steps}(X)(F \in \operatorname{childtrees}(A)(E)) \wedge \\
& \left.\quad \forall E \in \operatorname{leaves}(X)\left(\operatorname{ideal}\left(A, E^{\mathrm{T}}\right)\right)\right)
\end{aligned}
$$

That is, for any idealising summation aligned decomposition that is not ideal conjecture that there can always be found an idealising summation aligned super-decomposition,

$$
\forall A \in \mathcal{A}_{U} \cap \mathcal{A}_{\mathrm{xi}} \forall D \in \mathcal{D}_{\Sigma, \mathrm{k}}(A)\left(\neg \operatorname{ideal}\left(A, D^{\mathrm{T}}\right) \Longrightarrow \operatorname{desctrees}(A)(D) \neq \emptyset\right)
$$

This requires that any non-independent component of the partition, $A * C^{\mathrm{U}} \neq$ $\left(A * C^{\mathrm{U}}\right)^{\mathrm{X}}$ where $C \in D^{\mathrm{P}}$, may be diagonalised such that the formal histogram is equivalent to abstract histogram, the derived histogram is not independent and the formal histogram is independent, $\exists T \in \mathcal{T}_{U, \mathrm{f}, 1}\left(\operatorname{diagonal}\left(A * C^{\mathrm{U}} * T\right) \wedge\right.$ $\left(A^{\mathrm{X}} * C^{\mathrm{U}} * T \equiv\left(A * C^{\mathrm{U}} * T\right)^{\mathrm{X}}\right) \wedge \neg\left(A * C^{\mathrm{U}} * T \equiv\left(A * C^{\mathrm{U}} * T\right)^{\mathrm{X}}\right) \wedge\left(\left(A * C^{\mathrm{U}}\right)^{\mathrm{X}} * T \equiv\right.$ $\left.\left.\left(\left(A * C^{\mathrm{U}}\right)^{\mathrm{X}} * T\right)^{\mathrm{X}}\right)\right)$.

If it is the case that the derived alignments of a decomposition $D \in \mathcal{D}$ always decrease along the paths,

$$
\begin{aligned}
& \forall\left(\left(C_{1}, T_{1}\right),\left(C_{2}, T_{2}\right)\right) \in \operatorname{steps}(\text { contingents }(D)) \\
& \quad\left(\operatorname{algn}\left(A * C_{1} * T_{1}\right)>\operatorname{algn}\left(A * C_{2} * T_{2}\right)\right)
\end{aligned}
$$

the decomposition, $D$, is said to be slowing. It is sometimes, but not necessarily, the case that an idealising summation aligned decomposition $D \in \mathcal{D}_{\Sigma, \mathrm{k}}(A)$ is slowing,

$$
\begin{aligned}
& \exists A \in \mathcal{A}_{U} \cap \mathcal{A}_{\mathrm{xi}} \exists D \in \mathcal{D}_{\Sigma, \mathrm{k}}(A) \\
& \quad \forall\left(\left(C_{1}, T_{1}\right),\left(C_{2}, T_{2}\right)\right) \in \operatorname{steps}(\text { contingents }(D)) \\
& \quad\left(\operatorname{algn}\left(A * C_{1} * T_{1}\right)>\operatorname{algn}\left(A * C_{2} * T_{2}\right)\right)
\end{aligned}
$$

There are several reasons why this is so. Firstly, the slice sizes must decrease,

$$
\forall\left(\left(C_{1}, \cdot\right),\left(C_{2}, \cdot\right)\right) \in \operatorname{steps}(\operatorname{contingents}(D))\left(\operatorname{size}\left(A * C_{1}\right)>\operatorname{size}\left(A * C_{2}\right)\right)
$$

The contingent derived alignments are each limited to the maximum alignment,

$$
\operatorname{algn}(A * C * T) \leq \operatorname{alignmentMaximum}(U)(\operatorname{der}(T), \operatorname{size}(A * C))
$$

The maximum alignment is limited by the slice size, $\operatorname{size}(A * C)$. For regular derived histograms of slice size $z=\operatorname{size}(A * C)$, dimension $n=|\operatorname{der}(T)|$ and valency $\{d\}=\left\{\left|U_{w}\right|: w \in \operatorname{der}(T)\right\}$, the maximum alignment approximates to $z(n-1) \ln d$.

Secondly, it is conjectured above that idealising summation aligned superdecompositions have higher idealisation alignment than their ancestor idealising summation aligned decompositions. That is, the super-decompositions are more ideal. Therefore the slices are progressively more independent along the paths of a decomposition,

$$
\forall\left(\left(C_{1}, \cdot\right),\left(C_{2}, \cdot\right)\right) \in \operatorname{steps}(\operatorname{contingents}(D))\left(\operatorname{algn}\left(A * C_{1}\right)>\operatorname{algn}\left(A * C_{2}\right)\right)
$$

If it is the case that the descendant slice is more independent because it is partially independent, that is $\exists Q \in \mathrm{~B}(V)\left(A * C_{2} \equiv Z_{A * C_{2}} * \prod\left(A / Z_{A * C_{2}} \% K\right.\right.$ : $K \in Q)$ ) where $V=\operatorname{vars}(A)$ and $Z_{X}=\operatorname{scalar}(\operatorname{size}(X))$, but the ancestor slice is not partially independent according to this partition, $Q$, of the variables, $\neg\left(A * C_{1} \equiv Z_{A * C_{1}} * \prod\left(A / Z_{A * C_{1}} \% K: K \in Q\right)\right)$, then there must exist fewer transforms of the descendant slice that have non-zero derived alignment. This is because the transform $T_{Q}$ constructed with self partition transforms of the components of the variables partition, $Q$, has zero derived alignment, $A * C_{2} * T_{Q} \equiv\left(A * C_{2} * T_{Q}\right)^{\mathrm{X}}$, where $T_{Q}=\left\{K^{\mathrm{CS}\{ \} \mathrm{T}}: K \in Q\right\}^{\mathrm{T}}$.

Thirdly, a slice $A * C$ cannot contain any of the derived alignments of its ancestor slices, because the derived histogram is an effective singleton,

$$
\begin{aligned}
& \forall L \in \text { paths }(\text { contingents }(D)) \\
& \left.\qquad \forall\left(i,\left(C_{i}, T_{i}\right)\right),\left(j,\left(C_{j}, T_{j}\right)\right) \in L\left(i<j \Longrightarrow\left|\left(A * C_{j} * T_{i}\right)^{\mathrm{F}}\right|=1\right)\right)
\end{aligned}
$$

Exclusion of the derived alignments of the ancestor slices means that there must exist fewer transforms of the descendant slice that have non-zero derived alignment.

So, for the reasons that (i) slice sizes must decrease, (ii) slice alignments must decrease, and (iii) slices cannot contain ancestor derived alignments, it is sometimes the case that the idealising summation aligned decomposition is slowing.

It is therefore the case that the additional content alignment of an immediate child slowing idealising summation aligned super-decomposition $E$, of a slowing idealising summation aligned decomposition $D$, is less than that of D,

$$
\operatorname{algnSum}(A, E)-\operatorname{algnSum}(A, D)<\operatorname{algnSum}(A, D)
$$

or

$$
\operatorname{algnSum}(A, D)<\operatorname{algnSum}(A, E)<2 \times \operatorname{algnSum}(A, D)
$$

So it is sometimes, but not necessarily, the case that the content alignment decreases in a fully searched slowing idealising summation aligned decomposition tree $X \in \operatorname{trees}\left(\mathcal{D}_{\Sigma, \mathbf{k}}(A)\right)$. That is, sometimes, $\operatorname{algnSum}(A, F)-$ $\operatorname{algnSum}(A, E)<\operatorname{algnSum}(A, E)-\operatorname{algnSum}(A, D)$, where $(D, E),(E, F) \in$ $\operatorname{steps}(X)$.

The set of idealising summation aligned decompositions, $\mathcal{D}_{\Sigma, \mathrm{k}}(A)$, excludes decompositions containing variable symmetries. Consider a well behaved decomposition $D \in \mathcal{D}_{\mathrm{w}, U}$ that contains a transform symmetry, $|\operatorname{nodes}(D)|>$ $|\operatorname{transforms}(D)|$, which is a special case of a decomposition containing variable symmetries. The decomposition, $D$, unions slices having the same transform $T$ by means of alternate slice transforms in the nullable fud. For example, $\left\{C_{1}, C_{2}\right\}=$ inverse $(\operatorname{cont}(D))(T)$ implies a unioned slice, $A *\left(C_{1}+C_{2}\right)$. The alignment of the unioned slice is greater than or equal to the sum of the alignments of the slices separately, $\operatorname{algn}\left(A *\left(C_{1}+C_{2}\right) * T\right) \geq \operatorname{algn}\left(A * C_{1} *\right.$ $T)+\operatorname{algn}\left(A * C_{2} * T\right)$. Therefore conjecture that decompositions that contain variable symmetries, but are otherwise subject to the same constraints as the idealising summation aligned decompositions, have content alignment greater than or equal to the summation alignment, $\operatorname{algn}\left(A * D^{\mathrm{T}}\right)-\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right) \geq$ $\operatorname{algnSum}(A, D)$.

The independent formal slice constraint, $\forall(C, T) \in \operatorname{cont}(D)\left((A * C)^{\mathrm{X}} *\right.$ $\left.T \equiv\left((A * C)^{\mathrm{X}} * T\right)^{\mathrm{X}}\right)$, is not as strict as constraining each transform to be non-overlapping, $\forall T \in \operatorname{ran}(\operatorname{cont}(D))(\neg \operatorname{overlap}(T))$, and therefore not as
strict as constraining the entire fud of transforms to be non-overlapping, $\neg \operatorname{overlap}(G)$ where $G=\operatorname{transforms}(D)=\operatorname{ran}(\operatorname{cont}(D))$. In any case nonoverlapping transforms, $\neg \operatorname{overlap}(G)$, does not necessarily imply that the nullable transform, $D^{\mathrm{T}}$, of an idealising summation aligned decomposition $D \in \mathcal{D}_{\Sigma, \mathrm{k}}(A)$, is non-overlapping. In fact, it is only in the case where the decomposition, $D$, contains only a root transform, $|G|=1$, that it is nonoverlapping

$$
|\operatorname{transforms}(D)|=1 \Longleftrightarrow \neg \operatorname{overlap}\left(D^{\mathrm{T}}\right)
$$

A well behaved decomposition containing more than one transform is necessarily overlapping because the nullable variables depend on the underlying variables of their ancestor slice variables.

Similarly, the contingent formal-abstract equivalence constraint,

$$
\forall(C, T) \in \operatorname{cont}(D)\left(A^{\mathrm{X}} * C * T \equiv(A * C * T)^{\mathrm{x}}\right)
$$

does not necessarily imply that the formal histogram equals the abstract histogram for the nullable transform, $D^{\mathrm{T}}$, of a summation aligned decomposition $D \in \mathcal{D}_{\Sigma}(A)$. In the case where the decomposition, $D$, contains only a root transform, $|G|=1$, the formal histogram is necessarily equivalent to the abstract histogram

$$
|\operatorname{transforms}(D)|=1 \Longrightarrow A^{\mathrm{X}} * D^{\mathrm{T}} \equiv\left(A * D^{\mathrm{T}}\right)^{\mathrm{X}}
$$

### 4.18 Derived alignment and conditional probability

Consider the complete integral congruent support sample histogram $A \in$ $\mathcal{A}_{U, \mathrm{i}, V, z}$ drawn with replacement from distribution histogram $E \in \mathcal{A}_{U, V, z_{E}}$, where the distribution histogram $E$ is as effective as the independent sample, $E^{\mathrm{F}} \geq A^{\mathrm{XF}}$. Given some one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$, where und $(T)=$ $V$, the set of integral iso-transform-independents is

$$
Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{x}}\right)\right) \subseteq \mathcal{A}_{U, \mathrm{i}, V, z}
$$

where the integral iso-transform-independent function, $Y_{U, \mathrm{i}, T, z} \in \mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow$ $\left(\mathcal{A}_{U, W, z} \times \mathcal{A}_{U, W, z}\right)$, is defined

$$
Y_{U, \mathbf{i}, T, z}=\left\{\left(B,\left(\left(B^{\mathrm{X}} * T\right),(B * T)^{\mathrm{x}}\right)\right): B \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
$$

where $W=\operatorname{der}(T)$. For convenience, let the integral iso-transform-independents be abbreviated

$$
\begin{aligned}
\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A) & =Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{x}}\right)\right) \\
& =\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{x}} * T=A^{\mathrm{x}} * T,(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}\right\}
\end{aligned}
$$

The generalised multinomial probability of the sample histogram, $\hat{Q}_{\mathrm{m}, U}(E, z)(A)$, may be decomposed into (i) the iso-transform-independents multinomial probability and (ii) iso-transform-independent conditional dependent multinomial probability

$$
\hat{Q}_{\mathrm{m}, U}(E, z)(A)=\sum_{B \in \mathcal{A}_{U, i, y, T, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)(B) \times \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \mathcal{A}_{U, i, y, z, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}
$$

Compare to the iso-independent conditional dependent case, where the generalised multinomial probability of the sample histogram, $\hat{Q}_{\mathrm{m}, U}(E, z)(A)$, is decomposed into (i) the iso-independents multinomial probability and (ii) the iso-independent conditional dependent multinomial probability

$$
\hat{Q}_{\mathrm{m}, U}(E, z)(A)=\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \hat{Q}_{\mathrm{m}, U}(E, z)(B) \times \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}
$$

where integral iso-independents is

$$
Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{X}}=A^{\mathrm{X}}\right\} \subseteq \mathcal{A}_{U, \mathrm{i}, V, z}
$$

Compare to the relative dependent case, where the generalised multinomial probability is decomposed into (i) the independent multinomial probability and (ii) relative dependent multinomial probability

$$
\hat{Q}_{\mathrm{m}, U}(E, z)(A)=\hat{Q}_{\mathrm{m}, U}(E, z)\left(A^{\mathrm{x}}\right) \times \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\hat{Q}_{\mathrm{m}, U}(E, z)\left(A^{\mathrm{x}}\right)}
$$

Unlike in the relative dependent case, where the independent histogram must be integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathfrak{i}}$, in the iso-transform-independent conditional dependent case there is no need for the independent histogram to be integral because the integral iso-transform-independents is non-empty, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)=$ $Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \neq \emptyset$.

Defined in terms of the generalised multinomial probability, the generalised iso-transform-independent conditional multinomial probability distribution is

$$
\begin{aligned}
& \hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}(E, z)= \\
& \quad \text { normalise }\left(\left\{\left(A, \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \mathcal{A}_{U, i, y, T, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, i, \mathrm{i}, z, z}\right\}\right)
\end{aligned}
$$

So

$$
\hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}(E, z)(A)=\frac{1}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, T, z}\right)\right|} \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}
$$

and the generalised multinomial probability may be decomposed

$$
\hat{Q}_{\mathrm{m}, U}(E, z)(A)=\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)(B) \times\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, T, z}\right)\right| \hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}(E, z)(A)
$$

The cardinality of the components of the partition of $\mathcal{A}_{U, \mathbf{i}, T, z}$ is the normalisation factor,

$$
\left|\operatorname{ran}\left(Y_{U, \mathbf{i}, T, z}\right)\right| \leq \prod_{w \in V} \frac{\left(z+\left|U_{w}\right|-1\right)!}{z!} \times \prod_{w \in W} \frac{\left(z+\left|U_{w}\right|-1\right)!}{z!\left(\left|U_{w}\right|-1\right)!}
$$

where $W=\operatorname{der}(T)$. The cardinality of the set of integral iso-transformindependent sets is also such that

$$
\left|\operatorname{ran}\left(Y_{U, \mathbf{i}, T, z}\right)\right| \leq\left|\operatorname{dom}\left(Y_{U, \mathbf{i}, T, z}\right)\right|=\left|\mathcal{A}_{U, \mathbf{i}, V, z}\right|=\frac{(z+v-1)!}{z!(v-1)!}
$$

The relative dependent multinomial probability equals the iso-transformindependent conditional dependent multinomial probability if the iso-transformindependents set is a singleton containing the independent. In this case, however, the sample must be independent,

$$
Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)=\left\{A^{\mathrm{X}}\right\} \Longrightarrow A=A^{\mathrm{X}}
$$

and therefore the probability is 1 ,

$$
\frac{\hat{Q}_{\mathrm{m}, U}(E, z)\left(A^{\mathrm{x}}\right)}{\sum_{B \in\left\{A^{\mathrm{x}}\right\}} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}=\frac{\hat{Q}_{\mathrm{m}, U}(E, z)\left(A^{\mathrm{x}}\right)}{\hat{Q}_{\mathrm{m}, U}(E, z)\left(A^{\mathrm{x}}\right)}=1
$$

In this case, the generalised iso-transform-independent conditional multinomial probability does not depend on $A^{\mathrm{X}}$

$$
\hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}(E, z)\left(A^{\mathrm{x}}\right)=\frac{1}{\left|\operatorname{ran}\left(Y_{U, \mathbf{i}, T, z}\right)\right|}
$$

The iso-transform-independent conditional dependent multinomial probability is greater than 0 and less than or equal to 1

$$
0<\frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)} \leq 1
$$

because

$$
0<\hat{Q}_{\mathrm{m}, U}(E, z)(A) \leq \sum_{B \in \mathcal{A}_{U, i, y, T, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)(B) \leq 1
$$

The iso-transform-independent conditional dependent multinomial probability is a probability proper because the conditional probability is always between zero and one, yielding a probability function,

$$
\left\{\left(C, \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(C)}{\sum_{B \in \mathcal{A}_{U, i, \mathrm{i}, T, T, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}\right): C \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right\} \in \mathcal{P}
$$

The iso-transform-independent conditional dependent multinomial probability may be generalised to a probability density. Instead of drawing an integral sample histogram from the finite integral congruent support, $\mathcal{A}_{U, i, V, z}$, the sample histogram is drawn from the infinite complete congruent histograms, $A \in \mathcal{A}_{U, V, z}$. The iso-transform-independent conditional dependent multinomial probability density given the infinite iso-transform-independents is

$$
\frac{\operatorname{mpdf}(U)(E, z)(A)}{\int_{B \in \mathcal{A}_{U, y, T, z}(A)} \operatorname{mpdf}(U)(E, z)(B) d B}
$$

which is defined if the distribution histogram $E$ is as effective as the independent sample, $E^{\mathrm{F}} \geq A^{\mathrm{XF}}$.

The iso-transform-independent conditional dependent multinomial probability density is greater than 0 and less than or equal to 1

$$
0<\frac{\operatorname{mpdf}(U)(E, z)(A)}{\int_{B \in \mathcal{A}_{U, y, T, z}(A)} \operatorname{mpdf}(U)(E, z)(B) d B} \leq 1
$$

because

$$
0<\operatorname{mpdf}(U)(E, z)(A) \leq \int_{B \in \mathcal{A}_{U, y, T, z}(A)} \operatorname{mpdf}(U)(E, z)(B) d B \leq 1
$$

The iso-transform-independent conditional dependent multinomial probability tends to the iso-transform-independent conditional dependent multinomial probability density as the size increases
$\lim _{k \rightarrow \infty} \frac{\hat{Q}_{\mathrm{m}, U}(E, k z)\left(Z_{k} * A\right)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, k z}\left(Z_{k} * A\right)} \hat{Q}_{\mathrm{m}, U}(E, k z)(B)}=\frac{\operatorname{mpdf}(U)(E, z)(A)}{\int_{B \in \mathcal{A}_{U, \mathrm{y}, T, z}(A)} \operatorname{mpdf}(U)(E, z)(B) d B}$
where $Z_{k}=\operatorname{scalar}(k)$. This is because the finite integral iso-transformindependents becomes a larger subset of the iso-transform-independents as the size increases,

$$
Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \subset Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)
$$

If the transform is a self partition transform, for example $T_{\mathrm{s}}=V^{\mathrm{CS}\{ \} \mathrm{T}} \in$ $\mathcal{T}_{U, \mathrm{f}, 1}$, or it is value full functional, for example $T_{\mathrm{s}}=\left\{\{w\}^{\mathrm{CS}\{ \}^{\mathrm{T}}}: w \in V\right\}^{\mathrm{T}} \in$ $\mathcal{T}_{U, f, 1}$, then the set of integral iso-transform-independents equals the set of integral iso-independents, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{s}}, z}(A)=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$. In this case the iso-transform-independent conditional dependent multinomial probability equals the iso-independent conditional dependent multinomial probability

$$
\frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \mathcal{A}_{U, i, y, T, T_{\mathrm{s}}, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}=\frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}
$$

If the transform is a unary partition, for example $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, \mathrm{f}, 1}$, then the set of integral iso-transform-independents equals the integral congruent support, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}(A)=\mathcal{A}_{U, \mathrm{i}, V, z}$. In this case the iso-transform-independent conditional dependent multinomial probability equals the generalised multinomial probability

$$
\frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}=\hat{Q}_{\mathrm{m}, U}(E, z)(A)
$$

Thus the iso-transform-independent conditional dependent multinomial probability for the self partition transform case, $T_{\mathrm{s}}$, is greater than or equal to that for the unary partition transform case, $T_{\mathrm{u}}$,

$$
\frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{s}}, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)} \geq \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}
$$

That is, the conditional probability of the sample given a self partition transform, $T_{\mathrm{s}}$, is greater than or equal to the conditional probability of the sample given a unary partition transform, $T_{\mathrm{u}}$, regardless of the distribution histogram, $E$. The larger the intersection between the integral iso-transformindependents of the two transforms, $T_{\mathrm{s}}, T_{\mathrm{u}}$, which is the intersection between
the integral iso-independents and the integral congruent support, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{s}}, z}(A) \cap$ $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}(A)=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right) \cap \mathcal{A}_{U, \mathrm{i}, V, z}=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, the smaller the difference in conditional probabilities. So the less independent the sample, $A \neq A^{\mathrm{X}}$, the greater the difference in iso-transform-independent conditional dependent multinomial probability between these extreme cases.

In the case where (i) the sample is completely effective, $A^{\mathrm{F}}=A^{\mathrm{C}}$, (ii) the distribution histogram equals the sample, $E=A$, and (iii) the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, which implies that the idealisations are integral, $A * T_{\mathrm{s}} * T_{\mathrm{s}}^{\dagger A}=A \in \mathcal{A}_{\mathrm{i}}$ and $A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger A}=A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, then the same inequality holds

$$
\frac{\hat{Q}_{\mathrm{m}, U}(A, z)\left(A * T_{\mathrm{s}} * T_{\mathrm{s}}^{\dagger A}\right)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, \mathrm{~T}_{\mathrm{s}}, z}(A)} \hat{Q}_{\mathrm{m}, U}(A, z)(B)} \geq \frac{\hat{Q}_{\mathrm{m}, U}(A, z)\left(A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger A}\right)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}(A)} \hat{Q}_{\mathrm{m}, U}(A, z)(B)}
$$

because $\hat{Q}_{\mathrm{m}, U}(A, z)(A) \geq \hat{Q}_{\mathrm{m}, U}(A, z)\left(A^{\mathrm{X}}\right)$. Note, however, that in the case where the distribution histogram equals the independent sample, $E=A^{\mathrm{X}}$, the inequality between the idealisations does not necessarily hold, because $\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A) \leq \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)$, given the integral mean multinomial probability distribution conjecture. That is, in some cases

$$
\frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A * T_{\mathrm{s}} * T_{\mathrm{s}}^{\dagger A}\right)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{s}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B)}<\frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger A}\right)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B)}
$$

In the section 'Alignment and conditional probability', above, the negative logarithm independently-distributed iso-independent conditional dependent multinomial probability, where the distribution histogram is (i) independent, $E=E^{\mathrm{X}}$, and (ii) sufficiently effective, $E^{\mathrm{XF}} \geq A^{\mathrm{XF}}$, was shown to be

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}: E^{\mathrm{XF}} \geq A^{\mathrm{XF}}\right) \\
= & \sum_{S \in A^{\mathrm{S}}} \ln A_{S}!+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{1}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}
\end{aligned}
$$

because

$$
\begin{aligned}
& \forall B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right) \\
& \qquad\left(\sum_{S \in B^{\mathrm{S}}} B_{S} \ln E_{S}^{\mathrm{X}}=\sum_{S \in B^{\mathrm{XS}}} B_{S}^{\mathrm{X}} \ln E_{S}^{\mathrm{X}}=\sum_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}} \ln E_{S}^{\mathrm{X}}=\sum_{S \in A^{\mathrm{S}}} A_{S} \ln E_{S}^{\mathrm{X}}\right)
\end{aligned}
$$

However, the same reasoning cannot be applied to the negative logarithm independently-distributed iso transform independent conditional dependent multinomial probability even given independent distribution histogram. This is because it is not necessarily the case that there is the common factor,

$$
\prod_{S \in A^{\mathrm{xS}}}\left(E_{S}^{\mathrm{X}}\right)^{A_{S}^{\mathrm{X}}}
$$

in the numerator and denominator of the independently-distributed iso transform independent conditional dependent multinomial probability,

$$
\frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{x}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, i, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}
$$

That is, in some cases $\exists B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\left(B^{\mathrm{X}} \neq A^{\mathrm{X}}\right)$.
However, consider the case where (i) the distribution histogram is the independent sample histogram, $E=A^{\mathrm{X}}$, (ii) the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, and (iii) formal independent histogram equals the abstract histogram which implies that the independent is in the iso-transform-independents, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=$ $(A * T)^{\mathrm{X}} \Longrightarrow A^{\mathrm{X}} \in Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)$. So the independent is in the integral iso-transform-independents

$$
\left(A^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}}\right) \wedge\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}\right) \Longrightarrow A^{\mathrm{X}} \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{x}}\right)\right)
$$

Note that the third constraint is weaker than the case where the formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$. The mean histogram of the generalised multinomial probability distribution is the independent, $\operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\right)=A^{\mathrm{X}}$. The integral mean multinomial probability distribution conjecture, defined above in 'Multinomial distributions', states that if the mean of the multinomial probability distribution is integral then it is also modal

$$
\operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right) \in \mathcal{A}_{i} \Longrightarrow \operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right) \in \operatorname{modes}\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)
$$

If this conjecture is true then

$$
\forall B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\left(\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(B) \leq \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)\right)
$$

Hence the negative logarithm independent-sample-distributed iso-transformindependent conditional dependent multinomial probability is

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B)}: A^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}},\left(A^{\mathrm{x}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}\right) \\
= & -\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A^{\mathrm{x}}\right)}+\ln \sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(B)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A^{\mathrm{x}}\right)}
\end{aligned}
$$

The independent is an iso-transform-independent, $A^{\mathrm{X}} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)$, and hence the summation is such that

$$
1 \leq \sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A^{\mathrm{x}}\right)} \leq\left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right|
$$

Thus the negative logarithm independent-sample-distributed iso-transformindependent conditional dependent multinomial probability, where the independent is an iso-transform-independent, is bounded by the alignment

$$
\begin{aligned}
& \quad \hat{a l g n}(A) \quad\left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B)}: A^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}},\left(A^{\mathrm{x}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}\right) \\
& \leq \operatorname{algn}(A)+\ln \left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right|
\end{aligned}
$$

The negative logarithm independently-distributed relative dependent multinomial probability of the sample, where the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, which is the alignment,

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}: A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right) \\
= & \sum_{S \in A^{\mathrm{S}}} \ln A_{S}!-\sum_{S \in A^{\mathrm{xS}}} \ln A_{S}^{\mathrm{X}}! \\
= & \operatorname{algn}(A)
\end{aligned}
$$

does not depend on the distribution histogram. Nor does the negative logarithm independently-distributed iso-independent conditional dependent multinomial probability, where the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, which is the alignment-bounded iso-independent space,

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}: E^{\mathrm{XF}} \geq A^{\mathrm{XF}}, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right) \\
= & \sum_{S \in A^{\mathrm{S}}} \ln A_{S}!+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{1}{\prod_{S \in B^{\mathrm{S}}} B_{S}!} \\
= & \operatorname{algn}(A)+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{\prod_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}}!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}
\end{aligned}
$$

Contrast the negative logarithm independent-sample-distributed iso-transformindependent conditional dependent multinomial probability, where the independent is an integral iso-transform-independent, $A^{\mathrm{X}} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)$,

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B)}: A^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}},\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{x}}\right) \\
= & \operatorname{algn}(A)+\ln \sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(B)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A^{\mathrm{x}}\right)}
\end{aligned}
$$

which does depend on the distribution histogram, $A^{\mathrm{X}}$.

Let integral congruent delta $(D, I) \in \mathcal{A}_{\mathrm{i}} \times \mathcal{A}_{\mathrm{i}}$ be such that its perturbation, $A-D+I$, is (i) iso-transform-independence conserving, $A-D+I \in$ $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)$, and (ii) iso-independence conserving, $A-D+I \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, so that $(A-D+I)^{\mathrm{X}}=A^{\mathrm{X}}$. That is, delta, $(D, I)$, is iso-independent and iso-abstract, $A-D+I \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$. Let (iii) the formal independent equal the abstract, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$, so that the integral independent, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, is an integral iso-transform-independent, $A^{\mathrm{X}} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)$. The change in negative logarithm independent-sampledistributed iso-transform-independent conditional dependent multinomial probability, given the integral mean multinomial probability distribution conjecture, because of the application of the delta, $(D, I)$, is the difference in alignments,

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A-D+I)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left((A-D+I)^{\mathrm{X}}\right)}+\right. \\
& \left.\ln \sum_{B \in \mathcal{A}_{U, \mathrm{i}, y, T, z}(A-D+I)} \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left((A-D+I)^{\mathrm{X}}\right)}\right)- \\
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}+\ln \sum_{B \in \mathcal{A}_{U, i, y, y, z}(A)} \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(B)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}\right) \\
& =\left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A-D+I)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A^{\mathrm{X}}\right)}+\ln \sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A-D+I)} \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}\right)- \\
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(A)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A^{\mathrm{x}}\right)}+\ln \sum_{B \in \mathcal{A}_{U, i, y, T, z}(A)} \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(B)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A^{\mathrm{X}}\right)}\right) \\
& =\operatorname{algn}(A-D+I)-\operatorname{algn}(A)
\end{aligned}
$$

So the change in conditional probability, because of the application of the delta, $(D, I)$, does not depend on the transform, $T$, under these constraints.

The integral idealisation of a histogram given an effective transform, $A *$ $T * T^{\dagger A}$, is in both the integral iso-transform-independents, $A * T * T^{\dagger A} \in$ $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)$, and the integral iso-independents, $A * T * T^{\dagger A} \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$. The integral idealisation has a corresponding iso-transform-independence and isoindependence conserving delta, $A * T * T^{\dagger} A=A-D+I$. The change in negative logarithm independent-sample-distributed iso-transform-independent conditional dependent multinomial probability, given the integral mean multinomial probability distribution conjecture, where the independent is an iso-transformindependent, $A^{\mathrm{X}} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)$, because of the integral idealisation of the sample histogram is the difference in alignments,

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A * T * T^{\dagger A}\right)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A^{\mathrm{X}}\right)}+\ln \sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}\left(A * T * T^{\dagger A}\right)} \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(B)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{x}}\right)}\right)- \\
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A^{\mathrm{x}}\right)}+\ln \sum_{B \in \mathcal{A}_{U, i, \mathrm{i}, T, z, z}(A)} \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A^{\mathrm{X}}\right)}\right) \\
= & \operatorname{algn}\left(A * T * T^{\dagger A}\right)-\operatorname{algn}(A)
\end{aligned}
$$

Consider the case where distribution histogram is not necessarily equal to the independent sample histogram. If (i) the distribution histogram is independent, $E=E^{\mathrm{X}}$, and (ii) sufficiently effective, $E^{\mathrm{XF}} \geq A^{\mathrm{XF}}$, (iii) the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, and (iv) the iso-transform-independents equals the iso-independents, $Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, then the negative logarithm independently-distributed iso-transform-independent conditional dependent multinomial probability equals the negative logarithm independently-distributed iso-independent conditional dependent multinomial
probability, which is the alignment-bounded iso-independent space

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{x}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}:\right. \\
& \left.E^{\mathrm{XF}} \geq A^{\mathrm{XF}}, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}, \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right) \\
& =\left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}: E^{\mathrm{XF}} \geq A^{\mathrm{XF}}, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right) \\
& =\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{1}{\prod_{S \in B^{\mathrm{S}}} B_{S}!} \\
& =\operatorname{algn}(A)+\ln \sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{\prod_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}}!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}
\end{aligned}
$$

This is the case, for example, if the transform is value full functional, $T=$ $\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in V\right\}^{\mathrm{T}}$.

In this case, where the iso-transform-independents equals the iso-independents, the negative logarithm independently-distributed iso-transform-independent conditional dependent multinomial probability is bounded by the alignment

$$
\begin{aligned}
& \operatorname{algn}(A) \\
& \leq\left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}:\right. \\
& \left.E^{\mathrm{XF}} \geq A^{\mathrm{XF}}, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}, \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right) \\
& \leq \operatorname{algn}(A)+\ln \left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|
\end{aligned}
$$

Now consider the lifted case. For convenience, let the lifted integral iso-transform-independents be abbreviated

$$
\begin{aligned}
\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A) & =\left\{B * T: B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right\} \\
& \left.=\left\{B * T: B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{x}}\right)\right)\right\} \\
& =\left\{B * T: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{X}} * T=A^{\mathrm{X}} * T,(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}\right\}
\end{aligned}
$$

The lifted iso-transform-independent quasi-conditional dependent multinomial probability is

$$
\frac{\hat{Q}_{\mathrm{m}, U}(E * T, z)(A * T)}{\sum_{B^{\prime} \in \mathcal{A}^{\prime}, \mathrm{i}, \mathrm{y}, T, z, z}(A)} \hat{Q}_{\mathrm{m}, U}(E * T, z)\left(B^{\prime}\right) \quad
$$

As noted above in section 'Iso-sets', it is only in the subset where the formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, that the lifted iso-transform-independent relation is functional

$$
\begin{aligned}
& \left\{\left(A * T,\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{X}}\right)\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A^{\mathrm{x}} * T=(A * T)^{\mathrm{X}}\right\} \\
\in & \mathcal{A}_{U, \mathrm{i}, W, z} \rightarrow\left(\mathcal{A}_{U, W, z} \times \mathcal{A}_{U, W, z}\right)
\end{aligned}
$$

and hence the lifted integral iso-transform-independent sets do not partition the integral congruent support in the derived variables, $\mathcal{A}_{U, \mathrm{i}, W, z}$, except where the formal histogram equals the abstract histogram

$$
\begin{aligned}
& \operatorname{ran}\left(\left\{\left(A * T,\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{x}}\right)\right):\right.\right. \\
& \quad\left.\left.\left(A,\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{x}}\right)\right) \in Y_{U, \mathrm{i}, T, z}, A^{\mathrm{x}} * T=(A * T)^{\mathrm{x}}\right\}^{-1}\right) \\
& \in \quad \mathrm{B}\left(\left\{B * T: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{x}} * T=(B * T)^{\mathrm{x}}\right\}\right)
\end{aligned}
$$

For this reason the lifted iso-transform-independent quasi-conditional dependent multinomial probability is only quasi-conditional. That is, conditional for the subset of the derived integral congruent support where the formal histogram equals the abstract histogram.

If the transform is a self partition transform, for example $T_{\mathrm{s}}=V^{\mathrm{CS}\{ \} \mathrm{T}} \in$ $\mathcal{T}_{U, \mathrm{f}, 1}$, or it is value full functional, for example $T_{\mathrm{s}}=\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in V\right\}^{\mathrm{T}} \in$ $\mathcal{T}_{U, \mathrm{f}, 1}$, then the set of lifted integral iso-transform-independents equals the set of lifted integral iso-independents, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{s}}, z}^{\prime}(A)=\left\{B * T_{\mathrm{s}}: B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right\}$. The lifted iso-transform-independent quasi-conditional dependent multinomial probability equals the iso-transform-independent conditional dependent multinomial probability, which in turn equals the iso-independent conditional dependent multinomial probability

$$
\begin{aligned}
& \frac{\hat{Q}_{\mathrm{m}, U}\left(E * T_{\mathrm{s}}, z\right)\left(A * T_{\mathrm{s}}\right)}{\sum_{B^{\prime} \in \mathcal{A}_{U}^{\prime}, \mathrm{i}, \mathrm{y}, T_{\mathrm{s}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E * T_{\mathrm{s}}, z\right)\left(B^{\prime}\right) \\
= & \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{s}}, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)} \\
= & \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}
\end{aligned}
$$

If the transform is a unary partition, for example $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, \mathrm{f}, 1}$, then the set of lifted integral iso-transform-independents equals the singleton lifted integral congruent support, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}^{\prime}(A)=\left\{B * T_{\mathrm{u}}: B \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}=$ $\left\{A * T_{\mathrm{u}}\right\}$. The lifted generalised multinomial probability is equal to one, $\hat{Q}_{\mathrm{m}, U}\left(E * T_{\mathrm{u}}, z\right)\left(A * T_{\mathrm{u}}\right)=1$. So the lifted iso-transform-independent quasiconditional dependent multinomial probability equals 1,

$$
\frac{\hat{Q}_{\mathrm{m}, U}\left(E * T_{\mathrm{u}}, z\right)\left(A * T_{\mathrm{u}}\right)}{\sum_{B^{\prime} \in \mathcal{A}^{\prime} U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E * T_{\mathrm{u}}, z\right)\left(B^{\prime}\right) \quad=1
$$

In the case of unary partition transform, the lifted iso-transform-independent quasi-conditional dependent multinomial probability is not necessarily equal to the corresponding iso-transform-independent conditional dependent multinomial probability. The iso-transform-independent conditional dependent multinomial probability equals the generalised multinomial probability, $\hat{Q}_{\mathrm{m}, U}(E, z)(A)$, which may be less than one,

$$
\frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \mathcal{A}_{U, i, \mathrm{y}, T_{\mathrm{u}}, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}=\hat{Q}_{\mathrm{m}, U}(E, z)(A) \leq 1
$$

Whereas the iso-transform-independent conditional dependent multinomial probability for the self partition transform case is greater than or equal to that for the unary partition transform case,

$$
\frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{i}, T_{\mathrm{s}}, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)} \geq \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)}
$$

the lifted iso-transform-independent quasi-conditional dependent multinomial probability for the self partition transform case is less than or equal to that for the unary partition transform case
$\frac{\hat{Q}_{\mathrm{m}, U}\left(E * T_{\mathrm{s}}, z\right)\left(A * T_{\mathrm{s}}\right)}{\sum_{B^{\prime} \in \mathcal{A}^{\prime}}{ }_{\mathrm{i}, \mathrm{i}, T_{\mathrm{s}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E * T_{\mathrm{s}}, z\right)\left(B^{\prime}\right) \quad \leq \frac{\hat{Q}_{\mathrm{m}, U}\left(E * T_{\mathrm{u}}, z\right)\left(A * T_{\mathrm{u}}\right)}{\sum_{B^{\prime} \in \mathcal{A}^{\prime} U, \mathrm{i},, T_{\mathrm{u}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E * T_{\mathrm{u}}, z\right)\left(B^{\prime}\right)$
That is, the lifted quasi-conditional probability of the sample given a self partition transform, $T_{\mathrm{s}}$, is less than or equal to the lifted quasi-conditional probability of the sample given a unary partition transform, $T_{\mathrm{u}}$, regardless of the distribution histogram, $E$.

If the distribution histogram equals the independent sample, $E=A^{\mathrm{X}}$, however, it is sometimes the case that the direction of the non-lifted conditional probability inequality is the same as the lifted case for the corresponding idealisations, $A * T_{\mathrm{s}} * T_{\mathrm{s}}^{\dagger A}=A$ and $A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger A}=A^{\mathrm{X}}$, because
$\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(A) \leq \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A^{\mathrm{X}}\right)$, given the integral mean multinomial probability distribution conjecture. So it is sometimes the case that

$$
\frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A * T_{\mathrm{s}} * T_{\mathrm{s}}^{\dagger A}\right)}{\sum_{B \in \mathcal{A}_{U, i, v, T,}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B) \quad<\frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger A}\right)}{\sum_{B \in \mathcal{A}_{U, i, v, T,}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B),
$$

In the case where (i) the independent is integral, $A^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}}$, and (ii) the formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, then the independent is an integral iso-transform-independent, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$,

$$
\left(\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}=A^{\mathrm{x}} * T\right) \wedge\left(A^{\mathrm{X}} * T=(A * T)^{\mathrm{x}}\right) \Longrightarrow A^{\mathrm{x}} \in Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{x}}\right)\right)
$$

and the lifted integral iso-transform-independents contains the abstract histogram

$$
(A * T)^{\mathrm{X}}=A^{\mathrm{X}} * T \in\left\{B * T: B \in Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right\}
$$

That is, $(A * T)^{\mathrm{X}} \in \mathcal{A}_{U, i, \mathrm{i}, T, z}^{\prime}(A)$.
The lifted integral iso-abstracts is a superset of the lifted integral iso-transformindependents

$$
\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A) \subseteq\left\{B * T: B \in Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right\}
$$

So the lifted integral iso-transform-independents is a subset of the derived integral iso-independents

$$
\mathcal{A}_{U, i, y, T, z}^{\prime}(A) \subseteq Y_{U, i, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)
$$

Thus the independent derived, $(A * T)^{\mathrm{x}}$, is the independent for all of the lifted integral iso-transform-independents, $\forall B^{\prime} \in \mathcal{A}_{U, i, \mathrm{i}, T, z}^{\prime}(A)\left(B^{\prime \mathrm{X}}=(A * T)^{\mathrm{X}}\right)$.

The abstract histogram, $(A * T)^{\mathrm{x}}$, is integral because the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, and the formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$,

$$
\left(A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right) \wedge\left(A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right) \Longrightarrow(A * T)^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}
$$

If, additionally, (iii) the distribution histogram is independent, $E=E^{\mathrm{X}}$, and (iv) formal distribution histogram is independent, $E^{\mathrm{X}} * T=\left(E^{\mathrm{X}} * T\right)^{\mathrm{x}}$, the independent distribution histogram, $E^{\mathrm{X}}$, is lifted to an independent derived distribution histogram, $E^{\mathrm{X}} * T=(E * T)^{\mathrm{x}}$. That is, the formal distribution histogram equals the abstract distribution histogram.

Lastly, if (v) the distribution histogram is sufficiently effective, $E^{\mathrm{XF}} \geq A^{\mathrm{XF}}$, then the negative logarithm lifted independently-distributed iso-transformindependent quasi-conditional dependent multinomial probability can be rearranged in terms of derived multinomial coefficients and thence in terms of the derived alignment,

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}} * T, z\right)(A * T)}{\sum_{B^{\prime} \in \mathcal{A}^{\prime} U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}} * T, z\right)\left(B^{\prime}\right) \quad:\right. \\
& \left.E^{\mathrm{X}} * T=\left(E^{\mathrm{X}} * T\right)^{\mathrm{x}}, E^{\mathrm{XF}} \geq A^{\mathrm{XF}}, A^{\mathrm{x}} \in \mathcal{A}_{\mathfrak{i}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{x}}\right) \\
& =\sum_{R \in(A * T)^{\mathrm{S}}} \ln (A * T)_{R}!+\ln \sum_{B^{\prime} \in \mathcal{A}^{\prime} U, \mathrm{i}, \mathrm{y}, T, z, z} \frac{1}{\prod_{R \in B^{\prime \mathrm{S}}} B_{R}^{\prime}!} \\
& =\operatorname{algn}(A * T)+\ln \sum_{B^{\prime} \in \mathcal{A}^{\prime} U, \mathrm{i}, \mathrm{y}, T, z}(A) \quad \frac{\prod_{R \in(A * T)^{\mathrm{xS}}}(A * T)_{R}^{\mathrm{X}}!}{\prod_{R \in B^{\prime s}} B_{R}^{\prime}!}
\end{aligned}
$$

Now because $\forall B^{\prime} \in \mathcal{A}_{U, i, \mathrm{y}, T, z}^{\prime}(A)\left(B^{\prime \mathrm{X}}=(A * T)^{\mathrm{X}}\right)$ and given the minimum alignment conjecture,

$$
\forall B^{\prime} \in \mathcal{A}_{U, i, \mathrm{y}, T, \mathrm{z}}^{\prime}(A) \quad\left(\frac{\prod_{S \in(A * T)^{\mathrm{xs}}}(A * T)_{S}^{\mathrm{x}}!}{\prod_{S \in B^{\prime S}} B_{S}^{\prime}!} \leq 1\right)
$$

and because $(A * T)^{\mathrm{X}} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)$,

$$
1 \leq \sum_{B^{\prime} \in \mathcal{A}^{\prime} U, i, \mathrm{y}, T, z}(A), ~ \frac{\prod_{R \in(A * T)^{\mathrm{xS}}}(A * T)_{R}^{\mathrm{X}}!}{\prod_{R \in B^{\prime} \mathrm{S}} B_{R}^{\prime}!} \leq\left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right|
$$

then

$$
\begin{aligned}
& \leq \sum_{R_{R \in(A * T)^{\mathrm{S}}} \ln (A * T)_{R}!+\ln \sum_{B^{\prime} \in \mathcal{A}^{\prime}} \sum_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \frac{1}{\prod_{R \in B^{\prime} \mathrm{S}} B_{R}^{\prime}!} \\
& \leq \operatorname{algn}(A * T)+\ln \left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right|
\end{aligned}
$$

In other words in this case, where (i) $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, (ii) $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, (iii) $E=E^{\mathrm{X}}$, (iv) $E^{\mathrm{X}} * T=\left(E^{\mathrm{X}} * T\right)^{\mathrm{X}}$, and (v) $E^{\mathrm{XF}} \geq A^{\mathrm{XF}}$, the negative logarithm lifted independently-distributed iso-transform-independent quasi-conditional
dependent multinomial probability is such that

$$
\begin{aligned}
& \operatorname{algn}(A * T) \\
& \leq\left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}} * T, z\right)(A * T)}{\sum_{B^{\prime} \in \mathcal{A}^{\prime}, \mathrm{i}, \mathrm{y}, T, z, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}} * T, z\right)\left(B^{\prime}\right) \quad:\right. \\
& \left.E^{\mathrm{X}} * T=\left(E^{\mathrm{X}} * T\right)^{\mathrm{X}}, E^{\mathrm{XF}} \geq A^{\mathrm{XF}}, A^{\mathrm{X}} \in \mathcal{A}_{\mathfrak{i}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right) \\
& \leq \operatorname{algn}(A * T)+\ln \left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right|
\end{aligned}
$$

That is, given these conditions, the derived alignment, $\operatorname{algn}(A * T)$, is a bounded underestimate of the negative logarithm lifted independently-distributed iso-transform-independent quasi-conditional dependent multinomial probability.

The cardinality of the lifted integral iso-transform-independents must be less than or equal to the cardinality of the derived integral congruent support,

$$
\left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right| \leq\left|\mathcal{A}_{U, \mathrm{i}, W, z}\right|=\frac{(z+w-1)!}{z!(w-1)!}
$$

where $w=\left|W^{\mathrm{C}}\right|$. Thus $\ln \left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right|<\bar{w} \ln z$ if $z>w$. So

$$
\sum_{R \in(A * T)^{\mathrm{S}}} \ln (A * T)_{R}!+\ln \sum_{B^{\prime} \in \mathcal{A}^{\prime} U, \mathrm{i}, \mathrm{y}, T, z}(A) \mathrm{M} \frac{1}{\prod_{R \in B^{\prime \mathrm{S}}} B_{R}^{\prime}!}<\operatorname{algn}(A * T)+\bar{w} \ln z
$$

Compare this to derived maximum alignment, alignmentMaximum $(U)(W, z)$, which for large size, $z \gg w$, approximates to $z(n-1) \ln d$ for a regular histogram of dimension $n=|W|$ and valency $\{d\}=\left\{\left|U_{u}\right|: u \in V\right\}$. Therefore, in some cases the difference between the derived alignment and the negative logarithm lifted independently-distributed iso-transform-independent quasi-conditional dependent multinomial probability is less than the derived alignment, $\ln \left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right|<\bar{w} \ln z<\operatorname{alignment}(A * T)$. That is, in some cases

$$
\begin{aligned}
& \leq \sum_{R_{R \in(A * T)^{\mathrm{S}}} \operatorname{lngn}(A * T)}^{\operatorname{alg}(A * T)_{R}!+\ln \sum_{B^{\prime} \in \mathcal{A}^{\prime} U, \mathrm{i}, \mathrm{y}, T, z}(A)}{ }^{\leq} \frac{1}{\prod_{R \in B^{\prime \mathrm{S}}} B_{R}^{\prime}!}
\end{aligned}
$$

In the case of the conditions given above, the negative logarithm lifted independently-distributed iso-transform-independent quasi-conditional dependent multinomial probability,

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{x}} * T, z\right)(A * T)}{\sum_{B^{\prime} \in \mathcal{A}^{\prime} U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}} * T, z\right)\left(B^{\prime}\right) \quad:\right. \\
& \left.E^{\mathrm{X}} * T=\left(E^{\mathrm{X}} * T\right)^{\mathrm{X}}, E^{\mathrm{XF}} \geq A^{\mathrm{XF}}, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right) \\
& =\left(\operatorname{algn}(A * T)+\ln \sum_{B^{\prime} \in \mathcal{A}^{\prime} U \mathrm{i}, \mathrm{y}, T, z, z} \frac{\prod_{R \in(A * T)^{\mathrm{xS}}}(A * T)_{R}^{\mathrm{x}}!}{\prod_{R \in B^{\prime \mathrm{S}}} B_{R}^{\prime}!}\right) \in \ln \mathbf{Q}_{>0}
\end{aligned}
$$

may be abbreviated to the alignment-bounded lifted iso-transform space.
The corresponding negative logarithm independently-distributed iso-transformindependent conditional dependent multinomial probability,

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}:\right. \\
& \left.E^{\mathrm{X}} * T=\left(E^{\mathrm{X}} * T\right)^{\mathrm{x}}, E^{\mathrm{XF}} \geq A^{\mathrm{XF}}, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right) \in \ln \mathbf{Q}_{>0}
\end{aligned}
$$

may be abbreviated to the alignment-bounded iso-transform space. Strictly speaking, it is only the lifted space that is bounded by the alignment. However, the formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, and so the lifted iso-transform-independent relation is functional,

$$
\begin{aligned}
& \left\{\left(A * T,\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A^{\mathrm{x}} * T=(A * T)^{\mathrm{x}}\right\} \\
\in & \mathcal{A}_{U, \mathrm{i}, W, z} \rightarrow\left(\mathcal{A}_{U, W, z} \times \mathcal{A}_{U, W, z}\right)
\end{aligned}
$$

which implies that each derived histogram maps to exactly one set of iso-transform-independents,

$$
\begin{aligned}
& \left.\left\{\left(A * T, Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right)\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right\} \\
\in & \mathcal{A}_{U, \mathrm{i}, W, z} \rightarrow \mathrm{P}\left(\mathcal{A}_{U, \mathrm{i}, V, z}\right)
\end{aligned}
$$

Thus the alignment-bounded lifted iso-transform space is correlated with the alignment-bounded iso-transform space.

The difference between the alignment-bounded lifted iso-transform space and the derived alignment is the alignment-bounded lifted iso-transform error

$$
\ln \sum_{B^{\prime} \in \mathcal{A}^{\prime} U, \mathrm{i}, \mathrm{y}, T, z}(A), ~ \frac{\prod_{R \in(A * T)^{\mathrm{xS}}}(A * T)_{R}^{\mathrm{X}}!}{\prod_{R \in B^{\prime S}} B_{R}^{\prime}!}
$$

The negative logarithm independently-derived-distributed relative dependent derived multinomial probability of the sample, where the abstract histogram is integral, $(A * T)^{\mathrm{x}} \in \mathcal{A}_{\mathbf{i}}$, which is the derived alignment,

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left((E * T)^{\mathrm{x}}, z\right)(A * T)}{\hat{Q}_{\mathrm{m}, U}\left((E * T)^{\mathrm{X}}, z\right)\left((A * T)^{\mathrm{X}}\right)}:(A * T)^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right) \\
= & \sum_{R \in(A * T)^{\mathrm{s}}} \ln (A * T)_{R}!-\sum_{R \in(A * T)^{\mathrm{xs}}} \ln (A * T)_{R}^{\mathrm{x}}! \\
= & \operatorname{algn}(A * T)
\end{aligned}
$$

does not depend on the derived distribution histogram. Nor does the negative logarithm independently-derived-distributed iso-independent conditional dependent derived multinomial probability, where the abstract histogram is integral, $(A * T)^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, which is the derived-alignment-bounded iso-independent space,

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left((E * T)^{\mathrm{X}}, z\right)(A * T)}{\sum_{B^{\prime} \in Y_{U, i, W, z}^{-1}\left((A * T)^{\mathrm{x}}\right)} \hat{Q}_{\mathrm{m}, U}\left((E * T)^{\mathrm{X}}, z\right)\left(B^{\prime}\right)}:\right. \\
= & \left.(E * T)^{\mathrm{XF}} \geq(A * T)^{\mathrm{XF}},(A * T)^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}}\right) \\
= & \sum_{R \in(A * T)^{\mathrm{S}}} \ln (A * T)_{R}!+\ln \sum_{B^{\prime} \in Y_{U, i, W, z}^{-1}\left((A * T)^{\mathrm{x}}\right)} \frac{1}{\prod_{R \in B^{\prime \mathrm{S}}} B_{R}^{\prime}!} \\
& \operatorname{algn}(A * T)+\ln \sum_{B^{\prime} \in Y_{U U, W, z}^{-1}\left((A * T)^{\mathrm{x}}\right)} \frac{\prod_{R \in(A * T)^{\mathrm{xS}}}(A * T)_{R}^{\mathrm{X}}!}{\prod_{R \in B^{\prime \mathrm{S}}} B_{R}^{\prime}!}
\end{aligned}
$$

In the case of the conditions above, the negative logarithm lifted independentlydistributed iso-transform-independent quasi-conditional dependent multino-
mial probability, which is the alignment-bounded lifted iso-transform space,

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}} * T, z\right)(A * T)}{\sum_{B^{\prime} \in \mathcal{A}^{\prime} U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}} * T, z\right)\left(B^{\prime}\right) \quad:\right. \\
& \left.E^{\mathrm{x}} * T=\left(E^{\mathrm{X}} * T\right)^{\mathrm{X}}, E^{\mathrm{XF}} \geq A^{\mathrm{XF}}, A^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{x}} * T=(A * T)^{\mathrm{x}}\right) \\
& =\sum_{R \in(A * T)^{\mathrm{S}}} \ln (A * T)_{R}!+\ln \sum_{B^{\prime} \in \mathcal{A}^{\prime} U, \mathrm{i}, \mathrm{y}, T, z}(A) \mathrm{M} \frac{1}{\prod_{R \in B^{\prime \mathrm{S}}} B_{R}^{\prime}!} \\
& =\operatorname{algn}(A * T)+\ln \sum_{B^{\prime} \in \mathcal{A}^{\prime} U, \mathrm{i}, \mathrm{y}, T, z} \frac{\prod_{R \in(A * T)^{\mathrm{xS}}}(A * T)_{R}^{\mathrm{X}}!}{\prod_{R \in B^{\prime S}} B_{R}^{\prime}!}
\end{aligned}
$$

does not depend on the distribution histogram.

In the case where the distribution histogram is independent, $E=E^{\mathrm{X}}$, the alignment-bounded lifted iso-transform space is less than or equal to the derived-alignment-bounded iso-independent space

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}} * T, z\right)(A * T)}{\sum_{B^{\prime} \in \mathcal{A}_{U}^{\prime} U, \mathrm{i},, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}} * T, z\right)\left(B^{\prime}\right) \quad:\right. \\
& \left.E^{\mathrm{X}} * T=\left(E^{\mathrm{X}} * T\right)^{\mathrm{X}}, E^{\mathrm{XF}} \geq A^{\mathrm{XF}}, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{x}}\right) \\
& \leq\left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(\left(E^{\mathrm{X}} * T\right)^{\mathrm{X}}, z\right)(A * T)}{\sum_{B^{\prime} \in Y_{U, i, W, z}^{-1}\left((A * T)^{\mathrm{x}}\right)} \hat{Q}_{\mathrm{m}, U}\left(\left(E^{\mathrm{X}} * T\right)^{\mathrm{x}}, z\right)\left(B^{\prime}\right)}:\right. \\
& \left.\left(E^{\mathrm{X}} * T\right)^{\mathrm{XF}} \geq(A * T)^{\mathrm{XF}},(A * T)^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right)
\end{aligned}
$$

because $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A) \subseteq Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$. Thus the alignment-bounded lifted iso-transform error is less than or equal to the derived-alignment-bounded iso-independent error where $E=E^{\mathrm{X}}$,
$\ln \sum_{B^{\prime} \in \mathcal{A}^{\prime} U, \mathrm{i}, \mathrm{y}, T, z} \frac{\prod_{R \in(A * T)^{\mathrm{xs}}}(A * T)_{R}^{\mathrm{X}}!}{\prod_{R \in B^{\prime \mathrm{S}}} B_{R}^{\prime}!} \leq \ln \sum_{B^{\prime} \in Y_{U, i, W, z}^{-1}\left((A * T)^{\mathrm{x}}\right)} \frac{\prod_{R \in(A * T)^{\mathrm{xS}}}(A * T)_{R}^{\mathrm{X}}!}{\prod_{R \in B^{\prime \mathrm{S}}} B_{R}^{\prime}!}$
The numerator in the alignment-bounded lifted iso-transform error expression is derived from the independent term of the derived alignment,
$\sum_{R \in(A * T)^{\mathrm{xs}}} \ln (A * T)_{R}^{\mathrm{X}}$ !, which varies against the entropy of the abstract histogram, entropy $\left((A * T)^{\mathrm{X}}\right)$. In the case of uniform abstract histogram of size $z$ and derived volume $w$ where $z / w \in \mathbf{N}_{>0}$, the independent term is $w \ln (z / w)!\approx z \ln (z / w)$. So the alignment-bounded lifted iso-transform error with respect to the numerator varies with the size, $z$, and varies against the logarithm of the derived volume, $\ln w$. The abstract histogram, $(A * T)^{\mathrm{X}}$, tends to be more uniform at higher derived alignments.

The alignment-bounded lifted iso-transform error also varies with the cardinality of the lifted integral iso-transform-independents, $\left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right|$, which in turn varies with the cardinality of the integral derived iso-independents, $\left|Y_{U, i, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|$. As shown above, the average cardinality of the integral derived iso-independents is

$$
\frac{\left|\mathcal{A}_{U, \mathbf{i}, W, z}\right|}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, W, z}\right)\right|}=\frac{(z+w-1)!}{z!(w-1)!} / \prod_{u \in W} \frac{\left(z+\left|U_{u}\right|-1\right)!}{z!\left(\left|U_{u}\right|-1\right)!}
$$

The average cardinality of the integral derived iso-independents varies with both size, $z$, and derived volume, $w$.

In the case where the size is greater than the derived volume, $z>w$, the logarithm of the average cardinality is less than $\bar{w} \ln z$. In this case the negative contribution to the variation between the error and the derived volume from the numerator, $\ln w$, is outweighed by the positive contribution from the summation, $\bar{w}$. Hence, in the case where $z>w$, the error varies with both size, $z$, and derived volume, $w$.

For a given derived volume, $w$, the average cardinality of the integral derived iso-independents, $\left|Y_{U, i, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|$, varies with the entropy of the valencies, $\operatorname{entropy}\left(\left\{\left(u,\left|U_{u}\right|\right): u \in W\right\}\right)$. Hence the error also varies with derived valency entropy. The error tends to increase with derived dimension, $n=|W|$. Regular derived histograms tend to have higher error than irregular.

It is conjectured above that the cardinality of the set of integral derived iso-independents, $\left|Y_{U, i, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|$, corresponding to $(A * T)^{\mathrm{X}}$ varies with the entropy of the abstract histogram, $(A * T)^{\mathrm{X}}$. The cardinality of the subset lifted integral iso-transform-independents, $\left|\mathcal{A}^{\prime}{ }_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right|$, also varies with the entropy of the abstract histogram. Therefore the alignment-bounded lifted iso-transform error varies with the entropy of the abstract histogram. The formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, so the entropy of the abstract histogram equals the entropy of the formal indepen-
dent histogram, entropy $\left((A * T)^{\mathrm{X}}\right)=\operatorname{entropy}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right)$. The entropy of the abstract histogram equals the sum of the entropies of the reductions $\operatorname{entropy}\left((A * T)^{\mathrm{X}}\right)=\sum_{w \in W} \operatorname{entropy}(A * T \%\{w\})=\sum_{w \in W} \operatorname{entropy}\left(A^{\mathrm{X}} * T \%\{w\}\right)$

That is, the more uniform the perimeters, the larger the cardinality of the set of integral derived iso-independents, and the higher the error with respect to the cardinality.

The ratio of the alignment-bounded lifted iso-transform error to the derived alignment is

$$
\left(\ln \sum_{B^{\prime} \in \mathcal{A}^{\prime} U, \mathrm{i}, \mathrm{y}, T, z}(A), ~ \frac{\prod_{R \in(A * T)^{\mathrm{xS}}}(A * T)_{R}^{\mathrm{x}}!}{\prod_{R \in B^{\prime S}} B_{R}^{\prime}!}\right) / \operatorname{algn}(A * T)
$$

where the derived histogram is not independent, $A * T \neq(A * T)^{\mathrm{x}} \Longrightarrow$ $\operatorname{algn}(A * T)>0$.

As mentioned above, as the derived alignment increases to maximum derived alignment, alignmentMaximum $(U)(W, z) \approx z \ln w$ where $z \gg w$, the ratio decreases, $\bar{w} \ln z / z \ln w$.

On the other hand, as noted above, the derived alignment approximates to the difference in entropy between the abstract histogram and the derived histogram, $\operatorname{algn}(A * T) \approx z \times \operatorname{entropy}\left((A * T)^{\mathrm{X}}\right)-z \times \operatorname{entropy}(A * T)$. Hence increases in derived alignment imply increases in the entropy of the abstract histogram to some degree. So there is a tendency to increase the ratio of the alignment-bounded lifted iso-transform error to the alignment at higher derived alignments due to the abstract histogram entropy which partly counteracts the tendency to decrease the ratio at higher derived alignments due to the size.

In the case where the derived alignment is approximately equal to the expected derived alignment, it is conjectured above ('Minimum alignment') that the expected alignment varies as the volume, $w$, for constant size, $z$, greater than the volume, $z>w$. So in the case of expected derived alignment the alignment-bounded lifted iso-transform error tends to be greater than the derived alignment and the ratio is greater than one, $(\bar{w} \ln z) / w>1$.

If the transform is a self partition transform, for example $T_{\mathrm{s}}=V^{\mathrm{CS}\{ \} \mathrm{T}} \in$ $\mathcal{T}_{U, \mathrm{f}, 1}$, or it is value full functional, for example $T_{\mathrm{s}}=\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in\right.$
$V\}^{\mathrm{T}} \in \mathcal{T}_{U, \mathrm{f}, 1}$, then the set of lifted integral iso-transform-independents equals the set of lifted integral iso-independents, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{s}}, z}^{\prime}(A)=\left\{B * T_{\mathrm{s}}: B \in\right.$ $\left.Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right\}$, and the set of integral iso-transform-independents equals the set of integral iso-independents, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{s}}, z}(A)=Y_{U \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$. So the alignmentbounded iso-transform-independent space equals the alignment-bounded lifted iso-transform space, which in turn equals the alignment-bounded iso-independent space

$$
\begin{aligned}
& -\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, i, \mathrm{i}, T_{\mathrm{s}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)} \\
= & -\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}} * T_{\mathrm{s}}, z\right)\left(A * T_{\mathrm{s}}\right)}{\sum_{B^{\prime} \in \mathcal{A}^{\prime}, \mathrm{i}, \mathrm{y}, T_{\mathrm{s}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}} * T_{\mathrm{s}}, z\right)\left(B^{\prime}\right) \\
= & -\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}
\end{aligned}
$$

Therefore, in this case, $T_{\mathrm{s}}$, the alignment-bounded iso-transform space is bounded by the derived alignment,

$$
\begin{aligned}
& \operatorname{algn}\left(A * T_{\mathrm{s}}\right) \\
= & \operatorname{algn}(A) \\
\leq & \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{x}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{s}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{x}}, z\right)(B)}: E^{\mathrm{XF}} \geq A^{\mathrm{XF}}, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right) \\
\leq & \operatorname{algn}(A)+\ln \mid Y_{U, 1}^{-1}, V, z \\
= & \operatorname{algn}\left(A * T_{\mathrm{s}}\right)+\ln \left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{s}}, z}^{\mathrm{x}}(A)\right|
\end{aligned}
$$

If the transform is a unary partition, for example $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, \mathrm{f}, 1}$, then the set of integral iso-transform-independents equals the singleton lifted integral congruent support, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}^{\prime}(A)=\left\{B * T_{\mathrm{u}}: B \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}=\{A *$ $\left.T_{\mathrm{u}}\right\}$. The lifted generalised multinomial probability is equal to one, $\hat{Q}_{\mathrm{m}, U}(E *$ $\left.T_{\mathrm{u}}, z\right)\left(A * T_{\mathrm{u}}\right)=1$. So the alignment-bounded lifted iso-transform space is equal to zero,

$$
-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}} * T_{\mathrm{u}}, z\right)\left(A * T_{\mathrm{u}}\right)}{\sum_{B^{\prime} \in \mathcal{A}^{\prime} U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}} * T_{\mathrm{u}}, z\right)\left(B^{\prime}\right) \quad=0
$$

The lower bound is zero

$$
\operatorname{algn}\left(A * T_{\mathrm{u}}\right)=0
$$

because $A * T_{\mathrm{u}}=\left(A * T_{\mathrm{u}}\right)^{\mathrm{X}}$. The upper bound is also zero

$$
\operatorname{algn}\left(A * T_{\mathrm{u}}\right)+\ln \left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}^{\prime}(A)\right|=\operatorname{algn}\left(A * T_{\mathrm{u}}\right)+\ln \left|\left\{A * T_{\mathrm{u}}\right\}\right|=0
$$

The set of integral iso-transform-independents equals the integral congruent support, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{u}, z}(A)=\mathcal{A}_{U, \mathrm{i}, V, z}$, so the alignment-bounded iso-transform space equals the generalised multinomial space, which is greater than zero

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{Y}, \mathrm{~T}_{\mathrm{u}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}: E^{\mathrm{XF}} \geq A^{\mathrm{XF}}\right) \\
= & -\ln \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A) \\
> & 0
\end{aligned}
$$

where the distribution histogram is pluri-valent, $\left|E^{\mathrm{XF}}\right|>1$. In fact, it is greater than or equal to the self partition case

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}: E^{\mathrm{XF}} \geq A^{\mathrm{XF}}\right) \\
\geq & \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{s}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}: E^{\mathrm{XF}} \geq A^{\mathrm{XF}}, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right)
\end{aligned}
$$

Therefore, in this case, $T_{\mathrm{u}}$, the alignment-bounded iso-transform space is not bounded by the derived alignment.

In other words, although the alignment-bounded iso-transform space is functionally related to the alignment-bounded lifted iso-transform space, it is not always the case that the alignment-bounded iso-transform space is bounded by the derived alignment, $\operatorname{algn}(A * T)$, and so the prefix 'alignment-bounded' of alignment-bounded iso-transform space is sometimes a misnomer with respect to derived alignment at least.

Let integral congruent delta $(D, I) \in \mathcal{A}_{\mathrm{i}} \times \mathcal{A}_{\mathrm{i}}$ be such that its perturbation, $A-D+I$, is iso-transform-independence conserving, $A-D+I \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)$. So the delta, $(D, I)$, is iso-abstract, $A-D+I \in Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$. The change in alignment-bounded lifted iso-transform space due to the application of the iso-transform-independence conserving delta, $(D, I)$, is equal to the change
in derived alignment
because $((A-D+I) * T)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$ and therefore the alignment-bounded lifted iso-transform error is the same for both the histogram, $A$, and its iso-transform-independent perturbation, $A-D+I$.

A special case of an iso-transform-independence conserving perturbation is the integral idealisation, $A * T * T^{\dagger A} \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, where the change in alignment-bounded lifted iso-transform space because of the integral idealisation of the sample histogram is zero,

$$
=0
$$

because $A * T * T^{\dagger A} * T=A * T$. That is, the alignment-bounded lifted iso-transform space is the same for a sample histogram, $A$, and its integral idealisation, $A * T * T^{\dagger A}$.

Consider the case where (i) the independent distribution histogram equals the independent, $E^{\mathrm{X}}=A^{\mathrm{X}}$, and (ii) idealisation is integral, $A * T * T^{\dagger A} \in \mathcal{A}_{\mathrm{i}}$. The integral idealisation is in the integral iso-idealisations which is a subset

$$
\begin{aligned}
& \left(\operatorname{algn}\left(\left(A * T * T^{\dagger A}\right) * T\right)+\right.
\end{aligned}
$$

$$
\begin{aligned}
& \left(\operatorname{algn}(A * T)+\ln \sum_{B^{\prime} \in \mathcal{A}^{\prime}}^{U, \mathrm{i}, \mathrm{y}, T, z}(A) \quad \frac{\prod_{R \in(A * T)^{\mathrm{xS}}}(A * T)_{R}^{\mathrm{X}}!}{\prod_{R \in B^{\prime \mathrm{S}}} B_{R}^{\prime}!}\right) \\
& =\operatorname{algn}\left(A * T * T^{\dagger A} * T\right)-\operatorname{algn}(A * T)
\end{aligned}
$$

$$
\begin{aligned}
& (\operatorname{algn}((A-D+I) * T)+ \\
& \left.\ln \sum_{B^{\prime} \in \mathcal{A}^{\prime}} \sum_{U, \mathrm{i}, \mathrm{y}, T, z}(A-D+I) \quad \frac{\prod_{R \in((A-D+I) * T)^{\mathrm{xS}}}((A-D+I) * T)_{R}^{\mathrm{X}!}}{\prod_{R \in B^{\prime \mathrm{S}}} B_{R}^{\prime}!}\right)- \\
& \left(\operatorname{algn}(A * T)+\ln \sum_{B^{\prime} \in \mathcal{A}^{\prime}(\mathrm{i}, \mathrm{y}, T, z}(A) \quad \frac{\prod_{R \in(A * T)^{\mathrm{xS}}}(A * T)_{R}^{\mathrm{X}!}}{\prod_{R \in B^{\prime}} B_{R}^{\prime}!}\right) \\
& =\operatorname{algn}((A-D+I) * T)-\operatorname{algn}(A * T)
\end{aligned}
$$

of the integral iso-transform-independents,

$$
A * T * T^{\dagger A} \in Y_{U, i, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right) \subseteq Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)
$$

where the integral iso-idealisations is defined $Y_{U, \mathrm{i}, T, \uparrow, z}=\left\{\left(A, A * T * T^{\dagger A}\right)\right.$ : $\left.A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}$. The integral iso-idealisations is also the subset of the subset of the integral iso-transform-independents that have given alignment-bounded lifted iso-transform space, $(A-D+I) * T=A * T$, which is the intersection between the integral iso-transform-independents and the integral iso-deriveds, or the integral iso-liftisations,

$$
\begin{aligned}
Y_{U, i, T, \uparrow, z}^{-1}(A * T & \left.* T^{\dagger A}\right) \\
& \subseteq Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{x}}\right)\right) \cap D_{U, \mathbf{i}, T, z}^{-1}(A * T) \\
& =Y_{U, i, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{x}} * T\right) \cap D_{U \mathrm{i}, T, z}^{-1}(A * T)
\end{aligned}
$$

The idealisation perturbation conjecture states that of all the integral isoidealisations, $A-D+I \in Y_{U, i, T, t, z}^{-1}\left(A * T * T^{\dagger A}\right)$, that have given alignmentbounded lifted iso-transform space, $(A-D+I) * T=A * T$, the integral sample idealisation, $A * T * T^{\dagger A}$, has the greatest multinomial probability

$$
\begin{array}{r}
A * T * T^{\dagger A} \in \operatorname{maxd}\left(\left\{\left(A-D+I, \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A-D+I)\right):\right.\right. \\
\left.\left.A-D+I \in Y_{U, \mathrm{i}, T, \uparrow,, z}^{-1}\left(A * T * T^{\dagger A}\right)\right\}\right)
\end{array}
$$

and hence the least alignment-bounded iso-transform space

$$
\begin{gathered}
A * T * T^{\dagger A} \in \operatorname{mind}\left(\left\{\left(A-D+I,-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A-D+I)}{\sum_{B \in \mathcal{A}_{U \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(B)}\right):\right.\right. \\
\left.\left.A-D+I \in Y_{U, \mathrm{i}, T, \mathrm{t}, z}\left(A * T * T^{\dagger A}\right)\right\}\right)
\end{gathered}
$$

or

$$
\begin{aligned}
& \forall A-D+I \in Y_{U, i, T, \dagger, z}^{-1}\left(A * T * T^{\dagger A}\right) \\
& \qquad\left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A-D+I)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B)} \geq-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A * T * T^{\dagger A}\right)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(B)}\right)
\end{aligned}
$$

In other words, conjecture that the idealisation, $A * T * T^{\dagger A}$, is the most conservative choice of iso-idealisations of the sample histogram given the alignment-bounded lifted iso-transform space of the lifted sample. Depending on the degree to which the transform is formal, $A * T \approx A^{\mathrm{X}} * T$, the independent approximates to the neutralisation, $A^{\mathrm{X}}=A^{\mathrm{X}} * T * T^{\odot A^{\mathrm{X}}} \approx A * T * T^{\odot A^{\mathrm{X}}}$,
and thence to the idealisation, $A * T * T^{\odot} A^{\mathrm{x}} \approx A * T * T^{\dagger A}$. That is, the idealisation approximates most closely to the independent which is the mean of the distribution, $A * T * T^{\dagger A} \approx A^{\mathrm{X}}=\operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\right)$ and is therefore the most probable of the integral iso-idealisations.

The subset of the integral iso-transform-independents given $A * T$ is the intersection between the integral iso-transform-independents and the integral iso-deriveds, $Y_{U, \mathbf{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cap D_{U, \mathbf{i}, T, z}^{-1}(A * T)$, which is the integral iso-liftisations, $Y_{U, i, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap D_{U, \mathrm{i}, T, z}^{-1}(A * T)$. Note that the idealisation, $A * T * T^{\dagger A}$, does not necessarily have the least space of all of the iso-liftisations. The integral iso-liftisations with the least space is in

$$
\begin{aligned}
& \operatorname{mind}\left(\left\{\left(A-D+I, \quad-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A-D+I)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(B)}\right):\right.\right. \\
& \left.\left.A-D+I \in Y_{U, \mathrm{i}, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap D_{U \mathrm{i}, T, z}^{-1}(A * T)\right\}\right)
\end{aligned}
$$

For example, if the liftisation-independent is integral it is conjectured to be in the integral iso-liftisations, $A^{\mathrm{K}(T)} \in \mathcal{A}_{\mathrm{i}} \Longrightarrow A^{\mathrm{K}(T)} \in Y_{U, \mathrm{i}, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap$ $D_{U \mathrm{i}, T, z}^{-1}(A * T)$, but in some cases it is not computable.

Given the conditions (i) $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, (ii) $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, and (iii) $A * T * T^{\dagger A} \in$ $\mathcal{A}_{\mathrm{i}}$, let the negative logarithm independent-sample-distributed iso-transformindependent conditional dependent multinomial probability of the idealisation,

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A * T * T^{\dagger A}\right)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(B)}:\right. \\
& \left.A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}, A * T * T^{\dagger A} \in \mathcal{A}_{\mathrm{i}}\right) \in \ln \mathbf{Q}_{>0}
\end{aligned}
$$

be abbreviated to the alignment-bounded iso-transform idealisation space. The alignment-bounded iso-transform idealisation space is a special case of the alignment-bounded iso-transform space where $E^{\mathrm{X}}=A^{\mathrm{X}}$ and $A=A$ * $T * T^{\dagger A}$. The alignment-bounded iso-transform idealisation space and the alignment-bounded iso-transform space both lift to the same alignment-bounded lifted iso-transform space.

Formal equals abstract implies formal independent equals abstract, $A^{\mathrm{X}} * T=$ $(A * T)^{\mathrm{X}} \Longrightarrow\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$, so the independent is an iso-transformindependent, $A^{\mathrm{X}} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)$, and therefore the alignment-bounded isotransform idealisation space is bounded by the idealisation alignment, given
the integral mean multinomial probability distribution conjecture,

$$
\begin{aligned}
& \quad \operatorname{algn}\left(A * T * T^{\dagger A}\right) \\
& \leq\left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A * T * T^{\dagger A}\right)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B)}:\right. \\
& \left.\quad A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{x}} * T=(A * T)^{\mathrm{x}}, A * T * T^{\dagger A} \in \mathcal{A}_{\mathrm{i}}\right) \\
& \leq \\
& \quad \operatorname{algn}\left(A * T * T^{\dagger A}\right)+\ln \left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right|
\end{aligned}
$$

Note also that the set of integral iso-transform-independents given $A * T$, $Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cap D_{U, i, T, z}^{-1}(A * T)$, is partitioned by sets of integral iso-idealisations. This is because the equivalence classes corresponding to the intersection between the integral iso-transform-independents and the integral iso-deriveds is a parent partition of the equivalence classes of the integral isoidealisation function, parent $\left(\left\{\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{X}} * T=A^{\mathrm{X}} * T, B * T=\right.\right.\right.$ $\left.A * T\}: A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\},\left\{\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B * T * T^{\dagger B}=A * T * T^{\dagger A}\right\}:\right.$ $\left.\left.A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}\right)$. That is, $Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cap D_{U, \mathrm{i}, T, z}^{-1}(A * T) \in$ $\mathrm{P}\left(\operatorname{ran}\left(Y_{U, i, T, \uparrow, z}^{-1}\right)\right)$. However, only one of these sets of integral iso-transformindependents corresponds to the sample histogram, $Y_{U, i, T, \downarrow, z}^{-1}\left(A * T * T^{\dagger A}\right)$. This is the only set of integral iso-idealisations which is such that the independent of the idealisation equals the distribution histogram, $\left(A * T * T^{\dagger A}\right)^{\mathrm{X}}=A^{\mathrm{X}}$.

If the transform is a self partition transform, for example $T_{\mathrm{s}}=V^{\mathrm{CS}\{ \} \mathrm{T}} \in$ $\mathcal{T}_{U, f, 1}$, or it is value full functional, for example $T_{\mathrm{s}}=\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in V\right\}^{\mathrm{T}} \in$ $\mathcal{T}_{U, \mathrm{f}, 1}$, then the transform is ideal, $A * T_{\mathrm{s}} * T_{\mathrm{s}}^{\dagger A}=A$, and the alignment-bounded iso-transform idealisation space equals the alignment-bounded iso-transformindependent space. Therefore, in this case, $T_{\mathrm{s}}$, the alignment-bounded isotransform idealisation space is bounded by the derived alignment.

If the transform is a unary partition, for example $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U, \mathrm{f}, 1}$, then the idealisation equals the independent, $A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger A}=A^{\mathrm{X}}$. The alignmentbounded lifted iso-transform space is still equal to zero,

$$
-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}} * T_{\mathrm{u}}, z\right)\left(A^{\mathrm{X}} * T_{\mathrm{u}}\right)}{\sum_{B^{\prime} \in \mathcal{A}^{\prime}, \mathrm{i}, \mathrm{y}, \mathrm{y}, T_{\mathrm{u}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}} * T_{\mathrm{u}}, z\right)\left(B^{\prime}\right) \quad=0
$$

The lower bound is still zero

$$
\operatorname{algn}\left(A^{\mathrm{X}} * T_{\mathrm{u}}\right)=0
$$

because $A^{\mathrm{X}} * T_{\mathrm{u}}=\left(A^{\mathrm{X}} * T_{\mathrm{u}}\right)^{\mathrm{X}}$. The upper bound is also zero

$$
\operatorname{algn}\left(A^{\mathrm{X}} * T_{\mathrm{u}}\right)+\ln \left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}^{\prime}(A)\right|=0
$$

The alignment-bounded iso-transform idealised space is greater than zero

$$
\begin{aligned}
& -\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(B)} \\
= & -\ln \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right) \\
> & 0
\end{aligned}
$$

However, given the integral mean multinomial probability distribution conjecture, the alignment-bounded iso-transform idealised space is less than or equal to the alignment-bounded iso-transform space

$$
-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A^{\mathrm{X}}\right)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(B)} \leq-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B)}
$$

So the alignment-bounded iso-transform idealised space is less out of bounds than the alignment-bounded iso-transform space.

Given the complete integral congruent support sample histogram $A \in \mathcal{A}_{U, \mathrm{i}, V, z}$, consider the comparison of two transforms $T_{1}, T_{2} \in \mathcal{T}_{U, \mathrm{f}, 1}$, where $\operatorname{und}\left(T_{1}\right)=$ $\operatorname{und}\left(T_{2}\right)=V$. The sets of iso-transform-independents for each transform, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A)$ and $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)$, may or may not be equal,

$$
\begin{aligned}
& T_{1}=T_{2} \Longrightarrow \\
& \left.\quad Y_{U, \mathrm{i}, T_{1}, z}^{-1}\left(\left(A^{\mathrm{x}} * T_{1}\right),\left(A * T_{1}\right)^{\mathrm{x}}\right)\right)=Y_{U, \mathrm{i}, T_{2}, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T_{2}\right),\left(A * T_{2}\right)^{\mathrm{x}}\right)\right)
\end{aligned}
$$

Note that in the case that the derived variables are equal, $W_{1}=W_{2}$ where $W_{1}=\operatorname{der}\left(T_{1}\right)$ and $W_{2}=\operatorname{der}\left(T_{2}\right)$, but the transforms are not equal, $T_{1} \neq T_{2}$, it is not necessarily the case that the deriveds are not equal, $T_{1} \neq T_{2} \Longleftarrow$ $A * T_{1} \neq A * T_{2}$, the formals are not equal, $T_{1} \neq T_{2} \Longleftarrow A^{\mathrm{X}} * T_{1} \neq A^{\mathrm{X}} * T_{2}$, or the abstracts are not equal, $\left(A * T_{1}\right)^{\mathrm{X}} \neq\left(A * T_{2}\right)^{\mathrm{X}}$. Conversely, even if the formals are equal and the abstracts are equal, $\left(A^{\mathrm{X}} * T_{1}=A^{\mathrm{X}} * T_{2}\right) \wedge\left(\left(A * T_{1}\right)^{\mathrm{X}}=\right.$ $\left.\left(A * T_{2}\right)^{\mathrm{X}}\right)$, it is not necessarily the case that the iso-transform-independents are equal, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A)=\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)$.

In the case where the iso-transform-independents are not equal, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A) \neq$ $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)$, the difference in negative logarithm iso-transform-independent
conditional dependent multinomial probability is non-zero

$$
\begin{aligned}
&\left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B_{2} \in \mathcal{A}_{U, i, \mathrm{i}, T_{2}, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)\left(B_{2}\right)}\right)- \\
&\left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B_{1} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)\left(B_{1}\right)}\right) \\
& \neq 0
\end{aligned}
$$

unless it so happens that denominators are equal

$$
\sum_{B_{1} \in \mathcal{A}_{U, i, \mathrm{i},, T_{1}, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)\left(B_{1}\right)=\sum_{B_{2} \in \mathcal{A}_{U, i, \mathrm{i},, T_{2}, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)\left(B_{2}\right)
$$

In the case that the denominators are not equal, conjecture that in general the larger the intersection, $\left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A) \cap \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)\right|$, the less the difference in the iso-transform-independent conditional dependent multinomial probability because the denominators are more nearly equal. For example, consider the case where the derived variables are equal, $W_{1}=W_{2}$. Even if the transforms are not equal, $T_{1} \neq T_{2}$, the formals may sometimes be equal, $A^{\mathrm{X}} * T_{1}=A^{\mathrm{X}} *$ $T_{2}$. If that is the case, then the intersection of the iso-formals, $\mid Y_{U, 1, T_{1}, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} *\right.$ $\left.T_{1}\right) \cap Y_{U, i, T_{2}, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T_{2}\right) \mid$, tends to be larger because it is more often the case that iso-formal histograms $B_{1} \in Y_{U, \mathrm{i}, T_{1}, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T_{1}\right)$ and $B_{2} \in Y_{U, \mathrm{i}, T_{2}, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} *\right.$ $T_{2}$ ) are equal, $B_{1}=B_{2}$, because $B_{1}^{\mathrm{X}} * T_{1}=A^{\mathrm{X}} * T_{1}=A^{\mathrm{X}} * T_{2}=B_{2}^{\mathrm{X}} * T_{2}$. Similarly, the abstracts may sometimes be equal, $\left(A * T_{1}\right)^{\mathrm{X}}=\left(A * T_{2}\right)^{\mathrm{X}}$. If that is the case, then the intersection of the iso-abstracts, $\mid Y_{U, i, T, T, \mathrm{~W}, z}^{-1}\left(\left(A * T_{1}\right)^{\mathrm{X}}\right) \cap$ $Y_{U, i, T_{2}, \mathrm{~W}, z}^{-1}\left(\left(A * T_{2}\right)^{\mathrm{X}}\right) \mid$, tends to be larger because it is more often the case that iso-abstract histograms $B_{1} \in Y_{U,, 1, T, \mathrm{~W}, z}^{-1}\left(\left(A * T_{1}\right)^{\mathrm{X}}\right)$ and $B_{2} \in Y_{U, \mathrm{i}, T_{2}, \mathrm{~W}, z}^{-1}((A *$ $\left.T_{2}\right)^{\mathrm{X}}$ ) are equal, $B_{1}=B_{2}$, because $\left(B_{1} * T_{1}\right)^{\mathrm{X}}=\left(A * T_{1}\right)^{\mathrm{X}}=\left(A * T_{2}\right)^{\mathrm{X}}=$ $\left(B_{2} * T_{2}\right)^{\mathrm{X}}$. If either the iso-formals intersect or the iso-abstracts intersect, then it is sometimes the case that the iso-transform-independents intersect, because the iso-transform-independents is the intersection between the isoformals and iso-abstracts, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)=Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)=$ $Y_{U, i, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$.

Now consider the case where (i) the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, (ii) the idealisations are integral, $A * T_{1} * T_{1}^{\dagger A}, A * T_{2} * T_{2}^{\dagger A} \in \mathcal{A}_{\mathrm{i}}$, and so are in the same set of integral iso-independents, $A * T_{1} * T_{1}^{\dagger A}, A * T_{2} * T_{2}^{\dagger A} \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$. The difference in negative logarithm iso-transform-independent conditional
dependent multinomial idealisation probability is

$$
\left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}(E, z)\left(A * T_{2} * T_{2}^{\dagger A}\right)}{\sum_{B_{2} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)\left(B_{2}\right)}\right)-\left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}(E, z)\left(A * T_{1} * T_{1}^{\dagger A}\right)}{\sum_{B_{1} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A)} \hat{Q}_{\mathrm{m}, U}(E, z)\left(B_{1}\right)}\right)
$$

which is not necessarily zero even if the iso-transform-independents are equal, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A)=\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)$, unless it so happens that the numerators are also equal, $\hat{Q}_{\mathrm{m}, U}(E, z)\left(A * T_{1} * T_{1}^{\dagger A}\right)=\hat{Q}_{\mathrm{m}, U}(E, z)\left(A * T_{2} * T_{2}^{\dagger A}\right)$.

If it is the case that (iii) the iso-transform-independents are not equal, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A) \neq \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)$, but (iv) the derived variables are equal, $W_{1}=$ $W_{2}$, (v) the formals are equal, $A^{\mathrm{X}} * T_{1}=A^{\mathrm{X}} * T_{2}$, and (vi) the abstracts are equal, $\left(A * T_{1}\right)^{\mathrm{X}}=\left(A * T_{2}\right)^{\mathrm{X}}$, then the intersection of the iso-transformindependents includes both idealisations, $\left\{A * T_{1} * T_{1}^{\dagger A}, A * T_{2} * T_{2}^{\dagger A}\right\} \subset$ $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A) \cap \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)$. That is, the iso-transform-independents of the first transform includes the idealisation of the second transform, $A * T_{2} * T_{2}^{\dagger A} \in$ $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A)$, and vice-versa, $A * T_{1} * T_{1}^{\dagger A} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)$.

If it is the case instead that the derived variables are not necessarily equal, (iii) the distribution histogram is the independent sample, $E=A^{\mathrm{X}}$, and (iv) the formal independent equals the abstract of both transforms, $\left(A^{\mathrm{X}} *\right.$ $\left.T_{1}\right)^{\mathrm{X}}=\left(A * T_{1}\right)^{\mathrm{X}}$ and $\left(A^{\mathrm{X}} * T_{2}\right)^{\mathrm{X}}=\left(A * T_{2}\right)^{\mathrm{X}}$, so that the integral independent, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, is an integral iso-transform-independent for both transforms, $A^{\mathrm{X}} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A)$ and $A^{\mathrm{X}} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)$, then the change in negative logarithm independent-sample-distributed iso-transform-independent conditional dependent multinomial idealisation probability, given the integral mean multinomial probability distribution conjecture, is the difference in the alignments of the idealisations plus a difference in terms that do not depend on the idealisations but only on the iso-transform-independents

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A * T_{2} * T_{2}^{\dagger A}\right)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}+\ln \sum_{B_{2} \in \mathcal{A}_{U, i, \mathrm{i}, T_{2}, z}(A)} \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(B_{2}\right)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{x}}\right)}\right)- \\
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A * T_{1} * T_{1}^{\dagger A}\right)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A^{\mathrm{X}}\right)}+\ln \sum_{B_{1} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A)} \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(B_{1}\right)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{x}}\right)}\right) \\
& =\operatorname{algn}\left(A * T_{2} * T_{2}^{\dagger A}\right)-\operatorname{algn}\left(A * T_{1} * T_{1}^{\dagger A}\right)+ \\
& \left(\ln \sum_{B_{2} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)} \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(B_{2}\right)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{x}}\right)}-\ln \sum_{B_{1} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A)} \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(B_{1}\right)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A^{\mathrm{x}}\right)}\right)
\end{aligned}
$$

In the case where the iso-transform-independents are equal, $\mathcal{A}_{U, \mathrm{i}, \mathrm{i}, T_{1}, z}(A)=$ $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)$, then the difference is just the difference in alignments, $\operatorname{algn}(A *$ $\left.T_{2} * T_{2}^{\dagger A}\right)-\operatorname{algn}\left(A * T_{1} * T_{1}^{\dagger A}\right)$.

If it is the case instead that (iii) the distribution histogram is the independent sample, $E=A^{\mathrm{X}}$, and more strictly (iv) the formal equals the abstract of both transforms, $A^{\mathrm{X}} * T_{1}=\left(A * T_{1}\right)^{\mathrm{X}}$ and $A^{\mathrm{X}} * T_{2}=\left(A * T_{2}\right)^{\mathrm{X}}$, then the change in negative logarithm independent-sample-distributed iso-transformindependent conditional dependent multinomial idealisation probability is the change in alignment-bounded iso-transform idealisation space

$$
\left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A * T_{2} * T_{2}^{\dagger A}\right)}{\sum_{B_{2} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(B_{2}\right)}\right)-\left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)\left(A * T_{1} * T_{1}^{\dagger A}\right)}{\sum_{B_{1} \in \mathcal{A}_{U, i, y, T}, T_{1}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(B_{1}\right)\right)
$$

and the difference in alignment-bounded lifted iso-transform space is difference in derived alignments plus the difference in alignment-bounded lifted iso-transform errors

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}} * T_{2}, z\right)\left(A * T_{2}\right)}{\sum_{B_{2}^{\prime} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}} * T_{2}, z\right)\left(B_{2}^{\prime}\right)}\right)- \\
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}} * T_{1}, z\right)\left(A * T_{1}\right)}{\sum_{B_{1}^{\prime} \in \mathcal{A}_{U}^{\prime}, \mathrm{i}, \mathrm{y}, T_{1}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}} * T_{1}, z\right)\left(B_{1}^{\prime}\right)\right) \\
& =\operatorname{algn}\left(A * T_{2}\right)-\operatorname{algn}\left(A * T_{1}\right)+ \\
& \left(\ln \sum_{B_{2}^{\prime} \in \mathcal{A}^{\prime}} \sum_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A), ~ \frac{\prod_{R \in\left(A * T_{2}\right)^{\mathrm{xs}}}\left(A * T_{2}\right)_{R}^{\mathrm{X}}!}{\prod_{R \in B_{2}^{\prime \mathrm{S}}}\left(B_{2}^{\prime}\right)_{R}!}-\right. \\
& \left.\ln \sum_{B_{1}^{\prime} \in \mathcal{A}^{\prime} U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A), ~ \frac{\prod_{R \in\left(A * T_{1}\right)^{\mathrm{xS}}}\left(A * T_{1}\right)_{R}^{\mathrm{X}!}}{\prod_{R \in B_{1}^{\prime \mathrm{S}}}\left(B_{1}^{\prime}\right)_{R}!}\right)
\end{aligned}
$$

The difference in alignment-bounded lifted iso-transform errors is bounded

$$
\begin{aligned}
& -\ln \left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}^{\prime}(A)\right| \\
& \leq\left(\ln \sum_{B_{2}^{\prime} \in \mathcal{A}^{\prime}, i, \mathrm{i}, \mathrm{y}, T_{2}, z}(A), ~ \frac{\prod_{R \in\left(A * T_{2}\right)^{\mathrm{xS}}}\left(A * T_{2}\right)_{R}^{\mathrm{X}}!}{\prod_{R \in B_{2}^{\prime S}}\left(B_{2}^{\prime}\right)_{R}!}-\right. \\
& \left.\ln \sum_{B_{1}^{\prime} \in \mathcal{A}^{\prime} U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A), ~ \frac{\prod_{R \in\left(A * T_{1}\right)} \mathrm{xs}\left(A * T_{1}\right)_{R}^{\mathrm{X}!}}{\prod_{R \in B_{1}^{\prime}}\left(B_{1}^{\prime}\right)_{R}!}\right) \\
& \leq \ln \left|\mathcal{A}_{U, \mathrm{i}, \mathrm{i}, T_{2}, z}^{\prime}(A)\right|
\end{aligned}
$$

In the case where the derived variables are equal, $W_{1}=W_{2}$, and the abstracts are equal, $\left(A * T_{1}\right)^{\mathrm{X}}=\left(A * T_{2}\right)^{\mathrm{X}}$, then the numerators of the alignmentbounded lifted iso-transform errors are equal and so the difference in errors tends to be smaller. Conjecture that in the case where the derived variables are equal, $W_{1}=W_{2}$, in general the larger the intersection between the lifted iso-transform-independents, $\left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}^{\prime}(A) \cap \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}^{\prime}(A)\right|$, the less the difference in alignment-bounded lifted iso-transform errors and the more nearly the difference in alignment-bounded lifted iso-transform space equals the difference in derived alignments, $\operatorname{algn}\left(A * T_{2}\right)-\operatorname{algn}\left(A * T_{1}\right)$. Conjecture also that in the case where the derived variables are not equal, $W_{1} \neq W_{2}$, in general the larger the intersection between the iso-transform-independents, $\left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A) \cap \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)\right|$, the smaller the difference in alignment-bounded lifted iso-transform errors. As conjectured above, the alignment-bounded isotransform idealisation space is functionally related to the alignment-bounded lifted iso-transform space, so conjecture that in general the smaller the difference in alignment-bounded lifted iso-transform errors the more nearly the difference in alignment-bounded iso-transform idealisation space equals the difference in derived alignments, $\operatorname{algn}\left(A * T_{2} * T_{2}^{\dagger A}\right)-\operatorname{algn}\left(A * T_{1} * T_{1}^{\dagger A}\right)$.

For convenience, define $\ln !\in \mathcal{A}_{\mathbf{i}} \rightarrow \ln \mathbf{Q}_{>0}$ as

$$
\ln !(A):=\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!=\ln \prod_{S \in A^{\mathrm{S}}} A_{S}!
$$

$\ln !$ is undefined where $A=\emptyset$. The alignment of an integral-independent histogram, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, may be expressed in terms of the non-independent term and the independent term as

$$
\operatorname{algn}(A)=\ln !(A)-\ln !\left(A^{\mathrm{X}}\right)
$$

Define lnhar $!\in \mathrm{P}\left(\mathcal{A}_{\mathrm{i}}\right) \rightarrow \ln \mathrm{Q}_{>0}$ as

$$
\operatorname{lnhar}!(X):=\ln \sum_{B \in X} \frac{1}{\prod_{R \in B^{\mathrm{S}}} B_{R}!}
$$

$\operatorname{lnh} a r$ ! is undefined where $X=\emptyset$ or $\emptyset \in X$. The alignment-bounded lifted iso-transform space may be expressed

$$
\left.\begin{array}{rl} 
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}} * T, z\right)(A * T)}{\sum_{B^{\prime} \in \mathcal{A}_{U}^{\prime}, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}} * T, z\right)\left(B^{\prime}\right)\right.
\end{array}\right)
$$

The alignment-bounded lifted iso-transform space error may be expressed as $\ln !\left((A * T)^{\mathrm{X}}\right)+\operatorname{lnh} a r!\left(\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right)$ which is such that

$$
0 \leq \ln !\left((A * T)^{\mathrm{x}}\right)+\operatorname{lnhar}!\left(\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right) \leq \ln \left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right|
$$

A value roll $(V, v, s, t) \in \operatorname{rollValues}(U)$ is such that the independent of the application of the value roll, $(V, v, s, t)$, to a histogram $A$ is equal to the application of the value roll to the independent histogram, $\left(A *(V, v, s, t)^{\mathrm{R}}\right)^{\mathrm{X}}=A^{\mathrm{X}} *$ $(V, v, s, t)^{\mathrm{R}}$. The transform of the value roll, $T=(V, v, s, t)^{\mathrm{T}}$, is therefore such that the formal histogram equals the abstract histogram, $A^{\mathrm{X}} *(V, v, s, t)^{\mathrm{T}}=$ $\left(A *(V, v, s, t)^{\mathrm{T}}\right)^{\mathrm{X}}$. The iso-transform-independents, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)$, are the set of complete congruent histograms having the same perimeters as the value rolled histogram, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z},\left(B *(V, v, s, t)^{\mathrm{R}}\right)^{\mathrm{X}}=\right.$ $\left.\left(A *(V, v, s, t)^{\mathrm{R}}\right)^{\mathrm{X}}\right\}$.

The derived alignment in variables $\operatorname{der}(T)$ is equal to the alignment in variables $V$ of the rolled histogram, $\operatorname{algn}(A * T)=\operatorname{algn}\left(A *(V, v, s, t)^{\mathrm{R}}\right)$. If the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, then the value roll transform, $T$, satisfies the constraints required so that the negative logarithm lifted independent-sampledistributed iso-transform-independent quasi-conditional dependent multinomial probability is bounded by the derived alignment, $\operatorname{algn}\left(A *(V, v, s, t)^{\mathrm{T}}\right)$. That is, the alignment-bounded lifted iso-transform space of the value roll,
( $V, v, s, t$ ), is bounded by the value rolled histogram alignment

$$
\begin{aligned}
& \operatorname{algn}\left(A *(V, v, s, t)^{\mathrm{R}}\right) \\
\leq & \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}} * T, z\right)(A * T)}{\sum_{B^{\prime} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}} * T, z\right)\left(B^{\prime}\right)}: A^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{x}} * T=(A * T)^{\mathrm{x}}\right) \\
\leq & \operatorname{algn}\left(A *(V, v, s, t)^{\mathrm{R}}\right)+\ln \left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right|
\end{aligned}
$$

The value roll transform, $T=(V, v, s, t)^{\mathrm{T}}$, is ideal, $A=A * T * T^{\dagger} A$, if the source and target values, $s$ and $t$, are independent, $A *(\{v\} \times\{s, t\})^{\mathrm{U}}=$ $A^{\mathrm{X}} *(\{v\} \times\{s, t\})^{\mathrm{U}}$.

As shown above in section 'Deltas and Perturbations', the application of a value roll $(V, v, s, t) \in \operatorname{rollValues}(U)$ cannot be iso-independence conserving, $A *(V, v, s, t)^{\mathrm{R}} \notin Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, but it is iso-transform-independence conserving, $A *(V, v, s, t)^{\mathrm{R}} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)$, where $T=(V, v, s, t)^{\mathrm{T}}$.

A pair of non-circular value rolls $\left(V, v_{1}, s_{1}, t_{1}\right),\left(V, v_{2}, s_{2}, t_{2}\right) \in \operatorname{rollValues}(U)$ cannot be in the same set of iso-transform-independents, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A) \neq$ $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)$ where $T_{1}=\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{T}}$ and $T_{2}=\left(V, v_{2}, s_{2}, t_{2}\right)^{\mathrm{T}}$, unless it so happens that $\left(A *\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}}\right)^{\mathrm{X}}=\left(A *\left(V, v_{2}, s_{2}, t_{2}\right)^{\mathrm{R}}\right)^{\mathrm{X}}$, for example where $v_{1}=v_{2}, t_{1}=t_{2}$ and $A \%\left\{v_{1}\right\}\left(\left\{\left(v_{1}, s_{1}\right)\right\}\right)=A \%\left\{v_{1}\right\}\left(\left\{\left(v_{1}, s_{2}\right)\right\}\right)$. The alignment-bounded lifted iso-transform error varies with the derived volume. So the errors are more comparable if the derived volumes are equal, $\left|W_{1}^{\mathrm{C}}\right|=$ $\left|W_{2}^{\mathrm{C}}\right|$ where $W_{1}=\operatorname{der}\left(T_{1}\right)$ and $W_{2}=\operatorname{der}\left(T_{2}\right)$. That is, if the histogram is effectively regular in variables $v_{1}$ and $v_{2},\left|\left(A \%\left\{v_{1}\right\}\right)^{\mathrm{F}}\right|=\left|\left(A \%\left\{v_{2}\right\}\right)^{\mathrm{F}}\right|$.

Consider a pair of value rolls applied in sequence, $A *\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}} *\left(V, v_{2}, s_{2}, t_{2}\right)^{\mathrm{R}}$ where $T_{1}=\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{T}}$ and $T_{2}=\left(V, v_{2}, s_{2}, t_{2}\right)^{\mathrm{T}}$. The first value rolled histogram, $A *\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}}$, is a member of both sets of iso-transformindependents, $A *\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A) \cap \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}\left(A *\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}}\right)$.

The iso-transform-independents of the pair of value rolls applied in sequence, $A *\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}} *\left(V, v_{2}, s_{2}, t_{2}\right)^{\mathrm{R}}$ is $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)$ where $T=\left(\left(V, v_{2}, s_{2}, t_{2}\right)^{\mathrm{R}} \circ\right.$ $\left.\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}}\right)^{\mathrm{T}}$. This set is the union

$$
\begin{aligned}
& \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)= \\
& \quad\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A), B *\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}\left(A *\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}}\right)\right\} \cup \\
& \quad \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}\left(A *\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}}\right)
\end{aligned}
$$

The sets of iso-transform-independents intersect, $A *\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A) \cap$ $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}\left(A *\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}}\right)$. Therefore the cardinality of the sequence iso-
transform-independents is less than or equal to the sum of the cardinalities of the value rolls cumulatively or separately applied,

$$
\begin{aligned}
\left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right| & \left.\leq \mid \mathcal{A}_{U \mathrm{i}, \mathrm{y}, T_{1}, z}(A)\right\}\left|+\left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}\left(A *\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}}\right)\right|\right. \\
& \leq\left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A)\right|+\left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)\right|
\end{aligned}
$$

The cardinality of the sequence lifted iso-transform-independents is also less than or equal to the sum of the cardinalities of the lifted iso-transformindependents of the value rolls cumulatively or separately applied,

$$
\begin{aligned}
\left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right| & \left.\leq \mid \mathcal{A}_{U \mathrm{i}, \mathrm{y}, T_{1}, z}^{\prime}(A)\right\}\left|+\left|\mathcal{A}_{U \mathrm{i}, \mathrm{y}, T_{2}, z}^{\prime}\left(A *\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}}\right)\right|\right. \\
& \leq\left|\mathcal{A}_{U \mathrm{i}, \mathrm{y}, T_{1}, z}^{\prime}(A)\right|+\left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}^{\prime}(A)\right|
\end{aligned}
$$

The alignment-bounded lifted iso-transform error depends on the set of lifted iso-transform-independents, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)$, and so the alignment-bounded lifted iso-transform error of a pair of value rolls in sequence is conjectured to be less than or equal to the sum of the alignment-bounded lifted iso-transform errors of the value rolls cumulatively applied

$$
\begin{aligned}
& \quad \ln !\left((A * T)^{\mathrm{X}}\right)+\operatorname{lnhar}!\left(\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right) \\
& \leq \\
& \ln !\left(\left(A * T_{1}\right)^{\mathrm{X}}\right)+\operatorname{lnhar}!\left(\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A)\right)+ \\
& \\
& \ln !\left(\left(A *\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}} * T_{2}\right)^{\mathrm{X}}\right)+\operatorname{lnh} \operatorname{ar}!\left(\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}^{\prime}\left(A *\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}}\right)\right)
\end{aligned}
$$

or separately applied

$$
\begin{aligned}
& \quad \ln !\left((A * T)^{\mathrm{X}}\right)+\operatorname{lnhar}!\left(\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right) \\
& \leq \\
& \ln !\left(\left(A * T_{1}\right)^{\mathrm{X}}\right)+\operatorname{lnhar}!\left(\mathcal{A}_{U \mathrm{i}, \mathrm{y}, T_{1}, z}(A)\right)+ \\
& \ln !\left(\left(A * T_{2}\right)^{\mathrm{X}}\right)+\operatorname{lnh} \ln !\left(\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}^{\prime}(A)\right)
\end{aligned}
$$

Let $\mathcal{J}_{U, V}$ be the set of lists of value rolls in variables $V$ and system $U, \mathcal{J}_{U, V}=$ $\{L: L \in \mathcal{L}(\operatorname{rollValues}(U)),(\forall(W, \cdot, \cdot, \cdot) \in \operatorname{set}(L)(W=V))\}$. The transform of a non-circular value roll list $J \in \mathcal{J}_{U, V}$ is also formal abstract equivalent, $A^{\mathrm{X}} * J^{\mathrm{T}}=\left(A * J^{\mathrm{T}}\right)^{\mathrm{X}}$, so the alignment-bounded lifted iso-transform space of the value roll list, $J$, is also bounded by the derived alignment, $\operatorname{algn}\left(A * J^{\mathrm{T}}\right)$. That is, because the alignment-bounded lifted iso-transform space of each of the successive formal abstract equivalent applications of the value rolls in the value roll list, $A * J_{\{1 \ldots i-1\}}^{\mathrm{R}} * J_{i}^{\mathrm{R}}$, is bounded, the application of the entire value roll list at once, $A * J^{\mathrm{R}}$, must also be bounded. The change in derived alignment of the application value roll list equals the sum of the changes in derived alignment, $\operatorname{algn}\left(A * J^{\mathrm{R}}\right)-\operatorname{algn}(A)=\left(\operatorname{algn}\left(A * J_{1}^{\mathrm{R}}\right)-\operatorname{algn}(A)\right)+$ $\sum_{i \in 2 \ldots|J|}\left(\operatorname{algn}\left(A * J_{\{1 \ldots i-1\}}^{\mathrm{R}} * J_{i}^{\mathrm{R}}\right)-\operatorname{algn}\left(A * J_{\{1 \ldots i-2\}}^{\mathrm{R}} * J_{i-1}^{\mathrm{R}}\right)\right)$. The alignmentbounded lifted iso-transform error of the value roll list is conjectured to be
less than or equal to the sum of the alignment-bounded lifted iso-transform errors of the value rolls cumulatively applied,

$$
\leq \sum_{i \in 1 \ldots|J|}\left(\ln !\left(\left(A * J^{\mathrm{R}}\right)^{\mathrm{X}}\right)+\operatorname{lnhar}!\left(\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, J^{\mathrm{T}}, z}^{\prime}(A)\right)\right.
$$

or individually applied

$$
\leq \sum_{i \in 1 \ldots|J|}\left(\ln !\left(\left(A * J^{\mathrm{R}}\right)^{\mathrm{X}}\right)+\operatorname{lnhar}!\left(\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, J J^{\mathrm{T}}, z}^{\prime}(A)\right)\right.
$$

This is the case regardless of the order of the value roll list.
A reduction $A \% K$ of the histogram, $A$, to variables $K \subset V$ can be viewed as a set of value roll lists for each of the reduced variables, $V \backslash K$, such that the values are rolled to a single value. For example, in the case of a reduction by a single variable, let $\{v\}=V \backslash K, M \in \operatorname{enums}\left(U_{v}\right), L=\operatorname{flip}(M), d=\left|U_{v}\right|$ and $J=\left\{\left(i,\left(V, v, L_{i}, L_{d}\right)\right): i \in\{1 \ldots d-1\}\right\} \in \mathcal{J}_{U, V}$. Then $\operatorname{algn}\left(A * J^{\mathrm{R}}\right)=$ $\operatorname{algn}(A \%(V \backslash\{v\}))=\operatorname{algn}(A \% K)$. Therefore the alignment-bounded lifted iso-transform space of a reduction transform, $T=\left\{w^{\mathrm{CSVT}}: w \in K\right\}^{\mathrm{T}}$, is also bounded by the derived alignment, $\operatorname{algn}(A * T)=\operatorname{algn}(A \% K)$.

As noted above, two value rolls $\left(V, v_{1}, s_{1}, t_{1}\right),\left(V, v_{2}, s_{2}, t_{2}\right) \in \operatorname{rollValues}(U)$ cannot be in the same set of iso-transform-independents, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A) \neq$ $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)$ where $T_{1}=\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{T}}$ and $T_{2}=\left(V, v_{2}, s_{2}, t_{2}\right)^{\mathrm{T}}$, if the $a b-$ stract histograms are not equal, $\left(A *\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}}\right)^{\mathrm{X}} \neq\left(A *\left(V, v_{2}, s_{2}, t_{2}\right)^{\mathrm{R}}\right)^{\mathrm{X}}$. Thus the difference in alignment-bounded lifted iso-transform errors, $(\ln !((A *$ $\left.\left.\left.T_{2}\right)^{\mathrm{X}}\right)+\operatorname{lnhar}!\left(\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}^{\prime}(A)\right)\right)-\left(\ln !\left(\left(A * T_{1}\right)^{\mathrm{X}}\right)+\operatorname{lnh} \operatorname{ar}!\left(\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}^{\prime}(A)\right)\right)$, is sometimes non-zero. However, the intersection of the iso-transform independents includes both the sample, $A$, and the integral independent sample, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$. That is, $A, A^{\mathrm{X}} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}(A) \cap \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)$. In fact, although the abstract histograms are different, parts of the rolled histograms are common in each case, $A *\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}} * X=A *\left(V, v_{2}, s_{2}, t_{2}\right)^{\mathrm{R}} * X$ where $X=\left(\left\{v_{1}\right\}^{\mathrm{CS}} \backslash\left(\left\{v_{1}\right\} \times\left\{s_{1}, t_{1}\right\}\right)\right)^{\mathrm{U}} *\left(\left\{v_{2}\right\}^{\mathrm{CS}} \backslash\left(\left\{v_{2}\right\} \times\left\{s_{2}, t_{2}\right\}\right)\right)^{\mathrm{U}}$. That is, the perimeters of $A$ are unchanged except at four values, $\forall w \in V(A *$ $\left.\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}} \%\{w\} * X=A *\left(V, v_{2}, s_{2}, t_{2}\right)^{\mathrm{R}} \%\{w\} * X\right)$. The differences are fewer if $v_{1}=v_{2}$ and $\left|\left\{s_{1}, s_{2}, t_{1}, t_{2}\right\}\right|<4$. The difference in alignmentbounded lifted iso-transform errors is therefore sometimes smaller than would be the case if the value rolls were applied to different sample histograms,
$A *\left(V, v_{1}, s_{1}, t_{1}\right)^{\mathrm{R}}$ and $B *\left(V, v_{2}, s_{2}, t_{2}\right)^{\mathrm{R}}$ where $B \in \mathcal{A}_{U, \mathrm{i}, V, z} \backslash \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}(A)$. That is, in some cases $\mid\left(\ln !\left(\left(A * T_{2}\right)^{\mathrm{X}}\right)+\operatorname{lnhar}!\left(\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}^{\prime}(A)\right)\right)-(\ln !((A *$ $\left.\left.\left.T_{1}\right)^{\mathrm{X}}\right)+\operatorname{lnh} \operatorname{ar}!\left(\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}^{\prime}(A)\right)\right)|\leq|\left(\ln !\left(\left(B * T_{2}\right)^{\mathrm{X}}\right)+\operatorname{lnhar}\left(\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{2}, z}^{\prime}(B)\right)\right)-$ $\left(\ln !\left(\left(A * T_{1}\right)^{\mathrm{X}}\right)+\operatorname{lnhar}!\left(\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{1}, z}^{\prime}(A)\right)\right) \mid$. Similarly, two non-circular value roll lists $J_{x}, J_{y} \in \mathcal{J}_{U, V}$ applied to the same sample, $A * J_{x}^{\mathrm{R}}$ and $A * J_{y}^{\mathrm{R}}$, will sometimes have a smaller difference in the sum of alignment-bounded lifted iso-transform errors if they intersect, $\operatorname{set}\left(J_{x}\right) \cap \operatorname{set}\left(J_{y}\right) \neq \emptyset$.

In section 'Substrate structures', above, it is shown that the non-overlapping substrate transforms set, $\mathcal{T}_{U, V, \mathrm{n}}$, can be constructed from linear fuds where the first transform is a non-overlapping substrate self-cartesian transform, $\mathcal{T}_{U, V, \mathrm{c}} \cap \mathcal{T}_{U, V, \mathrm{n}}$, and the subsequent transforms are self substrate decremented transforms, $\mathcal{T}_{U, W,-} \cap \mathcal{T}_{U, W, \mathrm{n}, \mathrm{s}}$. In turn, the linear fuds of self substrate decremented transforms correspond bijectively to the non-circular unique-source value roll lists, $\mathcal{J}_{U, V,-} \subset \mathcal{J}_{U, V}$.

A non-overlapping transform $T \in \mathcal{T}_{U, f, 1}$, where und $(T)=V$ and $\neg \operatorname{overlap}(T)$, is such that the formal histogram is independent, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, but does not necessarily imply that the formal is abstract, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}} \Longleftarrow$ $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$. Therefore, even if the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathbf{i}}$, the transform, $T$, does not necessarily satisfy the constraint required so that the negative logarithm lifted independent-sample-distributed iso-transformindependent quasi-conditional dependent multinomial probability is bounded by the derived alignment, $\operatorname{algn}(A * T)$.

Even where the non-overlapping transform is a non-overlapping substrate self-cartesian transform, $T \in \mathcal{T}_{U, V, \mathrm{c}} \cap \mathcal{T}_{U, V, \mathrm{n}}$, it is not necessarily the case that the formal is abstract. However, in the special case where the transform is the singleton self substrate self-cartesian transform, $\{T\}=\mathcal{T}_{U, V, \mathrm{c}} \cap \mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$, it is then a value full functional transform, $T=\left\{\{v\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: v \in V\right\}^{\mathrm{T}}$, and hence the formal equals the abstract, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$.

In the case where a non-overlapping transform, $\neg \operatorname{overlap}(T)$, is mono-derivedvariate, $|\operatorname{der}(T)|=1$, then the derived histogram is necessarily independent, $A * T=(A * T)^{\mathrm{X}}$. In the case where the formal also equals the abstract, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, the derived histogram must be purely formal, $A * T=(A * T)^{\mathrm{X}}=A^{\mathrm{X}} * T$. In any case both the derived and formal have zero alignment, $\operatorname{algn}(A * T)=\operatorname{algn}\left(A^{\mathrm{X}} * T\right)=0$.

As shown above, value roll transforms, which correspond to self substrate
decremented transforms, are such that the formal equals the abstract. So a non-overlapping transform that can be constructed from a linear fud of the value full functional transform, $\mathcal{T}_{U, V, \mathrm{c}} \cap \mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}$, followed by sequence of self substrate decremented transforms, $\mathcal{T}_{U, W,-} \cap \mathcal{T}_{U, W, \mathrm{n}, \mathrm{s}}$, must also be such that the formal equals the abstract. This is because in this case the nonoverlapping transform is a self non-overlapping substrate transform, $\forall T \in$ $\mathcal{T}_{U, V, \mathrm{n}, \mathrm{s}}\left(A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right)$.

### 4.19 Substrate structures alignment

Some of the conjectures of approximations and relations between variables stated in the previous discussion of alignment may be formalised in terms of the statistics of real-valued functions on a support of distinct geometry sized cardinal substrate histograms. The set of sized cardinal substrate histograms $\mathcal{A}_{z}$, defined above in section 'Distinct geometry sized cardinal substrate histograms', is the set of complete integral cardinal substrate histograms of size $z$ and dimension less than or equal to the size such that the independent is completely effective

$$
\mathcal{A}_{z}=\left\{A: A \in \mathcal{A}_{\mathrm{c}} \cap \mathcal{A}_{\mathrm{i}}, \operatorname{size}(A)=z,\left|V_{A}\right| \leq z, A^{\mathrm{U}}=A^{\mathrm{XF}}=A^{\mathrm{C}}\right\}
$$

Each substrate histogram $A \in \mathcal{A}_{z}$ has $\left|V_{A}\right|!\prod_{w \in V_{A}}\left|U_{A}(w)\right|!$ cardinal substrate permutations. These frame mappings partition the substrate histograms into equivalence classes having the same geometry. Let $P_{z}$ be the partition, $P_{z} \in \mathrm{~B}\left(\mathcal{A}_{z}\right)$, such that the components of $P_{z}$ are the equivalence classes by cardinal substrate permutation, $\forall C \in P_{z} \forall A \in C\left(|C|=\left|V_{A}\right|!\prod_{w \in V_{A}}\left|U_{A}(w)\right|\right)$.

Each of the substrate histograms in a component of $P_{z}$, that are equivalent by cardinal substrate permutation, have the same alignment, $\forall C \in P_{z} \forall A, B \in$ $C(\operatorname{algn}(A)=\operatorname{algn}(B))$ where algn $=$ alignment.

If the substrate histograms are partitioned, for example to analyse correlations grouped by low or high alignment, then the partition should be a parent partition of $P_{z}$. That is, the substrate histograms partition should be independent of cardinal substrate permutation.

The central moment functions of the renormalised geometry-weighted probability function, $\hat{R}_{z}$, that operate on real-valued functions of the sized cardinal
substrate histograms, $\mathcal{A}_{z} \rightarrow \mathbf{R}$, are defined

$$
\begin{aligned}
\operatorname{ex}(z)(F) & :=\operatorname{expected}\left(\hat{R}_{z}\right)(F) \\
\operatorname{var}(z)(F) & :=\operatorname{variance}\left(\hat{R}_{z}\right)(F) \\
\operatorname{cov}(z)(F, G) & :=\operatorname{covariance}\left(\hat{R}_{z}\right)(F, G) \\
\operatorname{corr}(z)(F, G) & :=\operatorname{correlation}\left(\hat{R}_{z}\right)(F, G)
\end{aligned}
$$

where

$$
\hat{R}_{z}=\operatorname{normalise}\left(\left\{\left(A, \frac{1}{\left|V_{A}\right|!\prod_{w \in V_{A}}\left|U_{A}(w)\right|!}\right): A \in \operatorname{dom}(F)\right\}\right) \in \mathcal{P}
$$

### 4.19.1 Iso-independent conditional

Define the subset of the sized cardinal substrate histograms, $\mathcal{A}_{z}$, for which the independent, $A^{\mathrm{X}}$, is integral, and therefore also a substrate histogram, as the integral-independent substrate histograms,

$$
\mathcal{A}_{z, \mathrm{xi}}=\left\{A: A \in \mathcal{A}_{z}, A^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}}\right\}=\left\{A: A, A^{\mathrm{x}} \in \mathcal{A}_{z}\right\} \subset \mathcal{A}_{z}
$$

Define the alignment substrate function for some size $z, X_{z, \mathrm{a}} \in \mathcal{A}_{z} \rightarrow \mathbf{R}$, as

$$
X_{z, \mathrm{a}}=\left\{(A, \operatorname{algn}(A)): A \in \mathcal{A}_{z}\right\}
$$

This may be equally be expressed as the negative logarithm independent-sample-distributed relative dependent multinomial probability density substrate function

$$
X_{z, \mathrm{a}}=\left\{\left(A,-\ln \frac{\operatorname{mpdf}\left(U_{A}\right)\left(A^{\mathrm{X}}, z\right)(A)}{\operatorname{mpdf}\left(U_{A}\right)\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}\right): A \in \mathcal{A}_{z}\right\}
$$

where for some $(E, z) \in \mathcal{A}_{U} \times \mathbf{Q}_{\geq 0}$ the multinomial probability density function, $\operatorname{mpdf}(U)(E, z) \in \mathcal{A}_{U, V, z} \rightarrow \mathbf{R}_{\geq 0}$, is defined

$$
\operatorname{mpdf}(U)(E, z)(A):=\frac{\Gamma_{!} z}{\prod_{S \in A^{\mathrm{S}}} \Gamma_{!} A_{S}} \prod_{S \in A^{\mathrm{S}}}\left(\frac{E_{S}}{z_{E}}\right)^{A_{S}}
$$

Let the subset of the alignment substrate function for which the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, be defined the alignment integral-independent substrate function, $X_{z, \mathrm{xi}, \mathrm{a}} \in \mathcal{A}_{z, \mathrm{xi}} \rightarrow \ln \mathrm{Q}_{>0}$, as

$$
X_{z, \mathrm{xi}, \mathrm{a}}=\operatorname{filter}\left(\mathcal{A}_{z, \mathrm{xi}}, X_{z, \mathrm{a}}\right)=\left\{(A, \operatorname{algn}(A)): A \in \mathcal{A}_{z}, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right\} \subset X_{z, \mathrm{a}}
$$

which may be be expressed in terms of the generalised multinomial probability distribution as the independent-sample-distributed relative dependent multinomial space substrate function

$$
X_{z, \mathrm{xi}, \mathrm{a}}=\left\{\left(A,-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(A)}{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{x}}\right)}\right): A \in \mathcal{A}_{z, \mathrm{xi}}\right\}
$$

where for some $(E, z) \in \mathcal{A}_{U} \times \mathbf{N}$ the generalised multinomial probability distribution $\hat{Q}_{\mathrm{m}, U}(E, z) \in\left(\mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$ is defined

$$
\hat{Q}_{\mathrm{m}, U}(E, z)(A):=\frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}}\left(\frac{E_{S}}{z_{E}}\right)^{A_{S}}
$$

Define the independent-sample-distributed iso-independent conditional dependent multinomial space substrate function for some size $z, X_{z, \mathrm{y}} \in \mathcal{A}_{z} \rightarrow$ $\ln \mathrm{Q}_{>0}$, as

$$
X_{z, \mathrm{y}}=\left\{\left(A,-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(A)}{\sum_{B \in Y_{U_{A}, \mathrm{i}, V_{A}, z}^{-1}\left(A^{\mathrm{x}}\right)} \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(B)}\right): A \in \mathcal{A}_{z}\right\}
$$

where the integral iso-independent function, $Y_{U, \mathrm{i}, V, z} \in \mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathcal{A}_{U, V, z}$, is defined

$$
Y_{U, \mathrm{i}, V, z}=\left\{\left(A, A^{\mathrm{X}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\} \subset Y_{U, V, z} \subset \text { independent }
$$

In the case where the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, the independent-sample-distributed iso-independent conditional dependent multinomial space, $X_{z, \mathrm{y}}(A)$, is the alignment-bounded iso-independent space,

$$
\begin{aligned}
& \left(X_{z, \mathrm{y}}(A): A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right) \\
= & \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(A)}{\sum_{B \in Y_{U_{A}, \mathrm{i}, V_{A}, z}^{-1}\left(A^{\mathrm{X}}\right)} \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(B)}: A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right) \\
= & \operatorname{algn}(A)+\ln \sum_{B \in Y_{U_{A}, \mathrm{i}, V_{A}, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{\prod_{S \in A^{\mathrm{Xx}}} A_{S}^{\mathrm{X}}!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}
\end{aligned}
$$

As shown above, in 'Alignment and conditional probability', given the minimum alignment conjecture, the alignment-bounded iso-independent space is
bounded

$$
\begin{aligned}
& \operatorname{algn}(A) \\
\leq & \operatorname{algn}(A)+\ln \sum_{B \in Y_{U_{A}, i, V_{A}, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{\prod_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}}!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!} \\
\leq & \operatorname{algn}(A)+\ln \left|Y_{U_{A}, \mathrm{i}, V_{A}, z}^{-1}\left(A^{\mathrm{X}}\right)\right|
\end{aligned}
$$

Therefore the independent-sample-distributed iso-independent conditional dependent multinomial space integral-independent substrate function, defined $X_{z, \mathrm{xi}, \mathrm{y}}=\operatorname{filter}\left(\mathcal{A}_{z, \mathrm{xi}}, X_{z, \mathrm{y}}\right) \subset X_{z, \mathrm{y}}$, also known as the alignment-bounded iso-independent space substrate function, is correlated with the alignment integral-independent substrate function, $X_{z, \mathrm{xi}, \mathrm{a}}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(X_{z, \mathrm{xi}, \mathrm{y}}, X_{z, \mathrm{xi}, \mathrm{a}}\right) \geq 0\right)
$$

The alignment is an underestimate of the alignment-bounded iso-independent space and hence the expected alignment must be less than or equal to the expected alignment-bounded iso-independent space for all sizes of substrate histograms

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{ex}(z)\left(X_{z, \mathrm{xi}, \mathrm{y}}\right) \geq \operatorname{ex}(z)\left(X_{z, \mathrm{xi}, \mathrm{a}}\right)\right)
$$

This is derived from the expected alignment-bounded iso-independent error

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{ex}(z)\left(X_{z, \mathrm{xi}, \mathrm{y}}-X_{z, \mathrm{x}, \mathrm{a}}\right) \geq 0\right)
$$

where the alignment-bounded iso-independent error is

$$
X_{z, \mathrm{xi}, \mathrm{y}}(A)-X_{z, \mathrm{xi}, \mathrm{a}}(A)=\ln \sum_{B \in Y_{U_{A}, \mathrm{i}, V_{A}, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{\prod_{S \in A^{\mathrm{xS}}} A_{S}^{\mathrm{X}}!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}
$$

The alignment-bounded iso-independent error increases with size
$\forall z_{1}, z_{2} \in \mathbf{N}_{>0}\left(z_{2}>z_{1} \Longrightarrow \operatorname{ex}\left(z_{2}\right)\left(X_{z_{2}, \mathrm{xi}, \mathrm{y}}-X_{z_{2}, \mathrm{xi}, \mathrm{a}}\right) \geq \operatorname{ex}\left(z_{1}\right)\left(X_{z_{1}, \mathrm{xi}, \mathrm{y}}-X_{z_{1}, \mathrm{xi}, \mathrm{a}}\right)\right)$
The alignment-bounded iso-independent error varies with volume

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(X_{z, \mathrm{xi}, \mathrm{y}}-X_{z, \mathrm{xi}, \mathrm{a}},\left\{\left(A,\left|A^{\mathrm{C}}\right|\right): A \in \mathcal{A}_{z}\right\}\right) \geq 0\right)
$$

The alignment-bounded iso-independent error varies with valency entropy for given volume

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(X_{z, \mathrm{xi}, \mathrm{y}}-X_{z, \mathrm{xi}, \mathrm{a}}, X_{z, \mathrm{~h}, \mathrm{U}}\right) \geq 0\right)
$$

where $X_{z, \mathrm{~h}, \mathrm{U}}=\left\{\left(A, \operatorname{entropy}\left(\left\{\left(w,\left|U_{A}(w)\right|\right): w \in V_{A}\right\}\right) /\left|A^{\mathrm{C}}\right|\right): A \in \mathcal{A}_{z}\right\}$.
Conjecture that the alignment-bounded iso-independent error varies with the entropy of the independent

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(X_{z, \mathrm{xi}, \mathrm{y}}-X_{z, \mathrm{x}, \mathrm{a}}, X_{z, \mathrm{~h}, \mathrm{x}}\right) \geq 0\right)
$$

where $X_{z, \mathrm{~h}, \mathrm{x}}=\left\{\left(A, \operatorname{entropy}\left(A^{\mathrm{X}}\right)\right): A \in \mathcal{A}_{z}\right\}$.
Therefore conjecture that the alignment-bounded iso-independent error varies with the alignment

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(X_{z, \mathrm{xi}, \mathrm{y}}-X_{z, \mathrm{x}, \mathrm{a}}, X_{z, \mathrm{xi}, \mathrm{a}}\right) \geq 0\right)
$$

but that overall the alignment-bounded iso-independent error ratio varies against the alignment

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\left(X_{z, \mathrm{xi}, \mathrm{y}}-X_{z, \mathrm{xi}, \mathrm{a}}\right) / X_{z, \mathrm{xi}, \mathrm{a}}, X_{z, \mathrm{xi}, \mathrm{a}}\right) \leq 0\right)
$$

where the alignment-bounded iso-independent error ratio is

$$
\frac{X_{z, \mathrm{xi}, \mathrm{y}}(A)-X_{z, \mathrm{x}, \mathrm{a}}(A)}{X_{z, \mathrm{xi}, \mathrm{a}}(A)}=\left(\ln \sum_{B \in Y_{U_{A}, i, V_{A}, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{\prod_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}}!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}\right) / \operatorname{algn}(A)
$$

which is defined for non-independent sample, $A \neq A^{\mathrm{X}}$.
Conjecture that the correlation between the alignment-bounded iso independent space substrate function, $X_{z, \text { xi, }, ~}$, and the alignment integral independent substrate function, $X_{z, \mathrm{xi}, \mathrm{a}}$, can be extended from the integral-independent substrate histograms, $\mathcal{A}_{z, \mathrm{xi}}$, to all substrate histograms, $\mathcal{A}_{z}$. That is, conjecture that the independent-sample-distributed iso-independent conditional dependent multinomial space substrate function, $X_{z, \mathrm{y}}$, and the alignment substrate function, $X_{z, \mathrm{a}}$, are also correlated,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(X_{z, \mathrm{y}}, X_{z, \mathrm{a}}\right) \geq 0\right)
$$

Further, conjecture that the independent-sample-distributed iso-independent conditional dependent multinomial space error, $X_{z, \mathrm{y}}(A)-X_{z, \mathrm{a}}(A)$, increases with size,

$$
\forall z_{1}, z_{2} \in \mathbf{N}_{>0}\left(z_{2}>z_{1} \Longrightarrow \operatorname{ex}\left(z_{2}\right)\left(X_{z_{2}, \mathrm{y}}-X_{z_{2}, \mathrm{a}}\right) \geq \operatorname{ex}\left(z_{1}\right)\left(X_{z_{1}, \mathrm{y}}-X_{z_{1}, \mathrm{a}}\right)\right)
$$

varies with volume,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(X_{z, \mathrm{y}}-X_{z, \mathrm{a}},\left\{\left(A,\left|A^{\mathrm{C}}\right|\right): A \in \mathcal{A}_{z}\right\}\right) \geq 0\right)
$$

varies with valency entropy for given volume,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(X_{z, \mathrm{y}}-X_{z, \mathrm{a}}, X_{z, \mathrm{~h}, \mathrm{U}}\right) \geq 0\right)
$$

varies with the entropy of the independent,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(X_{z, \mathrm{y}}-X_{z, \mathrm{a}}, X_{z, \mathrm{~h}, \mathrm{x}}\right) \geq 0\right)
$$

and varies with the alignment,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(X_{z, \mathrm{y}}-X_{z, \mathrm{a}}, X_{z, \mathrm{a}}\right) \geq 0\right)
$$

Conjecture that the independent-sample-distributed iso-independent conditional dependent multinomial space error ratio, $\left(X_{z, \mathrm{y}}(A)-X_{z, \mathrm{a}}(A)\right) / X_{z, \mathrm{a}}(A)$, varies against the alignment

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\left(X_{z, \mathrm{y}}-X_{z, \mathrm{a}}\right) / X_{z, \mathrm{a}}, X_{z, \mathrm{a}}\right) \leq 0\right)
$$

However, although there is a correlation between the independent-sampledistributed iso-independent conditional dependent multinomial space substrate function, $X_{z, \mathrm{y}}$, and the alignment substrate function, $X_{z, \mathrm{a}}$, the correlation is less than for the subset where the independent is integral,

$$
\forall z \in \mathbf{N}_{\geq t}\left(\operatorname{corr}(z)\left(X_{z, \mathrm{xi}, \mathrm{y}}, X_{z, \mathrm{xi}, \mathrm{a}}\right) \geq \operatorname{corr}(z)\left(X_{z, \mathrm{y}}, X_{z, \mathrm{a}}\right)\right)
$$

where threshold $t \in \mathbf{N}_{>0}$ is the minimum size such that the variances are nonzero, $\forall z \in \mathbf{N}_{\geq t}\left(\operatorname{var}(z)\left(X_{z, \mathrm{xi}, \mathrm{y}}\right)>0 \wedge \operatorname{var}(z)\left(X_{z, \mathrm{xi}, \mathrm{a}}\right)>0\right)$. The correlation is lower because the independent-sample-distributed iso-independent conditional dependent multinomial space,

$$
X_{z, \mathrm{y}}(A)=-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{x}}, z\right)(A)}{\sum_{B \in Y_{U_{A}, \mathrm{i}, V_{A}, z}^{-1}\left(A^{\mathrm{x}}\right)} \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(B)}
$$

is not bounded by the alignment, $X_{z, \mathrm{a}}(A)=\operatorname{algn}(A)$. First, the upper bound, $\operatorname{algn}(A)+\ln \left|Y_{U_{A}, \mathrm{i}, V_{A}, z}^{-1}\left(A^{\mathrm{X}}\right)\right|$, of the alignment-bounded iso-independent space, $X_{z, \mathrm{xi}, \mathrm{y}}(A)=\left(X_{z, \mathrm{y}}(A): A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right)$, may be exceeded because non-integral independents are excluded from the minimum alignment conjecture. So, in some cases the alignment of an iso-independent histogram $B \in Y_{U_{A}, i, V_{A}, z}^{-1}\left(A^{\mathrm{X}}\right)$ may be negative

$$
\operatorname{algn}(B)<0 \Longrightarrow \frac{\prod_{S \in A^{\mathrm{xS}}} \Gamma_{!} A_{S}^{\mathrm{X}}}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}>1
$$

and thus in some cases

$$
\ln \sum_{B \in Y_{U_{A}, i, V_{A}, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{\prod_{S \in A^{\mathrm{XS}}} \Gamma_{!} A_{S}^{\mathrm{X}}}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}>\ln \left|Y_{U_{A}, \mathrm{i}, V_{A}, z}^{-1}\left(A^{\mathrm{X}}\right)\right|
$$

Second, the lower bound, $\operatorname{algn}(A)$, of the alignment-bounded iso-independent space, $X_{z, \mathrm{xi}, \mathrm{y}}(A)$, may not be reached in some other cases because the nonintegral independent is not an iso-independent, $A^{\mathrm{X}} \notin Y_{U_{A}, \mathrm{i}, V_{A}, z}^{-1}\left(A^{\mathrm{X}}\right)$, and hence there does not necessarily exist a term in

$$
\sum_{B \in Y_{U_{A}, i, V_{A}, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{\prod_{S \in A^{\mathrm{xS}}} \Gamma_{!} A_{S}^{\mathrm{X}}}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}
$$

which is equal to 1 . Thus in some cases

$$
\ln \sum_{B \in Y_{U_{A}, i, V_{A}, z}^{-1}\left(A^{\mathrm{X}}\right)} \frac{\prod_{S \in A^{\mathrm{XS}}} \Gamma_{!} A_{S}^{\mathrm{X}}}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}<0
$$

### 4.19.2 Iso-transform-independent conditional

Define the independent-sample-distributed iso-transform-independent conditional dependent multinomial space substrate transform search set, for some size $z, X_{z, \mathrm{~T}, \mathrm{y}} \in \mathcal{A}_{z} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow \ln \mathbf{Q}_{>0}\right)$, and for some $A \in \mathcal{A}_{z}$ define $X_{z, \mathrm{~T}, \mathrm{y}}(A) \in$ $\mathcal{T}_{U_{A}, V_{A}} \rightarrow \ln \mathbf{Q}_{>0}$ as

$$
X_{z, \mathrm{~T}, \mathrm{y}}(A)=\left\{\left(T,-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{x}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(B)}\right): T \in \mathcal{T}_{U_{A}, V_{A}}\right\}
$$

where the integral iso-transform-independents is abbreviated

$$
\begin{aligned}
\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A) & =Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \\
& =\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{x}} * T=A^{\mathrm{x}} * T,(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}\right\}
\end{aligned}
$$

and the substrate transforms set is defined

$$
\mathcal{T}_{U, V}=\left\{F^{\mathrm{T}}: F \subseteq\left\{P^{\mathrm{T}}: P \in \mathrm{~B}\left(V^{\mathrm{CS}}\right)\right\}\right\}
$$

In the case where (i) the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, and (ii) the formal independent histogram equals the abstract histogram, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=$
$(A * T)^{\mathrm{X}}$, which together imply that the independent is in the integral iso-transform-independents,

$$
\left(A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right) \wedge\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}\right) \Longrightarrow A^{\mathrm{X}} \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)
$$

the independent-sample-distributed iso-transform-independent conditional dependent multinomial space can be expressed in terms of the alignment,

$$
\begin{aligned}
& \left(X_{z, \mathrm{~T}, \mathrm{y}}(A)(T): A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}},\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}\right) \\
= & \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(B)}: A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}},\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}\right) \\
= & \operatorname{algn}(A)+\ln \sum_{B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)} \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(B)}{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}
\end{aligned}
$$

As conjectured above, in 'Derived alignment and conditional probability', given the integral mean multinomial probability distribution conjecture, the independent-sample-distributed iso-transform-independent conditional dependent multinomial space is bounded,

$$
\begin{aligned}
& \operatorname{algn}(A) \\
\leq & \operatorname{algn}(A)+\ln \sum_{B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)} \\
\leq & \operatorname{algn}(A)+\ln \left|\hat{Q}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)\right|
\end{aligned}
$$

Let the independent-sample-distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate independent-formalabstract transform search set, which is constrained such that (i) $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$ and (ii) $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$, be defined $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}} \in \mathcal{A}_{z, \mathrm{xi}} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow \ln \mathbf{Q}_{>0}\right)$, and for some $A \in \mathcal{A}_{z, \mathrm{xi}}$ define $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}}(A) \in \mathcal{T}_{U_{A}, V_{A}} \rightarrow \ln \mathbf{Q}_{>0}$ as
$X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}}(A)=\left\{(T, y):(T, y) \in X_{z, \mathrm{~T}, \mathrm{y}}(A), A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}},\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}\right\}$
Conjecture that, given these constraints, the independent-sample-distributed iso-transform-independent conditional dependent multinomial space integralindependent substrate independent-formal-abstract transform minimum function, minr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}}$, is correlated with the alignment integral-independent substrate function, $X_{z, \mathrm{xi}, \mathrm{a}}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{minr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{xfa}}, X_{z, \mathrm{xi}, \mathrm{a}}\right) \geq 0\right)
$$

As shown in section 'Derived alignment and conditional probability', above, the iso-transform-independent conditional dependent multinomial probability
for the self partition transform case, for example $T_{\mathrm{s}}=V_{A}^{\mathrm{CS}\{ \} \mathrm{T}} \in \mathcal{T}_{U_{A}, V_{A}}$, or the value full functional transform case, for example $T_{\mathrm{s}}=\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}\right.$ : $\left.w \in V_{A}\right\}^{\mathrm{T}} \in \mathcal{T}_{U_{A}, V_{A}}$, is greater than or equal to that for the unary partition transform case, $T_{\mathrm{u}}=\left\{V_{A}^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U_{A}, V_{A}}$,

$$
\frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{s}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(B)} \geq \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(B)}
$$

and hence the independent-sample-distributed iso-transform-independent conditional dependent multinomial space of the self partition case, $T_{\mathrm{s}}$, is less than or equal to that of the unary partition transform case, $T_{\mathrm{u}}$,

$$
-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{s}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B)} \leq-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B)}
$$

So, to the degree that the minimum transforms, $\operatorname{mind}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}}(A)\right) \subset$ $\mathcal{T}_{U_{A}, V_{A}}$, tend to be closer to self partition transforms, $T_{\mathrm{s}}$, rather than to the unary partition transforms, $T_{\mathrm{u}}$, the correlation between minro $X_{z, \mathrm{x}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}}$ and $X_{z, \mathrm{xi}, \mathrm{a}}$ is similar to that between $X_{z, \mathrm{xi}, \mathrm{y}}$ and $X_{z, \mathrm{xi}, \mathrm{a}}$. In the special case that the self partition is a minimum transform, $T_{\mathrm{s}} \in \operatorname{mind}\left(X_{z, \mathrm{x}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}}(A)\right)$, the set of integral iso-transform-independents equals the set of integral isoindependents, $\mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T_{s}, z}(A)=Y_{U_{A}, \mathrm{i}, V_{A}, z}^{-1}\left(A^{\mathrm{X}}\right)$ and hence

$$
\begin{aligned}
& T_{\mathrm{s}} \in \operatorname{mind}\left(X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{xfa}}(A)\right) \Longrightarrow \\
& \quad \operatorname{minr}\left(X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{xfa}}(A)\right)=X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{xfa}}(A)\left(T_{\mathrm{s}}\right)=X_{z, \mathrm{xi}, \mathrm{y}}(A)
\end{aligned}
$$

Consider, in contrast, the transform maximum function. The independent-sample-distributed iso-transform-independent conditional dependent multinomial probability

$$
\frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(B)}
$$

is always least where the transform is a unary partition, $T_{\mathrm{u}}=\left\{V_{A}^{\mathrm{CS}}\right\}^{\mathrm{T}} \in$ $\mathcal{T}_{U_{A}, V_{A}}$, because the set of integral iso-transform-independents equals the integral congruent support, $\mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}(A)=\mathcal{A}_{U_{A}, \mathrm{i}, V_{A}, z}$. The maximum counterpart, the independent-sample-distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate independent-formal-abstract transform maximum function, maxro $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}}$, is such that
$T_{\mathrm{u}} \in \operatorname{maxd}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}}(A)\right)$. The maximum function simply equals the generalised multinomial space,

$$
\begin{aligned}
\operatorname{maxr}\left(X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{xfa}}(A)\right) & =-\ln \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(A) \\
& =-\ln \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}}\left(\frac{A_{S}^{\mathrm{X}}}{z}\right)^{A_{S}} \\
& =\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!-\sum_{S \in A^{\mathrm{S}}} A_{S} \ln A_{S}^{\mathrm{X}}+z \ln z-\ln z! \\
& =\operatorname{algn}(A)-\sum_{S \in A^{\mathrm{S}}} A_{S} \ln A_{S}^{\mathrm{X}}+\sum_{S \in A^{\mathrm{XS}}} \ln A_{S}^{\mathrm{X}}!+z \ln z-\ln z!
\end{aligned}
$$

Therefore it is correlated with the alignment integral-independent substrate function

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{xfa}}, X_{z, \mathrm{xi}, \mathrm{a}}\right) \geq 0\right)
$$

but the correlation is lower
$\forall z \in \mathbf{N}_{\geq t}\left(\operatorname{corr}(z)\left(\operatorname{minro} X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}}, X_{z, \mathrm{xi}, \mathrm{a}}\right) \geq \operatorname{corr}(z)\left(\operatorname{maxro} X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}}, X_{z, \mathrm{xi}, \mathrm{a}}\right)\right)$
where the threshold $t \in \mathbf{N}_{>0}$ is the minimum size such that the variances are non-zero, $\forall z \in \mathbf{N}_{\geq t} \forall F \in\left\{\operatorname{minro} X_{z, \mathrm{x}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}}, \operatorname{maxro} X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}}, X_{z, \mathrm{xi}, \mathrm{a}}\right\}(\operatorname{var}(z)(F)>$ $0)$.

Conjecture that the transform minimum function correlation between the independent-sample-distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate independent-formalabstract transform minimum function, minr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}}$, and the alignment integral-independent substrate function, $X_{z, \mathrm{xi}, \mathrm{a}}$, is less than the corresponding correlation between the alignment-bounded iso-independent space substrate function, $X_{z, \mathrm{xi}, \mathrm{y}}$, and the alignment integral-independent substrate function, $X_{z, \mathrm{xi}, \mathrm{a}}$

$$
\forall z \in \mathbf{N}_{\geq t}\left(\operatorname{corr}(z)\left(X_{z, \mathrm{xi}, \mathrm{y}}, X_{z, \mathrm{xi}, \mathrm{a}}\right) \geq \operatorname{corr}(z)\left(\operatorname{minr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{xfa}}, X_{z, \mathrm{xi}, \mathrm{a}}\right)\right)
$$

where the threshold $t \in \mathbf{N}_{>0}$ is the minimum size such that the variances are non-zero, $\forall z \in \mathbf{N}_{\geq t} \forall F \in\left\{\operatorname{minr} \circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}}, X_{z, \mathrm{xi}, \mathrm{y}}, X_{z, \mathrm{xi}, \mathrm{a}}\right\}(\operatorname{var}(z)(F)>0)$.

Extending the transform minimum function correlation to the cases where the independent is not necessarily integral and hence not in the integral iso-transform-independents, conjecture that the independent-sample-distributed iso-transform-independent conditional dependent multinomial space substrate
transform minimum function, minr $\circ X_{z, \mathrm{~T}, \mathrm{y}}$, is correlated with the alignment substrate function,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{minr} \circ X_{z, \mathrm{~T}, \mathrm{y}}, X_{z, \mathrm{a}}\right) \geq 0\right)
$$

but conjecture that this correlation is less than the corresponding constrained correlation
$\forall z \in \mathbf{N}_{\geq t}\left(\operatorname{corr}(z)\left(\operatorname{minr} \circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}}, X_{z, \mathrm{xi}, \mathrm{a}}\right) \geq \operatorname{corr}(z)\left(\operatorname{minr} \circ X_{z, \mathrm{~T}, \mathrm{y}}, X_{z, \mathrm{a}}\right)\right)$
above the variance threshold size $t$.
Also conjecture that this correlation is less than the corresponding correlation between the independent-sample-distributed iso-independent conditional dependent multinomial space substrate function, $X_{z, y}$, and the alignment substrate function, $X_{z, \mathrm{a}}$

$$
\forall z \in \mathbf{N}_{\geq t}\left(\operatorname{corr}(z)\left(X_{z, \mathrm{y}}, X_{z, \mathrm{a}}\right) \geq \operatorname{corr}(z)\left(\operatorname{minr} \circ X_{z, \mathrm{~T}, \mathrm{y}}, X_{z, \mathrm{a}}\right)\right)
$$

above the variance threshold size $t$.

Consider a stricter case of the independent-sample-distributed iso-transformindependent conditional dependent multinomial space integral-independent substrate independent-formal-abstract transform search set, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}}$, which is also constrained such that the transforms are ideal. That is, given constraints (i) $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, (ii) $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$, and (iii) $A=A * T * T^{\dagger A}$, define the independent-sample-distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate ideal independent formal-abstract transform search set $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}, \mathrm{j}} \in \mathcal{A}_{z, \mathrm{xi}} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow\right.$ $\ln \mathbf{Q}_{>0}$ ), and for some $A \in \mathcal{A}_{z, \mathrm{xi}}$ define $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}, \mathrm{j}}(A) \in \mathcal{T}_{U_{A}, V_{A}} \rightarrow \ln \mathbf{Q}_{>0}$ as

$$
X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{xfa}, \mathrm{j}}(A)=\left\{(T, y):(T, y) \in X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{xfa}}(A), A=A * T * T^{\dagger A}\right\}
$$

Conjecture that the independent-sample-distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate ideal independent-formal-abstract transform maximum function, maxro $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}, \mathrm{j}}$, is better correlated with the alignment integral-independent substrate function, $X_{z, \mathrm{xi}, \mathrm{a}}$, than the case where non-ideal transforms are allowed
$\forall z \in \mathbf{N}_{\geq t}\left(\operatorname{corr}(z)\left(\operatorname{maxro} X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}, \mathrm{j}}, X_{z, \mathrm{xi}, \mathrm{a}}\right) \geq \operatorname{corr}(z)\left(\operatorname{maxro} X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}}, X_{z, \mathrm{xi}, \mathrm{a}}\right)\right)$
above the variance threshold size $t$. Here it is no longer the case that the unary partition transform, $T_{\mathrm{u}}=\left\{V_{A}^{\mathrm{CS}}\right\}^{\mathrm{T}}$, necessarily has the minimum probability and hence the maximum space. It is only for the independent sample,
$A=A^{\mathrm{X}}$, that the unary partition transform is ideal, ideal $\left(A^{\mathrm{X}}, T_{\mathrm{u}}\right)$.
Extending the ideal transform search set to the cases where the independent is not necessarily integral and hence not in the integral iso-transformindependents, define the independent-sample-distributed iso-transform independent conditional dependent multinomial space substrate ideal transform search set $X_{z, \mathrm{~T}, \mathrm{y}, \mathrm{j}} \in \mathcal{A}_{z} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow \ln \mathbf{Q}_{>0}\right)$, and for some $A \in \mathcal{A}_{z}$ define $X_{z, \mathrm{~T}, \mathrm{y}, \mathrm{j}}(A) \in \mathcal{T}_{U_{A}, V_{A}} \rightarrow \ln \mathbf{Q}_{>0}$ as

$$
\begin{aligned}
X_{z, \mathrm{~T}, \mathrm{y}, \mathrm{j}}(A)= & \left\{(T, y):(T, y) \in X_{z, \mathrm{~T}, \mathrm{y}}(A), A=A * T * T^{\dagger A}\right\} \\
= & \left\{\left(T,-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(B)}\right):\right. \\
& \left.T \in \mathcal{T}_{U_{A}, V_{A}}, A=A * T * T^{\dagger A}\right\}
\end{aligned}
$$

Conjecture that the independent-sample-distributed iso-transform-independent conditional dependent multinomial space substrate ideal transform maximum function, maxr $\circ X_{z, \mathrm{~T}, \mathrm{y}, \mathrm{j}}$, is correlated with the alignment substrate function,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{~T}, \mathrm{y}, \mathrm{j}}, X_{z, \mathrm{a}}\right) \geq 0\right)
$$

Certainly it is still the case that where the maximum transform is a self partition transform or a value full functional, the set of integral iso-transformindependents equals the set of integral iso-independents, $\mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T_{s}, z}(A)=$ $Y_{U_{A}, \mathrm{i}, V_{A}, z}^{-1}\left(A^{\mathrm{X}}\right)$, and so $X_{z, \mathrm{~T}, \mathrm{y}, \mathrm{j}}(A)\left(T_{\mathrm{s}}\right)=X_{z, \mathrm{y}}(A)$. Even so, conjecture that this correlation is less than the corresponding correlation between the independent-sample-distributed iso-independent conditional dependent multinomial space substrate function, $X_{z, \mathrm{y}}$, and the alignment substrate function, $X_{z, \mathrm{a}}$

$$
\forall z \in \mathbf{N}_{\geq t}\left(\operatorname{corr}(z)\left(X_{z, \mathrm{y}}, X_{z, \mathrm{a}}\right) \geq \operatorname{corr}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{~T}, \mathrm{y}, \mathrm{j}}, X_{z, \mathrm{a}}\right)\right)
$$

above the variance threshold size $t$.

Alignment, $X_{z, \mathrm{a}}$, by itself is a weaker proxy for the iso-transform independent case, maxr $\circ X_{z, \mathrm{~T}, \mathrm{y}, \mathrm{j}}$, than for the iso-independent case, $X_{z, \mathrm{y}}$, because the alignment expression does not depend on transform. To obtain a better correlated expression in terms of derived alignment, idealised alignment and actualised alignment, consider the lifted case.

Define the derived alignment substrate transform search set, for some size $z, X_{z, \mathrm{~T}, \mathrm{a}}^{\prime} \in \mathcal{A}_{z} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow \mathbf{R}\right)$, and for some $A \in \mathcal{A}_{z}$ define $X_{z, \mathrm{~T}, \mathrm{a}}^{\prime}(A) \in$ $\mathcal{T}_{U_{A}, V_{A}} \rightarrow \mathbf{R}$ as

$$
X_{z, \mathrm{~T}, \mathrm{a}}^{\prime}(A)=\left\{(T, \operatorname{algn}(A * T)): T \in \mathcal{T}_{U_{A}, V_{A}}\right\}
$$

In terms of the multinomial probability density function, $\operatorname{mpdf}(U)(E, z) \in$ $\mathcal{A}_{U, V, z} \rightarrow \mathbf{R}_{\geq 0}$, the derived alignment substrate transform search set is

$$
X_{z, \mathrm{~T}, \mathrm{a}}^{\prime}(A)=\left\{\left(T,-\ln \frac{\operatorname{mpdf}\left(U_{A}\right)\left((A * T)^{\mathrm{X}}, z\right)(A * T)}{\operatorname{mpdf}\left(U_{A}\right)\left((A * T)^{\mathrm{X}}, z\right)\left((A * T)^{\mathrm{X}}\right)}\right): T \in \mathcal{T}_{U_{A}, V_{A}}\right\}
$$

Define the derived alignment integral-independent substrate transform search set as $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}}^{\prime}=\operatorname{filter}\left(\mathcal{A}_{z, \mathrm{xi}}, X_{z, \mathrm{~T}, \mathrm{a}}^{\prime}\right) \subset X_{z, \mathrm{~T}, \mathrm{a}}^{\prime}$, which is such that $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}}^{\prime} \in$ $\mathcal{A}_{z, \mathrm{xi}} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow \mathbf{R}\right)$.

Define the derived alignment integral-independent substrate formal-abstract transform search set, which is constrained such that (i) the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$ and (ii) the formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, for some size $z, X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}}^{\prime} \in \mathcal{A}_{z, \mathrm{xi}} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow \ln \mathbf{Q}_{>0}\right)$, and for some $A \in \mathcal{A}_{z, \mathrm{xi}}$ define $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}}^{\prime}(A) \in \mathcal{T}_{U_{A}, V_{A}} \rightarrow \ln \mathbf{Q}_{>0}$ as

$$
\begin{aligned}
X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}}^{\prime}(A) & =\left\{(T, \operatorname{algn}(A * T)): T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{x}}\right\} \\
& =\left\{(T, a):(T, a) \in X_{z, \mathrm{~T}, \mathrm{a}}^{\prime}(A), A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right\}
\end{aligned}
$$

The independent is integral and the formal histogram equals the abstract histogram, so the independent derived histogram, or abstract histogram, must be integral, $\left(A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right) \wedge\left(A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right) \Longrightarrow(A * T)^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$. Thus the derived alignment integral-independent substrate formal-abstract transform search set can be defined in terms of the rational generalised multinomial probability distribution $\hat{Q}_{\mathrm{m}, U}(E, z) \in\left(\mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$

$$
\begin{aligned}
& X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}}^{\prime}(A)= \\
& \quad\left\{\left(T,-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left((A * T)^{\mathrm{X}}, z\right)(A * T)}{\hat{Q}_{\mathrm{m}, U_{A}}\left((A * T)^{\mathrm{X}}, z\right)\left((A * T)^{\mathrm{X}}\right)}\right): T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right\}
\end{aligned}
$$

The derived alignment integral-independent substrate formal-abstract transform search set can also be defined as the lifted alignment integral-independent substrate formal-abstract transform search set

$$
\begin{aligned}
& X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}}^{\prime}(A)= \\
& \quad\left\{\left(T,-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}} * T, z\right)(A * T)}{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}} * T, z\right)\left(A^{\mathrm{X}} * T\right)}\right): T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right\}
\end{aligned}
$$

because lifted equals derived when the formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}} \Longrightarrow(A * T=(A * T)) \wedge\left(A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right)$.

Define the derived alignment integral-independent substrate ideal formal-abstract transform search set, which is additionally constrained such that (iii) the transform is ideal, $A=A * T * T^{\dagger A}$, for some size $z, X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime} \in \mathcal{A}_{z, \mathrm{xi}} \rightarrow$ $\left(\mathcal{T}_{\mathrm{f}} \rightarrow \ln \mathrm{Q}_{>0}\right)$, and for some $A \in \mathcal{A}_{z, \mathrm{xi}}$ define $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}(A) \in \mathcal{T}_{U_{A}, V_{A}} \rightarrow$ $\ln \mathbf{Q}_{>0}$ as

$$
X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}(A)=\left\{(T, a):(T, a) \in X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}}^{\prime}(A), A=A * T * T^{\dagger A}\right\}
$$

Define the independent-sample-distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate formalabstract transform search set, which is constrained such that (i) the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, and (ii) the formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, for some size $z, X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}} \in \mathcal{A}_{z, \mathrm{xi}} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow\right.$ $\ln \mathbf{Q}_{>0}$ ), and for some $A \in \mathcal{A}_{z, \mathrm{xi}}$ define $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}(A) \in \mathcal{T}_{U_{A}, V_{A}} \rightarrow \ln \mathbf{Q}_{>0}$ as

$$
\begin{aligned}
X_{z, \mathrm{x}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}(A) & =\left\{\left(T, X_{z, \mathrm{~T}, \mathrm{y}}(A)(T)\right): T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right\} \\
& =\left\{(T, y):(T, y) \in X_{z, \mathrm{~T}, \mathrm{y}}(A), A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right\}
\end{aligned}
$$

The independent-sample-distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate formal-abstract transform search set, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}(A)$, is a subset of the independent-sample-distributed iso-transform-independent conditional dependent multinomial space integralindependent substrate independent-formal-abstract transform search set,

$$
X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}(A) \subseteq X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{xfa}}(A)
$$

because the constraints of (i) integral independent, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$ and (ii) formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, imply that the formal independent histogram equals the abstract histogram, ( $A^{\mathrm{X}} *$ $T)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$, and the independent is an iso-transform-independent, $A^{\mathrm{X}} \in$ $\mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)$.

The independent-sample-distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate formal-abstract transform search set, $X_{z, \text { xi,T,y,fa }}$, can be abbreviated to the alignment-bounded isotransform space transform search set,

$$
\begin{aligned}
& X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}(A)(T) \\
= & \left(X_{z, \mathrm{~T}, \mathrm{y}}(A)(T): A^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{x}}\right) \\
= & \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{x}}, z\right)(B)}: A^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{x}} * T=(A * T)^{\mathrm{x}}\right)
\end{aligned}
$$

Note that 'alignment-bounded' is a misnomer. That is, the alignment-bounded iso-transform space, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}(A)(T)$, is not strictly bounded by alignment or derived alignment. However, its lifted counterpart, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}^{\prime}(A)(T)$, below, is bounded by derived alignment under the same constraints.

Define the independent-sample-distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate ideal formalabstract transform search set, which is additionally constrained such that (iii) the transform is ideal, $A=A * T * T^{\dagger A}$, for some size $z, X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}} \in \mathcal{A}_{z, \mathrm{xi}} \rightarrow$ $\left(\mathcal{T}_{\mathrm{f}} \rightarrow \ln \mathrm{Q}_{>0}\right)$, and for some $A \in \mathcal{A}_{z, \mathrm{xi}}$ define $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A) \in \mathcal{T}_{U_{A}, V_{A}} \rightarrow$ $\ln \mathbf{Q}_{>0}$ as

$$
X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)=\left\{(T, y):(T, y) \in X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}(A), A=A * T * T^{\dagger A}\right\}
$$

As for the ideal-agnostic case, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}(A)$, the independent-sample-distributed iso-transform-independent conditional dependent multinomial space integralindependent substrate ideal formal-abstract transform search set, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)$, is a subset of the corresponding ideal independent-formal-abstract transform search set, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A) \subseteq X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{xfa}, \mathrm{j}}(A)$.

The independent-sample-distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate ideal formal-abstract transform search set, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}$, can be abbreviated to the alignment-bounded iso-transform space ideal transform search set,

$$
\left.\begin{array}{rl} 
& X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)(T) \\
= & \left(X_{z, \mathrm{~T}, \mathrm{y}}(A)(T): A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{x}} * T=(A * T)^{\mathrm{X}}, A=A * T * T^{\dagger A} \in \mathcal{A}_{\mathrm{i}}\right) \\
= & \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)\left(A * T * T^{\dagger A}\right)}{\sum_{B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(B)}:\right. \\
& A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}, A * T * T^{\dagger A} \in \mathcal{A}_{\mathrm{i}}
\end{array}\right)
$$

Again, this is a misnomer. That is, the alignment-bounded iso-transform idealisation space, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)(T)$, is not strictly bounded by alignment or derived alignment. However, its lifted counterpart, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}^{\prime}(A)(T)$, below, is bounded by derived alignment under the same constraints.

Define the lifted independent-sample-distributed iso-transform-independent quasi-conditional dependent multinomial space substrate transform search set,
for some size $z, X_{z, \mathrm{~T}, \mathrm{y}}^{\prime} \in \mathcal{A}_{z} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow \ln \mathrm{Q}_{>0}\right)$, and for some $A \in \mathcal{A}_{z}$ define $X_{z, \mathrm{~T}, \mathrm{y}}^{\prime}(A) \in \mathcal{T}_{U_{A}, V_{A}} \rightarrow \ln \mathbf{Q}_{>0}$ as

$$
X_{z, \mathrm{~T}, \mathrm{y}}^{\prime}(A)=\left\{\left(T,-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}} * T, z\right)(A * T)}{\sum_{B^{\prime} \in \mathcal{A}_{U_{A}}^{\prime}, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}} * T, z\right)\left(B^{\prime}\right)\right): T \in \mathcal{T}_{U_{A}, V_{A}}\right\}
$$

where the lifted integral iso-transform-independents is abbreviated

$$
\begin{aligned}
\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A) & =\left\{B * T: B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right\} \\
& =\left\{B * T: B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right\} \\
& =\left\{B * T: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{X}} * T=A^{\mathrm{X}} * T,(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}\right\}
\end{aligned}
$$

In the case where (i) the independent is integral, $A^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}}$, and (ii) the formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, the lifted independent-sample-distributed iso-transform-independent quasi-conditional dependent multinomial space, $X_{z, \mathrm{~T}, \mathrm{y}}^{\prime}(A)(T)$, is the alignment-bounded lifted iso-transform space

$$
\left.\left.\begin{array}{rl} 
& \left(X_{z, \mathrm{~T}, \mathrm{y}}^{\prime}(A)(T): A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right) \\
= & \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{x}} * T, z\right)(A * T)}{\sum_{B^{\prime} \in \mathcal{A}^{\prime} U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}} * T, z\right)\left(B^{\prime}\right)\right.
\end{array}\right) . A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right) .
$$

As shown above, in 'Derived alignment and conditional probability', given the minimum alignment conjecture, the alignment-bounded lifted iso-transform space is bounded

$$
\begin{aligned}
& \operatorname{algn}(A * T) \\
& \leq\left(-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}} * T, z\right)(A * T)}{\sum_{B^{\prime} \in \mathcal{A}_{U_{A}}, \mathrm{i}, \mathrm{y}, T, z, z}(A)} \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}} * T, z\right)\left(B^{\prime}\right) \quad:\right. \\
& \left.A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{x}} * T=(A * T)^{\mathrm{x}}\right) \\
& \leq \operatorname{algn}(A * T)+\ln \left|\mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right|
\end{aligned}
$$

So conjecture that the lifted independent-sample-distributed iso-transformindependent quasi-conditional dependent multinomial space substrate transform maximum function, maxr $\circ X_{z, \mathrm{~T}, \mathrm{y}}^{\prime}$, is correlated with the derived alignment substrate transform maximum function, maxro $X_{z, \mathrm{~T}, \mathrm{a}}^{\prime}$, when constrained such that (i) $A^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}}$, (ii) $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$.

Define the lifted independent-sample-distributed iso-transform-independent quasi-conditional dependent multinomial space integral-independent substrate formal-abstract transform search set, also known as the alignment-bounded lifted iso-transform space transform search set, for some size $z, X_{z,, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}^{\prime} \in$ $\mathcal{A}_{z, \mathrm{xi}} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow \ln \mathbf{Q}_{>0}\right)$, and for some $A \in \mathcal{A}_{z, \mathrm{xi}}$ define $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}^{\prime}(A) \in$ $\mathcal{T}_{U_{A}, V_{A}} \rightarrow \ln \mathbf{Q}_{>0}$ as

$$
X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}^{\prime}(A)=\left\{\left(T, X_{z, \mathrm{~T}, \mathrm{y}}^{\prime}(A)(T)\right): T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right\}
$$

That is,

$$
X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}^{\prime}(A)(T)=\left(X_{z, \mathrm{~T}, \mathrm{y}}^{\prime}(A)(T): A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right)
$$

Then the correlation between the alignment-bounded lifted iso-transform space transform maximum function, maxr $\circ X_{z, \mathrm{x}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}^{\prime}$, and the derived alignment integral-independent substrate formal-abstract transform maximum function, $\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}}^{\prime}$, is such that

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}^{\prime}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}_{\mathrm{a}}}^{\prime}\right) \geq 0\right)
$$

The derived alignment is an underestimate of the alignment-bounded lifted iso-transform space and hence the expected maximum derived alignment must be less than or equal to the expected maximum alignment-bounded lifted iso-transform space for all sizes of substrate histograms

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{ex}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}^{\prime}\right) \geq \operatorname{ex}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}}^{\prime}\right)\right)
$$

This is derived from the expected maximum alignment-bounded lifted isotransform error

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{ex}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}^{\prime}-\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}}^{\prime}\right) \geq 0\right)
$$

which is related to the expected average alignment-bounded lifted iso-transform error

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{ex}(z)\left(\text { average } \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}^{\prime}-\text { average } \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}}^{\prime}\right) \geq 0\right)
$$

where the alignment-bounded lifted iso-transform error for substrate transform $T \in \mathcal{T}_{U_{A}, V_{A}}$ is

$$
X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}^{\prime}(A)(T)-X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}}^{\prime}(A)(T)=\ln \sum_{B^{\prime} \in \mathcal{A}^{\prime} U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A), ~ \frac{\prod_{R \in(A * T)^{\mathrm{xs}}}(A * T)_{R}^{\mathrm{X}!}}{\prod_{R \in B^{\prime \mathrm{S}}} B_{R}^{\prime}!}
$$

Now consider the correlation relationship between the alignment-bounded iso-transform space and its lifted counterpart, the alignment-bounded lifted iso-transform space. Conjecture that the alignment-bounded lifted iso-transform space transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{f} a}^{\prime}$, is correlated with the corresponding alignment-bounded iso-transform space transform maximum function, $\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}$

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}^{\prime}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}\right) \geq 0\right)
$$

Further, conjecture that the alignment-bounded lifted iso-transform space transform average function, average $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}^{\prime}$, is correlated with the corresponding alignment-bounded iso-transform space transform average function, average $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}$

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\text { average } \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}^{\prime}, \text { average } \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}\right) \geq 0\right)
$$

and that the average function correlation is greater than the maximum function correlation

$$
\begin{aligned}
\forall z \in & \mathbf{N}_{\geq t} \\
& \left(\operatorname{corr}(z)\left(\text { average } \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}^{\prime}, \text { average } \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}\right)\right. \\
\geq & \left.\operatorname{corr}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}^{\prime}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}\right)\right)
\end{aligned}
$$

above the variance threshold size $t$.
Noting that the domains of the transform functions are equal,

$$
\operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}^{\prime}(A)\right)=\operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}(A)\right)
$$

consider a transform $T \in \operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}(A)\right)$.
If the transform $T$ approximates more closely to the self partition transform, $T_{\mathrm{s}}=V_{A}^{\mathrm{CS}\{ \} \mathrm{T}} \in \mathcal{T}_{U_{A}, V_{A}}$, or the value full functional transform, $T_{\mathrm{s}}=$ $\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in V_{A}\right\}^{\mathrm{T}} \in \mathcal{T}_{U_{A}, V_{A}}$, than it does to the unary partition transform, $T_{\mathrm{u}}=\left\{V_{A}^{\mathrm{CS}}\right\}^{\mathrm{T}} \in \mathcal{T}_{U_{A}, V_{A}}$, then the alignment-bounded iso-transform space is approximately equal to the alignment-bounded lifted iso-transform space, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}(A)(T) \approx X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}^{\prime}(A)(T)$. In the self partition case, $T_{\mathrm{s}}$, the set of integral iso-transform-independents is bijective to the set of lifted integral iso-transform-independents, and so the alignment-bounded iso-transform space equals the alignment-bounded lifted iso-transform space,

$$
\begin{gathered}
-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U_{A}}, \mathrm{i}, \mathrm{y}, T_{\mathrm{s}}, z}(A)} \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(B) \\
= \\
-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}} * T_{\mathrm{s}}, z\right)\left(A * T_{\mathrm{s}}\right)}{\sum_{B^{\prime} \in \mathcal{A}^{\prime}{ }_{U_{A}, \mathrm{i},, T_{\mathrm{S}}, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}} * T_{\mathrm{s}}, z\right)\left(B^{\prime}\right)}
\end{gathered}
$$

That is, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}(A)\left(T_{\mathrm{s}}\right)=X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}^{\prime}(A)\left(T_{\mathrm{s}}\right)$.
If the transform $T$ approximates more closely to the unary partition transform, $T_{\mathrm{u}}$, then the relationship between the alignment-bounded lifted isotransform space, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}^{\prime}(A)(T)$, and the alignment-bounded iso-transform space, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}(A)(T)$, is weaker. The unary partition transform, $T_{\mathrm{u}} \in$ $\operatorname{maxd}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}(A)\right)$, has the largest alignment-bounded iso-transform space, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}(A)\left(T_{\mathrm{u}}\right)=-\ln \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(A)$, but the alignment-bounded lifted iso-transform space is zero, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}^{\prime}(A)\left(T_{\mathrm{u}}\right)=0$. Thus the maximum function correlation is lower than the average function correlation. In pluri-valent cases, the maximum transforms do not intersect,

$$
\operatorname{maxd}\left(X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}(A)\right) \cap \operatorname{maxd}\left(X_{z,, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}^{\prime}(A)\right)=\emptyset
$$

because $T_{\mathrm{u}} \notin \operatorname{maxd}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}^{\prime}(A)\right)$.
In spite of the relatively weak correlation between the alignment-bounded iso-transform space transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}$, and its lifted counterpart, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}^{\prime}$, conjecture that the alignment-bounded iso-transform space transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}$, is transitively correlated with the derived alignment integral-independent substrate formal-abstract transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}}^{\prime}\right) \geq 0\right)
$$

Define the lifted independent-sample-distributed iso-transform-independent quasi-conditional dependent multinomial space integral-independent substrate ideal formal-abstract transform search set, also known as the alignmentbounded lifted iso-transform space ideal transform search set, which is additionally constrained such that (iii) the transform is ideal, $A=A * T * T^{\dagger A}$, for some size $z, X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}^{\prime} \in \mathcal{A}_{z, \mathrm{xi}} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow \ln \mathbf{Q}_{>0}\right)$, and for some $A \in \mathcal{A}_{z, \mathrm{xi}}$ as $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}^{\prime}(A) \in \mathcal{T}_{U_{A}, V_{A}} \rightarrow \ln \mathrm{Q}_{>0}$ as

$$
X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}^{\prime}(A)=\left\{(T, y):(T, y) \in X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}^{\prime}(A), A=A * T * T^{\dagger A}\right\}
$$

Just as for the ideal-agnostic case, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}^{\prime}$, above, there is a correlation between the alignment-bounded lifted iso-transform space ideal transform maximum function, maxr $\circ X_{z, \mathrm{x}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}^{\prime}$, and the derived alignment integralindependent substrate ideal formal-abstract transform maximum function, $\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{x}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}^{\prime}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}\right) \geq 0\right)
$$

But in this ideal case the correlation between the alignment-bounded lifted iso-transform space ideal transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}^{\prime}$, and the alignment-bounded iso-transform space ideal transform maximum function, maxr $\circ X_{z, \text { xi, }, \mathrm{y}, \mathrm{fa}, \mathrm{j}}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{x}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}^{\prime}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}\right) \geq 0\right)
$$

is stronger than for the ideal-agnostic case

$$
\begin{aligned}
\forall z \in & \mathbf{N}_{\geq t} \\
& \left(\operatorname{corr}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}^{\prime}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}\right)\right. \\
\geq & \left.\operatorname{corr}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}^{\prime}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}\right)\right)
\end{aligned}
$$

The reason is that now a transform $T \in \operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)\right)$ that approximates more closely to the unary partition transform, $T_{\mathrm{u}}$, must be ideal which is the case only for the subset of substrate histograms that are nearly independent, $A \approx A^{\mathrm{X}}$. So the variance of maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}$ is less than that for $\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}$

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{var}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}\right) \geq \operatorname{var}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}\right)\right)
$$

The variance is also conjectured to be lower as a consequence of the idealisation perturbation conjecture. Let integral-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$ have alignment-bounded iso-transform space ideal maximum transform, $T_{\mathrm{y}} \in \operatorname{maxd}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)\right) \subset \mathcal{T}_{U_{A}, V_{A}}$, which is such that

$$
\operatorname{maxr}\left(X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{f}, \mathrm{j}}(A)\right)=X_{z, \mathrm{~T}, \mathrm{y}}(A)\left(T_{\mathrm{y}}\right)=X_{z, \mathrm{~T}, \mathrm{y}}\left(A * T_{\mathrm{y}} * T_{\mathrm{y}}^{\dagger A}\right)\left(T_{\mathrm{y}}\right)
$$

The idealisation perturbation conjecture states that of all the integral isoidealisations, $B \in Y_{U_{A}, \mathrm{i}, T_{\mathrm{y}}, \uparrow, z}^{-1}\left(A * T_{\mathrm{y}} * T_{\mathrm{y}}^{\dagger A}\right)$, which have the given alignmentbounded lifted iso-transform space,

$$
B * T_{\mathrm{y}}=A * T_{\mathrm{y}} \Longrightarrow X_{z, \mathrm{~T}, \mathrm{y}}^{\prime}(B)\left(T_{\mathrm{y}}\right)=X_{z, \mathrm{~T}, \mathrm{y}}^{\prime}(A)\left(T_{\mathrm{y}}\right)
$$

the integral sample idealisation, $B=A * T_{\mathrm{y}} * T_{\mathrm{y}}^{\dagger A}=A$, has the least alignmentbounded iso-transform space. The integral iso-idealisations are a subset of the integral-independent substrate histograms, $Y_{U_{A}, \mathrm{i}, T_{y}, \uparrow, z}^{-1}\left(A * T_{\mathrm{y}} * T_{\mathrm{y}}^{\dagger A}\right) \subset \mathcal{A}_{z, \mathrm{xi}}$. According to the idealisation perturbation conjecture, this subset is such that

$$
\forall B \in Y_{U_{A}, \mathrm{i}, T_{\mathrm{Y}}, \uparrow, z}^{-1}\left(A * T_{\mathrm{y}} * T_{\mathrm{y}}^{\dagger A}\right)\left(X_{z, \mathrm{~T}, \mathrm{y}}(B)\left(T_{\mathrm{y}}\right) \geq X_{z, \mathrm{~T}, \mathrm{y}}(A)\left(T_{\mathrm{y}}\right)\right)
$$

But the iso-independents cannot have the same maximum ideal transform, $B \neq A \Longrightarrow T_{\mathrm{y}} \notin \operatorname{maxd}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(B)\right)$. Let the maximum ideal transform
of the iso-independent $B$ be $T_{\mathrm{n}} \in \operatorname{maxd}\left(X_{z, \mathrm{x}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(B)\right) \subset \mathcal{T}_{U_{B}, V_{B}}=\mathcal{T}_{U_{A}, V_{A}}$. The set of transforms of $B$ which are such that the alignment-bounded isotransform space is greater than the alignment-bounded iso-transform maximum space of $A$ is

$$
\left\{T: T \in \operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}(B)\right), \quad X_{z, \mathrm{~T}, \mathrm{y}}(B)(T) \geq X_{z, \mathrm{~T}, \mathrm{y}}(A)\left(T_{\mathrm{y}}\right)\right\}
$$

But in order for the maximum transform of $B$ to have greater alignmentbounded iso-transform space than the alignment-bounded iso-transform maximum space of $A, X_{z, \mathrm{~T}, \mathrm{y}}(B)\left(T_{\mathrm{n}}\right) \geq X_{z, \mathrm{~T}, \mathrm{y}}(A)\left(T_{\mathrm{y}}\right)$, it must be a member of a subset of these which has cardinality of one less,

$$
\begin{aligned}
& X_{z, \mathrm{~T}, \mathrm{y}}(B)\left(T_{\mathrm{n}}\right) \geq X_{z, \mathrm{~T}, \mathrm{y}}(A)\left(T_{\mathrm{y}}\right) \Longrightarrow \\
& \quad T_{\mathrm{n}} \in\left\{T: T \in \operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}(B)\right), \quad X_{z, \mathrm{~T}, \mathrm{y}}(B)(T) \geq X_{z, \mathrm{~T}, \mathrm{y}}(A)\left(T_{\mathrm{y}}\right)\right\} \backslash\left\{T_{\mathrm{y}}\right\}
\end{aligned}
$$

Thus the maximum transform, $T_{\mathrm{n}}$, of the iso-independent, $B$, is weakly constrained by the idealisation perturbation conjecture. In the ideal-agnostic case, by contrast, the maximum transform for iso-independents subset of the integral-independent substrate histograms is always the unary partition transform, $T_{\mathrm{u}} \in \operatorname{maxd}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}}(B)\right)$, and so the ideal-agnostic transform maximum space correlation is sometimes lower.

Therefore, conjecture that the independent-sample-distributed iso-transformindependent conditional dependent multinomial space integral-independent substrate ideal formal-abstract transform maximum function, also known as the alignment-bounded iso-transform space ideal transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}$, is transitively correlated with the derived alignment integral-independent substrate ideal formal-abstract transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j},}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}\right) \geq 0\right)
$$

Conjecture, further, that this correlation is greater than the ideal-agnostic correlation

$$
\begin{aligned}
\forall z \in & \mathbf{N}_{\geq t} \\
& \left(\operatorname{corr}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ X_{z, \mathrm{x}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}\right)\right. \\
\geq & \left.\operatorname{corr}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}}^{\prime}\right)\right)
\end{aligned}
$$

above the variance threshold size $t$.

### 4.20 Computation of alignment

### 4.20.1 Alignmenter

Given a histogram $A \in \mathcal{A}$ consider the computation time to calculate its alignment $\operatorname{alignment}(A)$. Let $I_{\mathrm{a}}=\operatorname{alignmenter} \in \operatorname{computers}$, domain $\left(I_{\mathrm{a}}\right)=$ $\mathcal{A}$, range $\left(I_{\mathrm{a}}\right)=\mathbf{Q}$, and $\operatorname{apply}\left(I_{\mathrm{a}}\right)(A) \approx \operatorname{alignment}(A)$. The alignmenter relies on independenter $I_{\mathrm{X}}$ to calculate exactly the independent histogram $A^{\mathrm{X}}$. The alignmenter also delegates the calculation of the logarithm of the gamma function. In order for the alignmenter to have finite time, $I_{\mathrm{a}}^{\mathrm{t}}(A)<\infty$, the real log gamma function must be approximated to some rational, for example by means of the Stirling's approximation or the Lanczos approximation. Let $I_{\approx n!}=$ logfactorialer $\in$ computers be some implementation such that $\operatorname{domain}\left(I_{\approx \operatorname{nn}!}\right)=\mathbf{Q}_{\geq 0}$, range $\left(I_{\approx n!}\right)=\mathbf{Q}$, and $\operatorname{apply}\left(I_{\approx \ln !}\right)(x) \approx \ln \Gamma_{!} x$ and such that $\operatorname{apply}\left(I_{\approx \operatorname{nn}!}\right)(0)=\operatorname{apply}\left(I_{\approx n!}\right)(1)=0$. Then

$$
\begin{aligned}
& I_{\mathrm{a}}^{\mathrm{t}}(A)> \\
& \quad I_{\mathrm{X}}^{\mathrm{t}}(A)+\sum_{S \in A^{\mathrm{FS}}} I_{\approx \ln !}^{\mathrm{t}}\left(A_{S}\right)+\sum_{S \in A^{\mathrm{XFS}}} I_{\approx \ln !}^{\mathrm{t}}\left(A_{S}^{\mathrm{X}}\right)+\left(\left|A^{\mathrm{F}}\right|+\left|A^{\mathrm{XF}}\right|+1\right) I_{+}^{\mathrm{t}}(0,0)
\end{aligned}
$$

where $I_{+}=$adder. Reducing the independenter to its underlying adder and multiplier

$$
\begin{aligned}
& I_{\mathrm{a}}^{\mathrm{t}}(A)> \\
& \quad\left(\left|A^{\mathrm{F}}\right| n+\left|A^{\mathrm{XF}}\right|+1\right) I_{+}^{\mathrm{t}}(0,0)+\left|A^{\mathrm{XF}}\right| n I_{\times}^{\mathrm{t}}(1,1)+\left(\left|A^{\mathrm{F}}\right|+\left|A^{\mathrm{XF}}\right|\right) I_{\approx \ln !}^{\mathrm{t}}(1)
\end{aligned}
$$

where $V=\operatorname{vars}(A), n=|V|$ and $I_{\times}=$multiplier. If it is the case that the $\log$ factorialer has constant time, $\exists m \in \mathbf{N}_{>0}\left(I_{\approx \mathrm{nn}!}^{\mathrm{t}} \in \mathrm{O}(\mathbf{Q} \times\{1\}, m)\right)$, and if the histograms are implemented in an array histogram representation on ordered list state representations

$$
\exists m \in \mathbf{N}_{>0}\left(I_{\mathrm{a}}^{\mathrm{t}} \in \mathrm{O}\left(\left\{(A, n y): A \in \mathcal{A}, y=\left|A^{\mathrm{xF}}\right|, n=\mid \operatorname{vars}(A)\right\} \mid, m\right)\right)
$$

If $A$ is a regular histogram in a system $U$ of dimension $n=|V|$ and valency $\{d\}=\left\{\left|U_{w}\right|: w \in V\right\}$ for which the independent is completely effective, $A^{\mathrm{XF}}=A^{\mathrm{C}}$, then the alignmenter time is of the same complexity as the independenter time, $n d^{n}$.

If the independent is completely effective, $A^{\mathrm{XF}}=A^{\mathrm{C}}$, then the space complexity of an array histogram representation, $v$, is less than the space complexity of a binary map histogram representation, $v \ln v$, where volume $v=\left|A^{\mathrm{C}}\right|$.

### 4.20.2 Single state roll computers

Define the set of single state rolls rollStateSingles $\subset$ rolls as the subset of rolls that are singletons, rollStateSingles $=\{R: R \in$ rolls, $|R|=1\}$.

Consider the application of a single state roll $R \in$ rollStateSingles to a histogram $A$ and the computation time of the pair of the rolled histogram and independent rolled histogram $\left(A * R,(A * R)^{\mathrm{X}}\right)$ given the pair of the histogram and independent histogram $\left(A, A^{\mathrm{X}}\right)$ prior to rolling. All four histograms are implemented in array histogram representations on ordered list state representations. Let $I=$ rollStateSingler $(U) \in$ computers in system $U$ such that $\operatorname{range}(I)=\left\{\left(A, A^{\mathrm{X}}\right): A \in \mathcal{A}_{U}\right\} \subset \mathcal{A}_{U} \times \mathcal{A}_{U}$, and domain $(I)=$ $\left\{\left(R,\left(A, A^{\mathrm{X}}\right)\right): A \in \mathcal{A}_{U}, R \in A^{\mathrm{CS}} \rightarrow A^{\mathrm{CS}},|R|=1\right\} \subset$ rollStateSingles $\times$ range $(I)$ such that apply $(I)\left(\left(R,\left(A, A^{\mathrm{X}}\right)\right)\right)=\left(A * R,(A * R)^{\mathrm{X}}\right)$. Let $\{(S, T)\}=$ $R$. The rolled pair can be separated into mutable and immutable parts. Thus for the first of the pair

$$
A * R=\left\{(S, 0),\left(T, A_{S}+A_{T}\right)\right\}+\left(A \backslash\left\{\left(S, A_{S}\right),\left(T, A_{T}\right)\right\}\right)
$$

To calculate the mutable parts of the independent only those states that are incident on either of the source or target states need be considered. Let $B=\bigcup\{$ incidence $(A, S, i) \cup$ incidence $(A, T, i): i \in\{1 \ldots|V|\}\}$ and $B_{\mathrm{X}}=$ $\bigcup\left\{\right.$ incidence $\left(A^{\mathrm{X}}, S, i\right)$ Uincidence $\left.\left(A^{\mathrm{X}}, T, i\right): i \in\{1 \ldots|V|\}\right\}$. Then separating into mutable and immutable

$$
(A * R)^{\mathrm{X}}=\left(B_{\mathrm{X}}^{\mathrm{F}} \backslash(B * R)^{\mathrm{XF}}\right)^{\mathrm{Z}}+(B * R)^{\mathrm{X}}+\left(A^{\mathrm{X}} \backslash B_{\mathrm{X}}\right)
$$

In the special case where $A$ is a regular histogram of dimension $n=|V|$ and valency $d$, where $\{d\}=\left\{\left|U_{v}\right|: v \in V\right\}$, and where $A^{\mathrm{X}}$ is completely effective, $A^{\mathrm{XF}}=A^{\mathrm{C}}$, and where the source state $S$ and target state $T$ have no degree of incidence, $\{T\}^{\mathrm{U}} \in$ incidence $\left(V^{\mathrm{C}}, S, 0\right)$, then the subset $B_{\mathrm{X}}$ forms a cartesian sub-volume of cardinality $d^{n}-(d-2)^{n}$ where $d \geq 2$. Compare this to the independenter $I_{\mathrm{X}} \in$ computers that calculates the independent histogram, $\operatorname{domain}\left(I_{\mathrm{X}}\right)=\operatorname{range}\left(I_{\mathrm{X}}\right)=\mathcal{A}$ and $\operatorname{apply}\left(I_{\mathrm{X}}\right)(A)=A^{\mathrm{X}}$, also implemented in the array histogram representation. As conjectured above, $I_{\mathrm{X}}$ has time complexity of $n y$ where $n=|\operatorname{vars}(A)|$ and $y$ is the effective independent cartesian sub-volume $y=\left|A^{\mathrm{XF}}\right|$. If $A \in \operatorname{dom}\left(\mathcal{O}_{U, z}\right)$ then $A^{\mathrm{X}}$ is completely effective and hence $y=\left|V^{\mathrm{C}}\right|=d^{n}$ in the case of the regular histogram. In this case the part of the computation time $I^{\mathrm{t}}\left(\left(R,\left(A, A^{\mathrm{X}}\right)\right)\right)$ for the independent rolled histogram is a fraction $\left(d^{n}-(d-2)^{n}\right) / d^{n}=1-(1-2 / d)^{n}$ of the time of the independenter $I_{\mathrm{X}}^{\mathrm{t}}(A * R)$. In other words, the roll only needs time $I_{\mathrm{X}}^{\mathrm{t}}(B * R)$ to calculate the independent rolled histogram as though $A$
was equal to its subset $B$ which corresponds to the cartesian sub-volume $B_{\mathrm{X}}$ of the independent $A^{\mathrm{X}}$ incident on the source or target states. This subset requires time complexity $n d^{n}-n(d-2)^{n}$. Given that the calculation of the rolled histogram requires only one addition and one reset then

$$
I^{\mathrm{t}}\left(\left(R,\left(A, A^{\mathrm{X}}\right)\right)\right)>I_{0}^{\mathrm{t}}(1)+I_{+}^{\mathrm{t}}(0,0)+\left|B_{\mathrm{X}}^{\mathrm{F}} \backslash(B * R)^{\mathrm{XF}}\right| I_{0}^{\mathrm{t}}(1)+I_{\mathrm{X}}^{\mathrm{t}}(B * R)
$$

where $I_{0}=$ resetter $\in$ computers and $I_{+}=$adder $\in$ computers. Conjecture that the overall time complexity is $n d^{n}-n(d-2)^{n}$.

Note that the roll computers are here defined such that the operations are in-place mutations to the array histogram representation. That is, the roll computers conclude the computations with list setter $I_{\mathrm{L}, \mathrm{s}}$ operations on the array representation. The implicit update to array has time complexity of the ordered list indexer, $n$, so the overall complexity is unchanged. Thus the domain of the roll computers is the roll crossed with the range. Contrast this to other computers, such as the independenter, which are defined here such that time of the implementation implies an instantiation of the array. Roll computers compute the roll by resetting and adding regardless of the effectiveness of the argument, whereas the independenter need only compute where effective. On the other hand, the independenter requires time for the cost of instantiation.

### 4.20.3 Value roll computers

Consider the application of a value roll $(V, v, s, t) \in \operatorname{rollValues}(U)$ in system $U$ to a histogram $A \in \mathcal{A}_{U}$ having variables $V=\operatorname{vars}(A)$, and the computation time of the pair of (i) the rolled histogram $A *(V, v, s, t)^{\mathrm{R}}$, and the (ii) the independent rolled histogram $\left(A *(V, v, s, t)^{\mathrm{R}}\right)^{\mathrm{X}}$, given the corresponding pair prior to rolling, $\left(A, A^{\mathrm{X}}\right)$, where all histograms are implemented in array histogram representations on ordered list state representations.

Let $I_{\mathrm{R}}=$ rollValuer $\in$ computers such that range $\left(I_{\mathrm{R}}\right) \subset \mathcal{A} \times \mathcal{A}$ is defined $\operatorname{range}\left(I_{\mathrm{R}}\right)=\left\{\left(A, A^{\mathrm{X}}\right): A \in \mathcal{A}\right\}$ and domain $\left(I_{\mathrm{R}}\right) \subset \bigcup\{$ rollValues $(U): U \in$ $\mathcal{U}\} \times$ range $\left(I_{\mathrm{R}}\right)$ is defined domain $\left(I_{\mathrm{R}}\right)=\left\{\left((V, v, s, t),\left(A, A^{\mathrm{X}}\right): U \in \mathcal{U}, A \in\right.\right.$ $\left.\mathcal{A}_{U},(V, v, s, t) \in \operatorname{rollValues}(U), V=\operatorname{vars}(A)\right\}$, such that

$$
\operatorname{apply}\left(I_{\mathrm{R}}\right)\left(\left((V, v, s, t),\left(A, A^{\mathrm{X}}\right)\right)\right)=\left(A *(V, v, s, t)^{\mathrm{R}},\left(A *(V, v, s, t)^{\mathrm{R}}\right)^{\mathrm{X}}\right)
$$

The independent rolled histogram equals the rolled independent histogram $\left(A *(V, v, s, t)^{\mathrm{R}}\right)^{\mathrm{X}}=A^{\mathrm{X}} *(V, v, s, t)^{\mathrm{R}}$, so only those states that reduce to either of the source or target states, $\{(v, s)\}$ or $\{(v, t)\}$, are changed by the value
roll, states $\left(A *\{\{(v, s)\},\{(v, t)\}\}^{\mathrm{U}}\right)$ and $\operatorname{states}\left(A^{\mathrm{X}} *\{\{(v, s)\},\{(v, t)\}\}^{\mathrm{U}}\right)$. In the case where the source and target values differ, $s \neq t$, the mutable and immutable parts of the application of the value roll $(V, v, s, t)$ to the histogram $A$ can be separated out

$$
\begin{aligned}
A *(V, v, s, t)^{\mathrm{R}}= & \left(A *\{\{(v, s)\}\}^{\mathrm{U}}\right)^{\mathrm{Z}}+ \\
& A *\{\{(v, t)\}\}^{\mathrm{U}}+ \\
& \left\{(S \backslash\{(v, s)\} \cup\{(v, t)\}, c):(S, c) \in A *\{\{(v, s)\}\}^{\mathrm{U}}\right\}+ \\
& \left(A \backslash\left(A *\{\{(v, s)\},\{(v, t)\}\}^{\mathrm{U}}\right)\right)
\end{aligned}
$$

Similarly the mutable and immutable parts of the application of the value roll $(V, v, s, t)$ to the independent $A^{\mathrm{X}}$ can be separated out where $s \neq t$

$$
\begin{aligned}
A^{\mathrm{X}} *(V, v, s, t)^{\mathrm{R}}= & \left(A^{\mathrm{X}} *\{\{(v, s)\}\}^{\mathrm{U}}\right)^{\mathrm{Z}}+ \\
& A^{\mathrm{X}} *\{\{(v, t)\}\}^{\mathrm{U}}+ \\
& \left\{(S \backslash\{(v, s)\} \cup\{(v, t)\}, c):(S, c) \in A^{\mathrm{X}} *\{\{(v, s)\}\}^{\mathrm{U}}\right\}+ \\
& \left(A^{\mathrm{X}} \backslash\left(A^{\mathrm{X}} *\{\{(v, s)\},\{(v, t)\}\}^{\mathrm{U}}\right)\right)
\end{aligned}
$$

The time is thus constrained to have a lower bound

$$
\begin{aligned}
I_{\mathrm{R}}^{\mathrm{t}}\left(\left((V, v, s, t),\left(A, A^{\mathrm{X}}\right)\right)\right) & >4 x\left(I_{\mathrm{S}, \mathrm{o}}^{\mathrm{t}}(\cdot)+I_{\mathrm{L}, \mathrm{~g}}^{\mathrm{t}}(\cdot)\right)+2 x I_{+}^{\mathrm{t}}(\cdot)+4 x\left(J_{\mathrm{S}, \mathrm{o}}^{\mathrm{t}}(\cdot)+I_{\mathrm{L}, \mathrm{~s}}^{\mathrm{t}}(\cdot)\right) \\
& >4 x I_{\mathrm{L}, \mathrm{~g}}^{\mathrm{t}}(\cdot)+8 n x I_{\mathrm{x}}^{\mathrm{t}}(\cdot)+2 x(4 n+1) I_{+}^{\mathrm{t}}(\cdot)+4 x I_{\mathrm{L}, \mathrm{~s}}^{\mathrm{t}}(\cdot)
\end{aligned}
$$

where $x=\left|V^{\mathrm{C}}\right| /\left|U_{v}\right|=\left|V^{\mathrm{C}} *\{\{(v, s)\}\}^{\mathrm{U}}\right|=\left|V^{\mathrm{C}} *\{\{(v, t)\}\}^{\mathrm{U}}\right|$ is the cardinality of the volumes incident on $\{(v, s)\}$ and on $\{(v, t)\}$, and $I_{\mathrm{L}, \mathrm{g}}$ and $I_{\mathrm{L}, \mathrm{s}}$ are the list getter and setter, and $I_{\mathrm{S}, \mathrm{o}}$ and $J_{\mathrm{S}, \mathrm{o}}$ are the state ordered indexer and its inverse.

In the special case where $A$ is a regular histogram of dimension $n=|V|$ and valency $d$, where $\{d\}=\left\{\left|U_{w}\right|: w \in V\right\}$, then the incident sub-volume has cardinality $x=\left|\operatorname{incidence}\left(V^{\mathrm{C}},\{(v, t)\}, 1\right)\right|=d^{n-1}$, so the complexity is $n d^{n-1}$. This complexity of time is less than or equal to that for the single state roller and for the independenter, $n d^{n-1} \leq n\left(d^{n}-(d-2)^{n}\right) \leq n d^{n}$.

Consider the application of a value roll $(V, v, s, t) \in \operatorname{rollValues}(U)$ in system $U$ to a histogram $A \in \mathcal{A}_{U}$, having variables $V=\operatorname{vars}(A)$, and the computation time of a triple of (i) an approximation to the rolled alignment $\operatorname{algn}\left(A *(V, v, s, t)^{\mathrm{R}}\right)$, (ii) the rolled histogram $A *(V, v, s, t)^{\mathrm{R}}$, and (iii) the independent rolled histogram $\left(A *(V, v, s, t)^{\mathrm{R}}\right)^{\mathrm{X}}$, given (a) the reductions by variable of the difference in $\log$ factorial approximations between $A$ and $A^{\mathrm{X}}$, and (b) the triple prior to rolling, $\left(\operatorname{algn}(A), A, A^{\mathrm{X}}\right)$.

Let rals $\in \mathcal{A} \rightarrow(\mathcal{V} \rightarrow(\mathcal{S} \rightarrow \mathrm{Q}))$ be defined as

```
\(\operatorname{rals}(A):=\)
    \(\left\{\left(w,\left\{\left(S, \sum\left(I_{\approx \operatorname{nn}!}^{*}\left(A_{T}\right): T \in A^{\mathrm{S}}, T \supseteq S\right)-\sum\left(I_{\approx \operatorname{nn}!}^{*}\left(A_{T}^{\mathrm{X}}\right): T \in A^{\mathrm{XS}}, T \supseteq S\right)\right):\right.\right.\right.\)
    \(\left.\left.\left.S \in(A \%\{w\})^{S}\right\}\right): w \in V\right\}\)
```

where $I_{\approx \mathrm{n}!}=\operatorname{logfactorialer} \in$ computers and $I^{*}:=\operatorname{apply}(I)$.
Let $I_{\mathrm{R}, \mathrm{a}}=$ rollValueAlignmenter $\in$ computers be such that range $\left(I_{\mathrm{R}, \mathrm{a}}\right) \subset$ $\mathrm{Q} \times \mathcal{A} \times \mathcal{A}$ defined as

$$
\operatorname{range}\left(I_{\mathrm{R}, \mathrm{a}}\right)=\left\{\left(I_{\mathrm{a}}^{*}(A), A, A^{\mathrm{X}}\right): A \in \mathcal{A}\right\}
$$

and such that domain $\left(I_{\mathrm{R}, \mathrm{a}}\right) \subset \bigcup\{$ rollValues $(U): U \in \mathcal{U}\} \times(\mathcal{V} \rightarrow(\mathcal{S} \rightarrow$ $\mathrm{Q})) \times \operatorname{range}\left(I_{\mathrm{R}, \mathrm{a}}\right)$ is defined as

$$
\begin{aligned}
\operatorname{domain}\left(I_{\mathrm{R}, \mathrm{a}}\right)= & \left\{\left((V, v, s, t), \operatorname{rals}(A),\left(a, A, A^{\mathrm{X}}\right)\right):\left(a, A, A^{\mathrm{X}}\right) \in \operatorname{range}\left(I_{\mathrm{R}, \mathrm{a}}\right),\right. \\
& U \in \mathcal{U},(V, v, s, t) \in \operatorname{rollValues}(U), V=\operatorname{vars}(A)\}
\end{aligned}
$$

and such that

$$
\begin{aligned}
& \operatorname{apply}\left(I_{\mathrm{R}, \mathrm{a}}\right)\left(\left((V, v, s, t), Y,\left(a, A, A^{\mathrm{X}}\right)\right)\right)= \\
& \quad\left(I_{\mathrm{a}}^{*}\left(A *(V, v, s, t)^{\mathrm{R}}\right), A *(V, v, s, t)^{\mathrm{R}},\left(A *(V, v, s, t)^{\mathrm{R}}\right)^{\mathrm{X}}\right)
\end{aligned}
$$

where $Y=\operatorname{rals}(A)$.
The computation of both the rolled histogram $A *(V, v, s, t)^{\mathrm{R}}$ and the independet rolled histogram $\left(A *(V, v, s, t)^{\mathrm{R}}\right)^{\mathrm{X}}$ is the same in the value rolled alignmenter $I_{\mathrm{R}, \mathrm{a}}$ as it is in the value roller $I_{\mathrm{R}}$. That is,

$$
\begin{aligned}
& A *(V, v, s, t)^{\mathrm{R}}= \\
& \quad\left(A *\left\{Q_{s}\right\}^{\mathrm{U}}\right)^{\mathrm{Z}}+A *\left\{Q_{t}\right\}^{\mathrm{U}}+\left\{\left(S \backslash Q_{s} \cup Q_{t}, c\right):(S, c) \in A *\left\{Q_{s}\right\}^{\mathrm{U}}\right\}+ \\
& \quad\left(A \backslash\left(A *\left\{Q_{s}, Q_{t}\right\}^{\mathrm{U}}\right)\right)
\end{aligned}
$$

where $s \neq t$, and $Q=\left\{(u,\{(v, u)\}): u \in U_{v}\right\} \in \mathcal{W}_{U} \rightarrow \mathcal{S}_{U}$. Similarly

$$
\begin{aligned}
& \left(A *(V, v, s, t)^{\mathrm{R}}\right)^{\mathrm{X}}= \\
& \quad\left(A^{\mathrm{X}} *\left\{Q_{s}\right\}^{\mathrm{U}}\right)^{\mathrm{Z}}+A^{\mathrm{X}} *\left\{Q_{t}\right\}^{\mathrm{U}}+\left\{\left(S \backslash Q_{s} \cup Q_{t}, c\right):(S, c) \in A^{\mathrm{X}} *\left\{Q_{s}\right\}^{\mathrm{U}}\right\}+ \\
& \quad\left(A^{\mathrm{X}} \backslash\left(A^{\mathrm{X}} *\left\{Q_{s}, Q_{t}\right\}^{\mathrm{U}}\right)\right)
\end{aligned}
$$

Then, given the approximate alignment prior to rolling, $a=I_{\mathrm{a}}^{*}(A) \in \mathbf{Q}$, the approximate rolled alignment can be calculated

$$
\begin{aligned}
I_{\mathrm{a}}^{*}\left(A *(V, v, s, t)^{\mathrm{R}}\right)= & a-Y_{v}\left(Q_{s}\right)-Y_{v}\left(Q_{t}\right)+ \\
& \sum\left(I_{\approx \mathrm{nn}!}^{*}(c):(S, c) \in A *(V, v, s, t)^{\mathrm{R}} *\left\{Q_{t}\right\}^{\mathrm{U}}\right)- \\
& \sum\left(I_{\approx \mathrm{nn}!}^{*}(c):(S, c) \in\left(A *(V, v, s, t)^{\mathrm{R}}\right)^{\mathrm{X}} *\left\{Q_{t}\right\}^{\mathrm{U}}\right)
\end{aligned}
$$

The time is thus constrained to have a lower bound

$$
\begin{aligned}
I_{\mathrm{R}, \mathrm{a}}^{\mathrm{t}}\left(\left((V, v, s, t), Y,\left(a, A, A^{\mathrm{X}}\right)\right)\right)> & I_{\mathrm{R}}^{\mathrm{t}}\left(\left((V, v, s, t),\left(A, A^{\mathrm{X}}\right)\right)\right)+ \\
& (2 x+1) I_{+}^{\mathrm{t}}(\cdot)+2 x I_{\approx \mathrm{n}!}^{\mathrm{t}}(\cdot)
\end{aligned}
$$

where $x=\left|V^{\mathrm{C}}\right| /\left|U_{v}\right|=\left|V^{\mathrm{C}} *\left\{Q_{t}\right\}^{\mathrm{U}}\right|$ is the cardinality of the volumes incident on $Q_{s}$ and on $Q_{t}$.

Therefore the value rolled alignmenter has time of the same complexity as the value roller, which is $n d^{n-1}$ in the case of the regular histogram of dimension $n$ and valency $d$.

### 4.21 Tractable alignment-bounding

Let the set of inducers be the subset of computers parameterised by integral size, $\operatorname{inducers}(z) \subset$ computers, such that (i) the domain is a subset of the substrate histograms and a superset of the integral-independent substrate histograms, $\forall I_{z} \in \operatorname{inducers}(z)\left(\mathcal{A}_{z, \mathrm{xi}} \subseteq\right.$ domain $\left.\left(I_{z}\right) \subseteq \mathcal{A}_{z}\right)$, (ii) the range is a non-empty rational-valued function, $\forall I_{z} \in \operatorname{inducers}(z)\left(I_{z}^{*} \in \operatorname{domain}\left(I_{z}\right) \rightarrow\right.$ $((\mathcal{X} \rightarrow \mathbf{Q}) \backslash\{\emptyset\}))$, such that application to a domain substrate histogram, $A \in$ domain $\left(I_{z}\right)$, returns a rational-valued function of the substrate models set, $I_{z}^{*}(A) \in \mathcal{M}_{U_{A}, V_{A}} \rightarrow \mathbf{Q}$, (iii) both the inducer time and space are finite, $I_{z}^{\mathrm{t}}(A)<\infty$ and $I_{z}^{\mathrm{s}}(A)<\infty$, and (iv) the maximum of the inducer application, $\operatorname{maxr} \circ I_{z}^{*}$, is positively correlated with the finite alignment-bounded iso-transform space ideal transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}$,

$$
\forall z \in \mathbf{N}_{>0} \forall I_{z} \in \operatorname{inducers}(z)\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ I_{z}^{*}\right) \geq 0\right)
$$

The correlation, $\operatorname{cov}(z)\left(\operatorname{maxro} X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{f}, \mathrm{j},}, \operatorname{maxro} I_{z}^{*}\right)$, is called the inducer correlation for size $z$. The substrate models of the substrate histogram, $\mathcal{M}_{U_{A}, V_{A}}$, each map to a substrate transform, transform $(U, V) \in \mathcal{M}_{U, V} \rightarrow \mathcal{T}_{U, V}$, so that the maximum induced transforms of inducer $I_{z}$ applied to substrate histogram $A$ are $\left\{\operatorname{transform}\left(U_{A}, V_{A}\right)(M): M \in \operatorname{maxd}\left(I_{z}^{*}(A)\right)\right\} \subset \mathcal{T}_{U_{A}, V_{A}}$.

Given an integral-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$, let the domain of the alignment-bounded iso-transform space ideal transform search set, $\operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)\right) \subset \mathcal{T}_{U_{A}, V_{A}}$, which consists of substrate transforms subject to the constraints of (i) formal-abstract equality, and (ii) ideality, be abbreviated to the literal substrate transforms

$$
\begin{aligned}
\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A) & =\operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)\right) \\
& =\left\{T: T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}
\end{aligned}
$$

The domain of the derived alignment integral-independent substrate ideal formal-abstract transform search set, $\operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}(A)\right)$, equals the domain of the alignment-bounded iso-transform space ideal transform search set, $\operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}(A)\right)=\operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)\right)$, and may also be abbreviated, $\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)=\operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}(A)\right)$.

Let the literal substrate decompositions $\mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A) \subset \mathcal{D}_{U_{A}, V_{A}}$, which are substrate decompositions subject to the constraints of (i) formal-abstract equality, and (ii) ideality, be defined

$$
\mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A)=\left\{D: D \in \mathcal{D}_{U_{A}, V_{A}}, A^{\mathrm{X}} * D^{\mathrm{T}}=\left(A * D^{\mathrm{T}}\right)^{\mathrm{X}}, A=A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}\right\}
$$

The literal substrate decompositions map to the literal substrate transforms, $\left\{D^{\mathrm{TV}}{ }^{A}: D \in \mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A)\right\}=\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)$. The cardinality of the literal substrate decompositions is greater than or equal to the literal substrate transforms, $\left|\mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A)\right| \geq\left|\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)\right|$, because the literal substrate decompositions includes those decompositions which consist solely of a literal substrate transform, $\left\{\{((\emptyset, T), \emptyset)\}: T \in \mathcal{T}_{\text {fa }, \mathrm{j}}(A)\right\} \subset \mathcal{D}_{\mathrm{fa} \mathrm{j}}(A)$.

Note that if a substrate decomposition $D \in \mathcal{D}_{U_{A}, V_{A}}$ contains more than a root transform, $|\operatorname{transforms}(D)|>1$, then the expanded nullable transform, $D^{\mathrm{T} V_{A}}$, is not necessarily in the literal substrate transforms, $\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)$. This is because the nullable transform of a multiple decomposition is overlapping, $|\operatorname{transforms}(D)|>1 \Longrightarrow \operatorname{overlap}\left(D^{\mathrm{T}}\right)$, even if it so happens that the transforms of the decomposition are each individually non-overlapping, $\forall T \in$ transforms $(D)(\neg \operatorname{overlap}(T))$. A non-overlapping transform implies that the formal histogram is independent, $\neg \operatorname{overlap}(T) \Longrightarrow A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, so it is sometimes the case that an overlapping transform, overlap $(T)$, has nonindependent formal histogram, $A^{\mathrm{X}} * T \neq\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$. If it is indeed the case that an overlapping nullable transform, overlap $\left(D^{\mathrm{T}}\right)$, has non-independent formal histogram, $A^{\mathrm{X}} * D^{\mathrm{T}} \neq\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)^{\mathrm{X}}$, then the formal histogram cannot be equal to the abstract histogram, $A^{\mathrm{X}} * D^{\mathrm{T}} \neq\left(A * D^{\mathrm{T}}\right)^{\mathrm{X}}$. So, in this case of non-independent formal histogram, the substrate decomposition, $D$, is not
a literal substrate decomposition, $D \notin \mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A)$. The multiple literal substrate decompositions, $\left\{D: D \in \mathcal{D}_{\mathrm{fa} \mathrm{j}}(A)\right.$, $\left.\operatorname{transforms}(D)>1\right\} \subset \mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A)$, all have overlapping nullable transform, but nonetheless all have independent formal histogram.

Similarly, let the literal substrate fuds $\mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A) \subset \mathcal{F}_{U_{A}, V_{A}}$, which are substrate fuds subject to the constraints of (i) formal-abstract equality, and (ii) ideality, be defined

$$
\mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A)=\left\{F: F \in \mathcal{F}_{U_{A}, V_{A}}, A^{\mathrm{X}} * F^{\mathrm{T}}=\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}, A=A * F^{\mathrm{T}} * F^{\mathrm{T} \dagger A}\right\}
$$

The literal substrate fuds map to the literal substrate transforms, $\left\{F^{\mathrm{T} V_{A}}: F \in\right.$ $\left.\mathcal{F}_{\text {fa, } \mathrm{j}}(A)\right\}=\mathcal{T}_{\text {fa, }}(A)$. The cardinality of the literal substrate fuds is greater than or equal to the literal substrate transforms, $\left|\mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A)\right| \geq\left|\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)\right|$, because the literal substrate fuds includes those fuds which consist solely of a literal substrate transform, $\left\{\{T\}: T \in \mathcal{T}_{\text {fa, } \mathrm{j}}(A)\right\} \subset \mathcal{F}_{\text {fa, }}(A)$.

Finally, let the literal substrate fud decompositions $\mathcal{D}_{\mathrm{F}, \mathrm{fa}, \mathrm{j}}(A) \subset \mathcal{D}_{\mathrm{F}, U_{A}, V_{A}}$, which are substrate fud decompositions subject to the constraints of (i) formalabstract equality, and (ii) ideality, be defined
$\mathcal{D}_{\mathrm{F}, \mathrm{fa}, \mathrm{j}}(A)=\left\{D: D \in \mathcal{D}_{\mathrm{F}, U_{A}, V_{A}}, A^{\mathrm{X}} * D^{\mathrm{T}}=\left(A * D^{\mathrm{T}}\right)^{\mathrm{X}}, A=A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}\right\}$
The substrate fud decompositions, $\mathcal{D}_{\mathrm{F}, U_{A}, V_{A}}$, is finite because the substrate fuds are constrained to appear no more than once in any path, $\forall L \in \operatorname{paths}(D)(\{(i, F)$ : $\left.(i,(\cdot, F)) \in L\} \in \mathbf{N} \leftrightarrow \mathcal{F}_{U_{A}, V_{A}}\right)$. The literal substrate fud decompositions map to the literal substrate transforms, $\left\{D^{\mathrm{T} V_{A}}: D \in \mathcal{D}_{\mathrm{F}, \mathrm{fa}, \mathrm{j}}(A)\right\}=\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)$. The cardinality of the literal substrate fud decompositions is greater than or equal to the literal substrate fuds, $\left|\mathcal{D}_{\mathrm{F}, \mathrm{fa}, \mathrm{j}}(A)\right| \geq\left|\mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A)\right|$, because the literal substrate fud decompositions includes those decompositions which consist solely of a literal substrate fud, $\left\{\{((\emptyset, F), \emptyset)\}: F \in \mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A)\right\} \subset \mathcal{D}_{\mathrm{F}, \mathrm{fa}, \mathrm{j}}(A)$. The cardinality of the literal substrate fud decompositions is therefore also greater than or equal to the literal substrate transforms, $\left|\mathcal{D}_{\mathrm{F}, \mathrm{fa}, \mathrm{j}}(A)\right| \geq\left|\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)\right|$.

The set of transforms of the substrate models searched by the inducer for a given substrate histogram $A,\left\{\operatorname{transform}\left(U_{A}, V_{A}\right)(M): M \in \operatorname{dom}\left(I_{z}^{*}(A)\right)\right\} \subset$ $\mathcal{T}_{U_{A}, V_{A}}$, need not intersect with the literal substrate transforms, $\mathcal{T}_{\text {fa, }, \mathrm{j}}(A)$. So in some cases $\left\{\operatorname{transform}\left(U_{A}, V_{A}\right)(M): M \in \operatorname{dom}\left(I_{z}^{*}(A)\right)\right\} \cap \mathcal{T}_{\text {fa, }}(A)=\emptyset$. All that is required of inducers is that there is a positive correlation between the maximum functions, not that the domains of the search sets intersect. This allows definitions of inducers that search substrate models which are overlapping, formal-abstract-inequivalent or non-ideal.

In addition, the definition of an inducer may be such that its domain is a proper superset of the integral-independent substrate histograms, $\mathcal{A}_{z, \mathrm{xi}} \subset$ domain $\left(I_{z}\right)$, and thus is a proper superset of the domain of the alignmentbounded iso-transform space ideal transform maximum function, dom(maxro $\left.X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}\right)=\operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}\right)=\mathcal{A}_{z, \mathrm{xi}} \subset \operatorname{domain}\left(I_{z}\right)$. The correlation, $\operatorname{cov}(z)\left(\operatorname{maxro} X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}\right.$, maxro $\left.I_{z}^{*}\right)$, is restricted to the intersection of the domains of the argument functions, which is $\mathcal{A}_{z, \mathrm{xi}}$. Thus no constraint is made by the correlation on the definition of the inducer for the part of its domain which is the disjoint set of non-integral-independent substrate histograms, $\mathcal{A}_{z} \backslash \mathcal{A}_{z, \mathrm{xi}}$. For example, the definition of an inducer could be extended into non-integral-independent substrate histograms by the use of approximations to the multinomial probability density function, $\operatorname{mpdf}(U)(E, z) \in \mathcal{A}_{U, V, z} \rightarrow$ $\mathbf{R}_{\geq 0}$, to interpolate, via the unit-translated gamma function, $\Gamma_{!}$, from the generalised multinomial probability distribution $\hat{Q}_{\mathrm{m}, U}(E, z) \in \mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathbf{Q}_{\geq 0}$, but the correlation would not imply this interpolation.

The tractable inducers subset of inducers is such that neither the computational time complexity nor the representational encoding space complexity of the application, $I_{z}^{*}$, is greater than polynomial. The complexities are always with respect to some underlying variable, for example valency or dimension. So the application of an intractable inducer may still be practicable. That is, its parameters may be such that the values of the underlying variables are small enough that the computation time and representation space are practicable. Conversely, a tractable inducer is not necessarily practicable. Practicability implies absolute limits on the time and space of the computation of the inducer, whereas tractable inducers may exceed these limits so long as the complexities are not exponential or higher.

Let the log-rational approxer $I_{\approx \ln \mathbf{Q}} \in$ computers be a computer that finitely approximates, to some degree of accuracy, between the log-positive-rational numbers, $\ln \mathbf{Q}_{>0}$, and the rational numbers, $\mathbf{Q}$. The domain is domain $\left(I_{\approx \ln \mathbf{Q}}\right)=$ $\ln \mathbf{Q}_{>0}$. The range is range $\left(I_{\approx \ln \mathbf{Q}}\right)=\mathbf{Q}$. The application is such that, $\forall x \in \ln \mathbf{Q}_{>0}\left(I_{\approx \ln \mathbf{Q}}^{*}(x) \approx x\right)$.

Let the real approxer $I_{\approx \mathbf{R}} \in$ computers be a computer that finitely approximates, to some degree of accuracy, between the real numbers, $\mathbf{R}$, and the rational numbers, $\mathbf{Q}$. The domain is domain $\left(I_{\approx \mathbf{R}}\right)=\mathbf{R}$. The range is $\operatorname{range}\left(I_{\approx \mathbf{R}}\right)=\mathbf{Q}$. The application is such that, $\forall x \in \mathbf{R}\left(I_{\approx \mathbf{R}}^{*}(x) \approx x\right)$. The application of the real approxer, $I_{\approx \mathbf{R}}$, is a superset of the application of the log-rational approxer, $I_{\approx \ln \mathbf{Q}}$. That is, $I_{\approx \ln \mathbf{Q}}^{*} \subset I_{\approx \mathbf{R}}^{*}$.

### 4.21.1 Literal inducers

Let the literal alignment-bounded iso-transform space ideal transform inducer $I_{z, \mathrm{y}, 1} \in \operatorname{inducers}(z)$ be a literal implementation of the alignmentbounded iso-transform space ideal transform search set, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}} \in \mathcal{A}_{z, \mathrm{xi}} \rightarrow$ $\left(\mathcal{T}_{f} \rightarrow \ln \mathrm{Q}_{>0}\right)$, except that the finite approximation of the log-rational approxer, $I_{\approx \ln \mathbf{Q}}$, is made between the log-positive-rational, $\ln \mathbf{Q}_{>0}$, valued range of the search set to the rational, $\mathbf{Q}$, valued range of the inducer application, $I_{z, \mathrm{y}, \mathrm{l}}^{*} \in \mathcal{A}_{z, \mathrm{xi}} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow \mathbf{Q}\right)$. That is,

$$
\operatorname{domain}\left(I_{z, \mathrm{y}, \mathrm{l}}\right)=\operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}\right)=\mathcal{A}_{z, \mathrm{xi}}
$$

and

$$
\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(I_{z, \mathrm{y}, \mathrm{l}}^{*}(A)=\left\{\left(T, I_{\approx \ln \mathbf{Q}}^{*}(y)\right):(T, y) \in X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)\right\}\right)
$$

The domain of the application of the literal alignment-bounded inducer, $I_{z, \mathrm{y}, \mathrm{l}}$, to integral-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$ is the literal substrate transforms, $\operatorname{dom}\left(I_{z, \mathrm{y}, \mathrm{l}}^{*}(A)\right)=\operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)\right)=\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)$.

The correlation between its maximum function and the alignment-bounded iso-transform space ideal transform maximum function is almost, but not exactly, one, because of the approximation made by the log-rational approxer, $I_{\approx \ln \mathbf{Q}}$,

$$
\begin{aligned}
& \forall z \in \mathbf{N}_{>0} \\
& \quad\left(\operatorname{var}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}\right)>0 \wedge \operatorname{var}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{y}, \mathrm{l}}^{*}\right)>0 \Longrightarrow\right. \\
& \left.\qquad \operatorname{corr}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ I_{z, \mathrm{y}, \mathrm{l}}^{*}\right) \approx 1\right)
\end{aligned}
$$

Similarly, let the literal derived alignment integral-independent substrate ideal formal-abstract transform inducer $I_{z, \mathrm{a}, 1}^{\prime} \in \operatorname{inducers}(z)$ be a literal implementation of the derived alignment integral-independent substrate ideal formal-abstract transform search set, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime} \in \mathcal{A}_{z, \mathrm{xi}} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow \ln \mathbf{Q}_{>0}\right)$, except that the finite approximation of the $\log$-rational approxer, $I_{\approx \ln \mathbf{Q}}$, is made between the log-positive-rational, $\ln \mathbf{Q}_{>0}$, valued range of the search set to the rational, $\mathbf{Q}$, valued range of the inducer application, $I_{z, \mathrm{a}, 1}^{\prime *} \in \mathcal{A}_{z, \mathrm{xi}} \rightarrow$ $\left(\mathcal{T}_{\mathrm{f}} \rightarrow \mathbf{Q}\right)$. That is,

$$
\operatorname{domain}\left(I_{z, \mathrm{a}, 1}^{\prime}\right)=\operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}\right)=\mathcal{A}_{z, \mathrm{xi}}
$$

and

$$
\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(I_{z, \mathrm{a}, \mathrm{l}}^{*}(A)=\left\{\left(T, I_{\approx \ln \mathbf{Q}}^{*}(a)\right):(T, a) \in X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{f}, \mathrm{j}}^{\prime}(A)\right\}\right)
$$

The domain of the application of the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l},}^{\prime}$, to integral-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$ is the literal substrate transforms, $\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}(A)\right)=\operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{f}, \mathrm{j}}^{\prime}(A)\right)=\mathcal{T}_{\mathrm{f}, \mathrm{j}, \mathrm{j}}(A)$. The application can therefore be expressed

$$
\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}(A)=\left\{\left(T, I_{\approx \ln \mathbf{Q}}^{*}(\operatorname{algn}(A * T))\right): T \in \mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)\right\}\right)
$$

In order to allow the comparison of space and time complexities between them, the two literal inducers, $I_{z, \mathrm{y}, 1}$ and $I_{z, \mathrm{a}, 1}^{\prime}$, are defined with (i) the same degree of accuracy of the log-positive-rational approximation of the log-rational approxer, $I_{\approx \ln \mathbf{Q}}$, and (ii) the same representations of histograms and transforms.

It is conjectured, in section 'Substrate structures alignment' above, that the alignment-bounded iso-transform space ideal transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}$, is correlated with the derived alignment integralindependent substrate ideal formal-abstract transform maximum function, $\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{f}, \mathrm{j}}^{\prime}\right) \geq 0\right)
$$

Hence conjecture that the maximum transform function of the literal derived alignment integral-independent substrate ideal formal-abstract transform inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, is positively correlated with that of the alignment-bounded isotransform space ideal transform search set, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j},}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{f}, \mathrm{j},}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}\right) \geq 0\right)
$$

but because of the introduction of log-positive-rational approximations, the correlation is lower

$$
\begin{aligned}
& \forall z \in \mathbf{N}_{>0} \\
& \quad\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{f}, \mathrm{j}, \mathrm{j}}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}\right) \geq\right. \\
& \left.\quad \operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j},}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}\right)\right)
\end{aligned}
$$

Although it is conjectured that the alignment-bounded iso-transform space ideal transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{f}, \mathrm{j}}$, is correlated with the derived alignment integral-independent substrate ideal formal-abstract transform maximum function, maxro $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}$, it is not necessarily the case that the sets of maximum transforms intersect for any given integral-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$. That is, it is sometimes the case that

$$
\operatorname{maxd}\left(X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)\right) \cap \operatorname{maxd}\left(X_{z, \mathrm{x}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}(A)\right)=\emptyset
$$

and so the correlation is not perfect,

$$
\exists z \in \mathbf{N}_{>0}\left(\operatorname{corr}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}\right)<1\right)
$$

This is also true for the correlation between the literal inducers,

$$
\exists z \in \mathbf{N}_{>0}\left(\operatorname{corr}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{y}, 1}^{*}, \operatorname{maxr} \circ I_{z, \mathrm{a}, 1}^{\prime *}\right)<1\right)
$$

The compromise of the less than perfect correlation may be required by a practicable computation, however, because the computation time of the literal derived alignment integral-independent substrate ideal formal-abstract transform inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime \mathrm{t}}(A)$, is less than that of the literal alignment-bounded iso-transform space ideal transform inducer, $I_{z, \mathrm{y}, 1}^{\mathrm{t}}(A)$.

For given integral-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$ the domains of the space functions are the literal substrate transforms, $\operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}(A)\right)=$ $\operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{f}, \mathrm{j}}(A)\right)=\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)$. Consider the difference in computation of literal substrate transform $T \in \mathcal{T}_{\text {fa }, \mathrm{j}}(A)$ in a literal implementation of expression

$$
\begin{aligned}
X_{z, \mathrm{x}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)(T) & =X_{z, \mathrm{~T}, \mathrm{y}}(A)(T) \\
& =-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{x}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U_{A}, i, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(B)}
\end{aligned}
$$

and of expression

$$
\begin{aligned}
X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}(A)(T) & =X_{z, \mathrm{~T}, \mathrm{a}}^{\prime}(A)(T) \\
& =\operatorname{algn}(A * T) \\
& =-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left((A * T)^{\mathrm{X}}, z\right)(A * T)}{\hat{Q}_{\mathrm{m}, U_{A}}\left((A * T)^{\mathrm{X}}, z\right)\left((A * T)^{\mathrm{X}}\right)} \\
& =-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}} * T, z\right)(A * T)}{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}} * T, z\right)\left(A^{\mathrm{X}} * T\right)}
\end{aligned}
$$

Define the independent-sample-distributed iso-transform-independent conditional dependent multinomial space computer $I_{U, V, z, \mathrm{~T}, \mathrm{y}} \in$ computers such that $\operatorname{domain}\left(I_{U, V, z, \mathrm{~T}, \mathrm{y}}\right)=\mathcal{A}_{U, \mathrm{i}, V, z} \times \mathcal{T}_{U, V}$ and

$$
I_{U, V, z, \mathrm{~T}, \mathrm{y}}^{*}((A, T)) \approx-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(B)}
$$

The independent-sample-distributed iso-transform-independent conditional dependent multinomial space computer, $I_{U, V, z, \mathrm{~T}, \mathrm{y}}$, is, in turn, defined in terms
of the multinomial space computer $I_{\mathrm{m}} \in$ computers. The multinomial space computer is such that $I_{\mathrm{m}}^{*} \in\left\{(E, A): E \in \mathcal{A}, A \in \mathcal{A}_{\mathrm{i}}, E^{\mathrm{F}} \geq A^{\mathrm{F}}, z_{E}>0\right\} \rightarrow$ Q,

$$
I_{\mathrm{m}}^{*}((E, A)) \approx-\ln \hat{Q}_{\mathrm{m}, U}\left(E, z_{A}\right)(A)=-\ln \frac{z_{A}!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}}\left(\frac{E_{S}}{z_{E}}\right)^{A_{S}}
$$

It is in the multinomial space computer, $I_{\mathrm{m}}$, that the approximation between $\log$-positive-rational, $\ln \mathbf{Q}_{>0}$, and rational, $\mathbf{Q}$, is made by means of the $\log$ rational approxer, $I_{\approx \ln \mathbf{Q}}$. Note that there is no need yet for an implementation of the unit-translated gamma function, $\Gamma_{!}$, such as in the log factorialer, $I_{\approx \ln !}$, because the factorial computations are integral.

The independent-sample-distributed iso-transform-independent conditional dependent multinomial space computer, $I_{U, V, z, \mathrm{~T}, \mathrm{y}}$, also requires an independenter, $I_{\mathrm{X}}^{*}(A)=A^{\mathrm{X}}$, where $I_{\mathrm{X}}=$ independenter. Thus the computation time of the independent-sample-distributed iso-transform-independent conditional dependent multinomial space computer, $I_{U, V, z, \mathrm{~T}, \mathrm{y}}^{\mathrm{t}}((A, T))$, is such that

$$
I_{U, V, z, \mathrm{~T}, \mathrm{y}}^{\mathrm{t}}((A, T))>I_{\mathrm{X}}^{\mathrm{t}}(A)+I_{\mathrm{m}}^{\mathrm{t}}\left(\left(A^{\mathrm{X}}, A\right)\right)+\sum I_{\mathrm{m}}^{\mathrm{t}}\left(\left(A^{\mathrm{X}}, B\right)\right): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)
$$

Let the literal alignment-bounded iso-transform space ideal transform inducer, $I_{z, \mathrm{y}, 1}$, be implemented in terms of an independent-sample-distributed iso-transform-independent conditional dependent multinomial space computer, $I_{U, V, z, \mathrm{~T}, \mathrm{y}}$, so that for integral-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$ and literal substrate transform $T \in \mathcal{T}_{\text {fa,j }}(A)$

$$
I_{z, \mathrm{y}, \mathrm{l}}^{*}(A)(T)=I_{U_{A}, V_{A}, z, \mathrm{~T}, \mathrm{y}}^{*}((A, T)) \approx X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)(T)
$$

The computation time of histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$ of the alignment-bounded inducer is therefore

$$
I_{z, \mathrm{y}, \mathrm{l}}^{\mathrm{t}}(A)>\sum I_{U_{A}, V_{A}, z, \mathrm{~T}, \mathrm{y}}^{\mathrm{t}}((A, T)): T \in \mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)
$$

Define the independent-sample-distributed relative dependent multinomial space computer $I_{U, V, z, \mathrm{a}} \in$ computers such that domain $\left(I_{U, V, z, \mathrm{a}}\right)=\left\{A: A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A^{\mathrm{X}} \in\right.$ $\left.\mathcal{A}_{i}\right\}$ and

$$
I_{U, V, z, \mathrm{a}}^{*}(A) \approx-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{x}}, z\right)(A)}{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)}
$$

The independent-sample-distributed relative dependent multinomial space computer, $I_{U, V, z, \mathrm{a}}$, is also defined in terms of an independenter, $I_{\mathrm{X}}$, and a multinomial space computer, $I_{\mathrm{m}}$. Thus the computation time of the independent-sample-distributed relative dependent multinomial space computer, $I_{U, V, z, \mathrm{a}}^{\mathrm{t}}(A)$,
is such that

$$
I_{U, V, z, \mathrm{a}}^{\mathrm{t}}(A)>I_{\mathrm{X}}^{\mathrm{t}}(A)+I_{\mathrm{m}}^{\mathrm{t}}\left(\left(A^{\mathrm{X}}, A\right)\right)+I_{\mathrm{m}}^{\mathrm{t}}\left(\left(A^{\mathrm{X}}, A^{\mathrm{X}}\right)\right)
$$

Consider a variation of the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, which is the relative literal derived alignment integral-independent substrate ideal formal-abstract transform inducer $I_{z, \mathrm{a}, \mathrm{l}, \mathrm{r}}^{\prime} \in \operatorname{inducers}(z)$. The relative literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}, \mathrm{r}}^{\prime}$, is implemented with a transformer, $I_{* \mathrm{~T}}=$ transformer, followed by an independent-sample-distributed relative dependent multinomial space computer, $I_{U, V, z, \mathrm{a}}$, so that for integral-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$ and literal substrate transform $T \in \mathcal{T}_{\text {fa, } \mathrm{j}}(A)$

$$
I_{z, \mathrm{a}, \mathrm{l}, \mathrm{r}}^{\prime *}(A)(T)=I_{U_{A}, W, z, \mathrm{a}}^{*}\left(I_{* \mathrm{~T}}^{*}((T, A))\right) \approx X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}(A)(T)
$$

where $W=\operatorname{der}(T)$. In this case the computation time of histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$ of the relative literal derived alignment inducer is therefore
$I_{z, \mathrm{a}, \mathrm{l}, \mathrm{r}}^{\prime \mathrm{t}}(A)>\sum I_{* \mathrm{~T}}^{\mathrm{t}}((T, A))+I_{U_{A}, W, z, \mathrm{a}}^{\mathrm{t}}(A * T): T \in \mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A), W=\operatorname{der}(T)$
In this case, for the sake of comparison, the derived alignment, $\operatorname{algn}(A * T)$, is computed in the independent-sample-distributed relative dependent multinomial space computer, $I_{U_{A}, W, z, \mathrm{a}}^{*}(A * T)$, as though it is derived relative dependent multinomial space.

Note that if the representation of the independent histogram, $A^{\mathrm{X}}$, has previously been computed, then a faster implementation of $I_{z, \mathrm{a}, \mathrm{l}, \mathrm{r}}^{\prime *}(A)(T)$ might be to lift rather than derive. That is, instead of the computation $I_{\mathrm{X}}^{*}(A * T)=$ $(A * T)^{\mathrm{X}}$ only the computation $I_{* \mathrm{~T}}^{*}\left(\left(T, A^{\mathrm{X}}\right)\right)=A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$ would be needed. The representation of the independent histogram, $A^{\mathrm{X}}$, might be known, for example, if computed for a previous transform.

Consider the numerators of the derived computation, $\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(A)$ and $\hat{Q}_{\mathrm{m}, U_{A}}\left((A * T)^{\mathrm{X}}, z\right)(A * T)$. The computation times of the numerators, at least $I_{\mathrm{X}}^{\mathrm{t}}(A)+I_{\mathrm{m}}^{\mathrm{t}}\left(\left(A^{\mathrm{X}}, A\right)\right)$ and at least $I_{* \mathrm{~T}}^{\mathrm{t}}((T, A))+I_{\mathrm{X}}^{\mathrm{t}}(A * T)+I_{\mathrm{m}}^{\mathrm{t}}\left(\left((A * T)^{\mathrm{X}}, A * T\right)\right)$, are similar, because the time to compute the derived histogram, $A * T$, in the transformer, $I_{* \mathrm{~T}}^{\mathrm{t}}((T, A))$, is sometimes offset by the time to calculate the generalised multinomial probability, $\hat{Q}_{\mathrm{m}, U_{A}}\left((A * T)^{\mathrm{X}}, z\right)(A * T)$, in the multinomial space computer, $I_{\mathrm{m}}^{\mathrm{t}}\left(\left((A * T)^{\mathrm{X}}, A * T\right)\right)$, because of the possibly smaller effective derived volume, $\left|(A * T)^{\mathrm{F}}\right| \leq\left|A^{\mathrm{F}}\right|$.

Consider the denominators of the derived computation, $\sum \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(B)$ :
$B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)$ and $\hat{Q}_{\mathrm{m}, U_{A}}\left((A * T)^{\mathrm{X}}, z\right)\left((A * T)^{\mathrm{X}}\right)$. In contrast to the computation times of the numerators, the computation time of the relative dependent denominator, at least $I_{\mathrm{m}}^{\mathrm{t}}\left(\left((A * T)^{\mathrm{X}},(A * T)^{\mathrm{X}}\right)\right)$, in $I_{z, \mathrm{a}, \mathrm{l}, \mathrm{r}}^{\prime *}(A)$ is less than the computation time of the iso-transform-independent conditional dependent denominator, at least $\sum I_{\mathrm{m}}^{\mathrm{t}}\left(\left(A^{\mathrm{X}}, B\right)\right): B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)$, in $I_{z, \mathrm{y}, \mathrm{l}}^{*}(A)$, if the set of iso-transform-independents is not singleton, $\left|\mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)\right|>1$. Therefore, summing over all of the literal substrate transforms, $\mathcal{T}_{\text {fa, }}(A)$, the computation time of the relative literal derived alignment integral-independent substrate ideal formal-abstract transform inducer, $I_{z, \mathrm{a}, \mathrm{l}, \mathrm{r}}^{\prime \mathrm{t}}(A)$, must be less than that of the literal alignment-bounded iso-transform space ideal transform inducer, $I_{z, \mathrm{y}, 1}^{\mathrm{t}}(A)$. That is,

$$
\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(I_{z, \mathrm{a}, \mathrm{l}, \mathrm{r}}^{\prime \mathrm{t}}(A)<I_{z, \mathrm{y}, \mathrm{l}}^{\mathrm{t}}(A)\right)
$$

The computation time of the iso-transform-independent conditional dependent denominator varies as the cardinality of the integral iso-transformindependents, $\left|\mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)\right|$. For comparison, the average cardinality of the integral iso-independents is

$$
\frac{\left|\mathcal{A}_{U_{A}, i, V_{A}, z}\right|}{\left|\operatorname{ran}\left(Y_{U_{A}, i, V_{A}, z}\right)\right|}=\frac{(z+v-1)!}{z!(v-1)!} / \prod_{w \in V_{A}} \frac{\left(z+\left|U_{A}(w)\right|-1\right)!}{z!\left(\left|U_{A}(w)\right|-1\right)!}
$$

where volume $v=\left|V^{\mathrm{C}}\right|$. The cardinality of the integral iso-transformindependents, $\left|\mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)\right|$, is less than or equal to the cardinality of the integal congruent support

$$
\left|\mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T,, z}(A)\right| \leq\left|\mathcal{A}_{U_{A}, \mathrm{i}, V_{A}, z}\right|=\frac{(z+v-1)!}{z!(v-1)!}=\frac{v}{z} \frac{z^{\bar{v}}}{v^{\underline{v}}}=\frac{v^{\bar{z}}}{z^{\underline{z}}}
$$

If the independent-sample-distributed iso-transform-independent conditional dependent multinomial space computer, $I_{U, V, z, T, y}$, is implemented such that the computations $\left\{I_{\mathrm{m}}^{*}\left(\left(A^{\mathrm{X}}, B\right)\right): B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)\right\}$ are performed serially, the computation time complexity of $I_{U, V, z, \mathrm{~T}, \mathrm{y}}$ is at least exponential, $\operatorname{maximum}\left(z^{v}, v^{z}\right)$. If the computations are performed in parallel, then it is the computation space complexity which is at least exponential, maximum $\left(z^{v}, v^{z}\right)$. The corresponding computation time/space complexity of the alignmentbounded iso-transform space ideal transform inducer, $I_{z, \mathrm{y}, \mathrm{l}}$, which computes $\left\{I_{U_{A}, V_{A}, z, \mathrm{~T}, \mathrm{y}}^{*}((A, T)): T \in \mathcal{T}_{\text {fa, } \mathrm{j}}(A)\right\}$, is therefore also at least exponential in size, $z$, or substrate volume, $v$. The alignment-bounded iso-transform space ideal transform inducer, $I_{z, \mathrm{y}, \mathrm{l}}$, is therefore an intractable inducer.

The derived alignment, $\operatorname{algn}(A * T)$, is implemented above in the relative literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}, \mathrm{r}}^{\prime}$, as though it were relative dependent multinomial space for purposes of comparison. That is, by means of the independent-sample-distributed relative dependent multinomial space computer, $I_{U, V, z, \mathrm{a}}$, which in turn is implemented with the multinomial space computer, $I_{\mathrm{m}}$. However, the derived alignment does not in fact depend on the independent distribution histogram, $(A * T)^{\mathrm{X}}$, and so a faster implementation is by means of an alignmenter instead. As shown in sections 'Computation of the application of a transform' and 'Computation of alignment', above, the computation of the derived alignment can be performed by the application of a transformer, $I_{* \mathrm{~T}}$, followed by the application of an alignmenter, $I_{\mathrm{a}}=\operatorname{alignmenter}, I_{\mathrm{a}}^{*}\left(I_{* T}^{*}((T, A))\right) \approx \operatorname{algn}(A * T)$. The calculation of alignment in the alignmenter internally computes the independent derived in an independenter, $I_{\mathrm{X}}^{*}(A * T)=(A * T)^{\mathrm{X}}$. In the alignmenter implementation the computation time of histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$ of the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$, is simplified to

$$
I_{z, \mathrm{a}, \mathrm{l}}^{\mathrm{t}}(A)>\sum I_{* \mathrm{~T}}^{\mathrm{t}}((T, A))+I_{\mathrm{a}}^{\mathrm{t}}(A * T): T \in \mathcal{T}_{\mathrm{f}, \mathrm{j}}(A)
$$

Thus the computation time of literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l},}^{\prime}$, is less than the computation time of the relative literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}, \mathrm{r}}^{\prime}$,

$$
\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(I_{z, \mathrm{a}, \mathrm{l}}^{\prime \mathrm{t}}(A)<I_{z, \mathrm{a}, \mathrm{l}, \mathrm{r}}^{\mathrm{t}}(A)\right)
$$

Therefore the computation time of the literal derived alignment integralindependent substrate ideal formal-abstract transform inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\mathrm{t}}(A)$, must be less than that of the literal alignment-bounded iso-transform space ideal transform inducer, $I_{z, \mathrm{y}, 1}^{\mathrm{t}}(A)$. That is,

$$
\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(I_{z, \mathrm{a}, \mathrm{l}}^{\mathrm{t}}(A)<I_{z, \mathrm{y}, \mathrm{l}}^{\mathrm{t}}(A)\right)
$$

The time of the alignment computation, $I_{* \mathrm{~T}}^{\mathrm{t}}((T, A))+I_{\mathrm{a}}^{\mathrm{t}}(A * T)$, depends on the representations of the histogram and transform, as well as the implementation of the $\log$ factorialer, $I_{\approx \ln !}=\operatorname{logfactorialer}$. If the histogram, $A$, is implemented in an array histogram representation and the transform, $T$, is implemented in a binary map histogram representation, both on ordered list state representations, then the time complexity is maximum $(v \ln v, m w)$, where the underlying dimension $n=|V|$, the underlying volume $v=\left|V^{\mathrm{C}}\right|$, the derived dimension $m=|W|$, the derived volume $w=\left|W^{\mathrm{C}}\right|$ and the derived variables $W=\operatorname{der}(T)$. If the histogram, $A$, is implemented in a binary map histogram representation, then the time complexity is maximum $(b \ln v, m w)$,
where the effective volume $b=\left|A^{\mathrm{F}}\right|$. The time complexity of the independenter is $m w$.

Given that (i) the independent substrate histogram is completely effective, $A^{\mathrm{XF}}=V^{\mathrm{C}}$, and (ii) literal substrate transforms, $\mathcal{T}_{\text {fa, } \mathrm{j}}(A)$, are such that the formal histogram is independent, $A^{\mathrm{X}} * T \equiv(A * T)^{\mathrm{X}} \Longrightarrow A^{\mathrm{X}} * T \equiv\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, then the effective formal histogram is a cartesian sub-volume, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{F}}=$ $\left(V^{\mathrm{C}} * T\right)^{\mathrm{F}}=\left(V^{\mathrm{C}} * T\right)^{\mathrm{XF}}$. The derived variables of the transform, $T$, are partition variables, $\operatorname{der}(T) \subseteq \mathrm{B}\left(V^{\mathrm{CS}}\right)$, so the cartesian sub-volume must equal the cartesian derived, $\left(V^{\mathrm{C}} * T\right)^{\mathrm{XF}}=W^{\mathrm{C}}$. Therefore the effective formal equals the cartesian derived, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{F}}=W^{\mathrm{C}}$. The transform is functional, $T \in \mathcal{T}_{\mathrm{f}}$, so the derived volume is no greater than the underlying volume, $w \leq v$. Thus the computation time complexity of the alignmenter implementation of the literal derived alignment integral-independent substrate ideal formal-abstract transform inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}(A)$, for a literal substrate transform, $T \in \mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)$, is $\operatorname{maximum}(v \ln v, m v)$.

In the stricter case that the transform is non-overlapping, $\neg \operatorname{overlap}(T) \Longrightarrow$ $A^{\mathrm{X}} * T \equiv\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, then the derived dimension is no greater than the underlying dimension, $m \leq n$. In this case, the computation time complexity of the alignmenter implementation of the literal derived alignment integralindependent substrate ideal formal-abstract transform inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}(A)$, for a non-overlapping literal substrate transform, $T \in \mathcal{T}_{\text {fa, }}(A) \cap \mathcal{T}_{U_{A}, V_{A}, \mathrm{n}}$, is at most $\log$-linear in $v$, maximum $(v \ln v, n v)=v \ln v$

$$
\begin{aligned}
\forall z \in & \mathbf{N}_{>0} \exists c \in \mathbf{N}_{>0} \\
& \left(\left\{\left((A, T), I_{* \mathrm{~T}}^{\mathrm{t}}((T, A))+I_{\mathrm{a}}^{\mathrm{t}}(A * T)\right): A \in \mathcal{A}_{z, \mathrm{xi}}, T \in \mathcal{T}_{U_{A}, V_{A}, \mathrm{n}}\right\}\right. \\
\in & \left.\mathrm{O}\left(\left\{((A, T), v \ln v): A \in \mathcal{A}_{z, \mathrm{xi}}, T \in \mathcal{T}_{U_{A}, V_{A}, \mathrm{n}}, v=\left|V_{A}^{\mathrm{C}}\right|\right\}, c\right)\right)
\end{aligned}
$$

The overall non-overlapping computation time complexity, $v \ln v$, is not $\lim -$ ited by the computation time complexity of the independenter, mw. However, if the independent histogram, $A^{\mathrm{X}}$, has previously been computed, then a faster implementation of $I_{z, \text { a,l }}^{\prime *}(A)(T)$ might be to lift rather than derive. In this case the alignmenter would not need to compute $I_{\mathrm{X}}^{*}(A * T)=(A * T)^{\mathrm{X}}$ but merely apply the log factorialer to $I_{* \mathrm{~T}}^{*}\left(\left(T, A^{\mathrm{X}}\right)\right)=A^{\mathrm{X}} * T$.

Contrast the non-overlapping computation time complexity, $v \ln v$, of the alignmenter implementation, in the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, to the serially implemented independent-sample-distributed iso-transformindependent conditional dependent multinomial space computer, $I_{U, V, z, \mathrm{~T}, \mathrm{y}}$, in the literal alignment-bounded inducer, $I_{z, \mathrm{y}, 1}$, which has at least exponential
computation time complexity in both $v$ and $z$, maximum $\left(z^{v}, v^{z}\right)$. Note that the time complexity of the alignmenter implementation in the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, whether overlapping or not, does not depend on $z$ at all.

Consider a literal derived alignment integral-independent substrate ideal formal-abstract fud inducer $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}}^{\prime} \in \operatorname{inducers}(z)$ which has, as its subset of the substrate models, the literal substrate fuds,

$$
\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{~F}, \mathrm{l}}^{\prime *}(A)\right)=\mathcal{F}_{\mathrm{f}, \mathrm{j}, \mathrm{j}}(A) \subset \mathcal{M}_{U_{A}, V_{A}}\right)
$$

where the literal substrate fuds is defined $\mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A)=\left\{F: F \in \mathcal{F}_{U_{A}, V_{A}}, A^{\mathrm{X}}{ }^{*}\right.$ $\left.F^{\mathrm{T}}=\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}, A=A * F^{\mathrm{T}} * F^{\mathrm{T} \dagger A}\right\} \subset \mathcal{F}_{U_{A}, V_{A}}$. The application of the literal derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, 1}^{\prime}$, makes the same finite approximation of the log-rational approxer, $I_{\approx \ln \mathbf{Q}}$, as is made in the literal transform inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$,

$$
\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(I_{z, \mathrm{a}, \mathrm{~F}, \mathrm{l}}^{\prime}(A)=\left\{\left(F, I_{\approx \ln \mathbf{Q}}^{*}\left(\operatorname{algn}\left(A * F^{\mathrm{T}}\right)\right)\right): F \in \mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A)\right\}\right)
$$

So the maximum transform function of the literal derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, 1}^{\prime}$, equals the maximum transform of the literal derived alignment transform inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$, maxr $\circ I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}}^{\prime *}=\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}$. Therefore the correlation of the maximum transform function of the literal derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, 1}^{\prime}$, with that of the alignment-bounded iso-transform space ideal transform search set, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}$, equals the correlation of the literal derived alignment transform inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$,

$$
\begin{aligned}
& \forall z \in \mathbf{N}_{>0} \\
& \quad\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j},}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}\right)=\right. \\
& \left.\quad \operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j},}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{~F}, \mathrm{l}}^{\prime *}\right)\right)
\end{aligned}
$$

The literal substrate fuds includes those fuds which consist solely of a literal substrate transform, $\left\{\{T\}: T \in \mathcal{T}_{\text {fa, }}(A)\right\} \subset \mathcal{F}_{\text {fa }, \mathrm{j}}(A)$. Therefore both the time and space of the literal fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, 1}^{\prime}$, are greater than the corresponding time and space of the literal transform inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, whether the implementation is serial or parallel, $\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}}^{\mathrm{t}}(A)>I_{z, \mathrm{a}, \mathrm{l}}^{\mathrm{t}}(A)\right)$ and $\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}}^{\prime \mathrm{s}}(A)>I_{z, \mathrm{a}, \mathrm{l}}^{\prime \mathrm{s}}(A)\right)$.

Similarly, consider a literal derived alignment integral-independent substrate ideal formal-abstract decomposition inducer $I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime} \in \operatorname{inducers}(z)$ which has, as its subset of the substrate models, the literal substrate decompositions,

$$
\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{D}, \mathrm{l}}^{\prime *}(A)\right)=\mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A) \subset \mathcal{M}_{U_{A}, V_{A}}\right)
$$

where the literal substrate decompositions is defined $\mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A)=\{D: D \in$ $\left.\mathcal{D}_{U_{A}, V_{A}}, \quad A^{\mathrm{X}} * D^{\mathrm{T}}=\left(A * D^{\mathrm{T}}\right)^{\mathrm{X}}, \quad A=A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}\right\} \subset \mathcal{D}_{U_{A}, V_{A}}$. The application of the literal derived alignment decomposition inducer, $I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime}$, makes the same finite approximation of the log-rational approxer, $I_{\approx \ln \mathbf{Q}}$, as is made in the literal transform inducer, $I_{z, \mathrm{a}, 1}^{\prime}$,

$$
\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(I_{z, \mathrm{a}, \mathrm{D}, \mathrm{l}}^{\prime *}(A)=\left\{\left(D, I_{\approx \ln \mathbf{Q}}^{*}\left(\operatorname{algn}\left(A * D^{\mathrm{T}}\right)\right)\right): D \in \mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A)\right\}\right)
$$

So the maximum transform function of the literal derived alignment decomposition inducer, $I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime}$, equals the maximum transform of the literal derived alignment transform inducer, $I_{z, \mathrm{a}, 1}^{\prime}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime *}=\operatorname{maxr} \circ I_{z, \mathrm{a}, 1}^{\prime *}$.

The literal substrate decompositions includes those decompositions which consist solely of a literal substrate transform, $\left\{\{((\emptyset, T), \emptyset)\}: T \in \mathcal{T}_{\text {fa, }}(A)\right\} \subset$ $\mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A)$. Therefore both the time and space of the literal decomposition inducer, $I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime}$, are greater than the corresponding time and space of the literal transform inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, whether the implementation is serial or parallel, $\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(I_{z, \mathrm{a}, \mathrm{D}, \mathrm{l}}^{\prime \prime}(A)>I_{z, \mathrm{a}, 1}^{\prime \mathrm{t}}(A)\right)$ and $\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime \mathrm{s}}(A)>I_{z, \mathrm{a}, 1}^{\prime \mathrm{s}}(A)\right)$.

Finally, consider a literal derived alignment integral-independent substrate ideal formal-abstract fud decomposition inducer $I_{z, \mathrm{a}, \mathrm{D}, \mathrm{F}, \mathrm{l}}^{\prime} \in \operatorname{inducers}(z)$ which has, as its subset of the substrate models, the literal substrate fud decompositions,

$$
\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{D}, \mathrm{~F}, \mathrm{l}}^{\prime *}(A)\right)=\mathcal{D}_{\mathrm{F}, \mathrm{fa}, \mathrm{j}}(A) \subset \mathcal{M}_{U_{A}, V_{A}}\right)
$$

where the literal substrate fud decompositions is defined $\mathcal{D}_{\mathrm{F}, \mathrm{fa}, \mathrm{j}}(A)=\{D$ : $\left.D \in \mathcal{D}_{\mathrm{F}, U_{A}, V_{A}}, \quad A^{\mathrm{X}} * D^{\mathrm{T}}=\left(A * D^{\mathrm{T}}\right)^{\mathrm{X}}, \quad A=A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}\right\} \subset \mathcal{D}_{\mathrm{F}, U_{A}, V_{A}}$. The application of the literal derived alignment fud decomposition inducer, $I_{z, \mathrm{a}, \mathrm{D}, \mathrm{F}, 1}^{\prime}$, makes the same finite approximation of the log-rational approxer, $I_{\approx \ln \mathbf{Q}}$, as is made in the literal transform inducer, $I_{z, \mathrm{a}, 1}^{\prime}$,

$$
\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(I_{z, \mathrm{a}, \mathrm{D}, \mathrm{~F}, \mathrm{l}}^{\prime *}(A)=\left\{\left(D, I_{\approx \ln \mathbf{Q}}^{*}\left(\operatorname{algn}\left(A * D^{\mathrm{T}}\right)\right)\right): D \in \mathcal{D}_{\mathrm{F}, \mathrm{fa}, \mathrm{j}}(A)\right\}\right)
$$

So the maximum transform function of the literal derived alignment fud decomposition inducer, $I_{z, \mathrm{a}, \mathrm{D}, \mathrm{F}, 1}^{\prime}$, equals the maximum transform of the literal derived alignment transform inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, \mathrm{F}, \mathrm{l}}^{\prime *}=\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}$.

The literal substrate fud decompositions includes those decompositions which consist solely of a literal substrate fud, $\left\{\{(\emptyset, F)\}: F \in \mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A)\right\} \subset \mathcal{D}_{\mathrm{F}, \mathrm{fa}, \mathrm{j}}(A)$. Therefore both the time and space of the literal fud decomposition inducer, $I_{z, \mathrm{a}, \mathrm{D}, \mathrm{F}, 1}^{\prime}$, are greater than the corresponding time and space of the literal fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, 1}^{\prime}$, whether the implementation is serial or parallel, $\forall A \in$ $\mathcal{A}_{z, \mathrm{xi}}\left(I_{z, \mathrm{a}, \mathrm{D}, \mathrm{F}, \mathrm{l}}^{\prime \mathrm{t}}(A)>I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}}^{\prime \mathrm{t}}(A)\right)$ and $\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(I_{z, \mathrm{a}, \mathrm{D}, \mathrm{F}, 1}^{\prime \mathrm{s}}(A)>I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}}^{\prime \mathrm{s}}(A)\right)$.

### 4.21.2 Summation aligned decomposition inducers

Consider non-literal inducers which have, as their subset of the substrate models, the subset of the substrate decompositions, $\mathcal{D}_{U_{A}, V_{A}}$, that are also summation aligned decompositions, $\mathcal{D}_{\Sigma}(A)$, where $A \in \mathcal{A}_{z, \mathrm{xi}}$. The summation aligned decompositions, $\mathcal{D}_{\Sigma}(A)$, are defined in section 'Decomposition alignment' above. Summation aligned decompositions (a) are well behaved distinct decompositions, $\mathcal{D}_{\Sigma}(A) \subset \mathcal{D}_{\mathrm{w}, U_{A}}$, (b) have no variable symmetries, $\{(w,(C, T)):(C, T) \in \operatorname{cont}(D), w \in \operatorname{der}(T)\} \in \operatorname{der}(G) \rightarrow \operatorname{cont}(D)$, and (c) are subject to the constraints of (i) contingent diagonalisation, $\forall(C, T) \in$ $\operatorname{cont}(D)$ (diagonal $(A * C * T)$ ), and (ii) contingent formal-abstract equivalence, $\forall(C, T) \in \operatorname{cont}(D)\left((A * C * T)^{\mathrm{X}}=A^{\mathrm{X}} * C * T\right)$, with respect to the histogram, $A$, where $G=\operatorname{transforms}(D)$ and cont $=$ elements o contingents. Summation aligned decompositions are such that the content alignment equals the summation alignment,

$$
\forall D \in \mathcal{D}_{\Sigma}(A)\left(\operatorname{algn}\left(A * D^{\mathrm{T}}\right)-\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)=\operatorname{alignmentSum}(A, D)\right)
$$

where $D^{\mathrm{T}}$ is the nullable transform, and the summation alignment is defined alignmentSum $\in \mathcal{A} \times \mathcal{D} \rightarrow \mathbf{R}$ as

$$
\operatorname{alignmentSum}(A, D):=\sum_{(C, T) \in \operatorname{cont}(D)} \operatorname{algn}(A * C * T)
$$

In order to calculate the summation alignment, alignmentSum $(A, D)$, only the contingent alignments, $\operatorname{algn}(A * C * T)$, of the recursive contingents tree, contingents $(D) \in \operatorname{trees}\left(\mathcal{A} \times \mathcal{T}_{\mathrm{f}}\right)$, need be computed. The contingents tree, contingents $(D)$, does not depend on the nullable fud, nullable $\left(U_{A}\right)(D)$, so there is no need to compute any of the slice transforms or their dependents. Thus the nullable transform, $D^{\mathrm{T}}$, need not be computed by the inducer. However, first consider an inducer where the nullable transform, $D^{\mathrm{T}}$, is computed.

Define the derived alignment integral independent substrate summation aligned decomposition inducer $I_{z, \mathrm{a}, \mathrm{D}, \Sigma}^{\prime} \in \operatorname{inducers}(z)$ such that the application to a substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$ is the nullable transform derived alignment approximation function of the substrate summation aligned decompositions,

$$
I_{z, \mathrm{a}, \mathrm{D}, \Sigma}^{*}(A)=\left\{\left(D, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}\left(A * D^{\mathrm{T}}\right)\right)\right): D \in \mathcal{D}_{U_{A}, V_{A}} \cap \mathcal{D}_{\Sigma}(A)\right\}
$$

The derived alignment summation aligned inducer, $I_{z, \mathrm{a}, \mathrm{D}, \Sigma}^{\prime}$, is defined with the real approxer, $I_{\approx \mathbf{R}}$, rather than the log-rational approxer, $I_{\approx \ln \mathbf{Q}}$, because
in some cases the abstract alignment is not integral, $\left(A * D^{\mathrm{T}}\right)^{\mathrm{X}} \notin \mathcal{A}_{\mathrm{i}}$. In these cases, the derived alignment, algn $\left(A * D^{\mathrm{T}}\right)$, must be computed in the alignmenter, $I_{\mathrm{a}}$, by means of an implementation of the unit-translated gamma function, $\Gamma_{!}$, such as in the $\log$ factorialer, $I_{\approx \ln !}$, because the factorial computations are not always integral.

However, the application of the real approxer is a superset of the application of the log-rational approxer, $I_{\approx \mathrm{n} \mathbf{Q}}^{*} \subset I_{\approx \mathrm{R}}^{*}$, and so there may exist an intersection between the application of the derived alignment summation aligned inducer, $I_{z, \mathrm{a}, \mathrm{D}, \Sigma}^{\prime}$, and the application of the literal derived alignment decomposition inducer, $I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime}$. That is, $\left|I_{z, \mathrm{a}, \mathrm{D}, \Sigma}^{\prime *}(A) \cap I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime}(A)\right| \geq 0$.

In order to consider this intersection, compare the substrate summation aligned decompositions, $\mathcal{D}_{U_{A}, V_{A}} \cap \mathcal{D}_{\Sigma}(A)$, to the literal substrate decompositions, $\mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A)=\left\{D: D \in \mathcal{D}_{U_{A}, V_{A}}, A^{\mathrm{X}} * D^{\mathrm{T}}=\left(A * D^{\mathrm{T}}\right)^{\mathrm{X}}, A=A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}\right\}$. The substrate summation aligned decompositions, $\mathcal{D}_{U_{A}, V_{A}} \cap \mathcal{D}_{\Sigma}(A)$, are interesting because inducers having them as their set of substrate models are able to avoid the computation of the nullable transform, $D^{\mathrm{T}}$. The literal substrate decompositions, $\mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A)$, are interesting because inducers having them as their set of substrate models have a maximum transform function of the derived alignment that is correlated with that of the alignment-bounded isotransform space ideal transform search set, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}$.

Intersecting decompositions $D \in \mathcal{D}_{\Sigma}(A) \cap \mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A)$, are such that they are (i) contingently diagonalised, $\forall(C, T) \in \operatorname{cont}(D)(\operatorname{diagonal}(A * C * T))$, (ii) contingently formal-abstract equal, $\forall(C, T) \in \operatorname{cont}(D)\left(A^{\mathrm{X}} * C * T=(A * C * T)^{\mathrm{x}}\right)$, (iii) formal-abstract equal, $A^{\mathrm{X}} * D^{\mathrm{T}}=\left(A * D^{\mathrm{T}}\right)^{\mathrm{X}}$, and (iv) ideal, $A=$ $A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}$. For example, a decomposition consisting solely of a root transform $D=\left\{\left(\left(\emptyset, T_{\mathrm{r}}\right), \emptyset\right)\right\}$ such that the root transform, $T_{\mathrm{r}}$, is both diagonal, diagonal $\left(A * T_{\mathrm{r}}\right)$, and ideal, $A=A * T_{\mathrm{r}} * T_{\mathrm{r}}^{\dagger A}$. In this case, the contingent formal-abstract equality and formal-abstract equality constraints are equivalent, $A^{\mathrm{X}} * V_{A}^{\mathrm{C}} * T_{\mathrm{r}}=\left(A * V_{A}^{\mathrm{C}} * T_{\mathrm{r}}\right)^{\mathrm{X}} \Longleftrightarrow A^{\mathrm{X}} * T_{\mathrm{r}}=\left(A * T_{\mathrm{r}}\right)^{\mathrm{X}}$, because $\operatorname{cont}(D)=\left\{\left(V_{A}^{\mathrm{C}}, T\right)\right\}$, so $\left\{\left(\left(\emptyset, T_{\mathrm{r}}\right), \emptyset\right)\right\} \in \mathcal{D}_{\Sigma}(A) \cap \mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A)$.

As noted above, the set of transforms of the substrate models searched by an inducer need not intersect with the literal substrate transforms. All that is required of the derived alignment summation aligned inducer, $I_{z, \mathrm{a}, \mathrm{D}, \Sigma}^{\prime}$, is that there is a positive correlation between the maximum function and the alignment-bounded iso-transform space ideal transform maximum function, $\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{f}, \mathrm{j},}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, \Sigma}^{\prime *}\right) \geq 0$. Conjecture that this is indeed
the case because of the positive, but not perfect, transitive correlation with the literal derived alignment decomposition inducer, $I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime}$

$$
\begin{aligned}
& \forall z \in \mathbf{N}_{>0} \\
& \begin{aligned}
\left(\operatorname{var}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, \mathrm{l}}^{\prime *}\right)\right. & >0 \wedge \operatorname{var}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, \Sigma}^{\prime *}\right)>0 \Longrightarrow \\
& \left.1>\operatorname{corr}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, \Sigma}^{\prime *}\right) \geq 0\right)
\end{aligned}
\end{aligned}
$$

As noted in section 'Tractable alignment-bounding', above, a substrate decomposition $D \in \mathcal{D}_{U_{A}, V_{A}}$ containing more than a root transform, $|G|>$ 1 where $G=\operatorname{transforms}(D)$, is necessarily overlapping, $|G|>1 \Longrightarrow$ $\operatorname{overlap}\left(D^{\mathrm{T}}\right)$, and so in some cases has non-independent formal histogram, $A^{\mathrm{X}} * D^{\mathrm{T}} \neq\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)^{\mathrm{X}}$. If this is the case, the formal histogram cannot be equal to the abstract histogram, $A^{\mathrm{X}} * D^{\mathrm{T}} \neq\left(A * D^{\mathrm{T}}\right)^{\mathrm{X}}$, and so the substrate decomposition, $D$, cannot be a literal substrate decomposition, $D \notin \mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A)$.

If the decomposition is also a summation aligned decomposition, $D \in \mathcal{D}_{U_{A}, V_{A}} \cap$ $\mathcal{D}_{\Sigma}(A)$, then the formal histogram is necessarily non-independent, $(D \in$ $\left.\mathcal{D}_{\Sigma}(A)\right) \wedge(|G|>1) \Longrightarrow A^{\mathrm{X}} * D^{\mathrm{T}} \neq\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)^{\mathrm{X}}$, because the skeletal contingent reduction $D^{\prime} \in \operatorname{reductions}(A, D)$ has formal alignment, $\operatorname{algn}\left(A^{\mathrm{X}} * D^{\prime \mathrm{T}}\right)>$ 0 . The derived alignment of the skeletal contingent reduction, $D^{\prime}$, is purely formal, $A * D^{\prime \mathrm{T}}=A^{\mathrm{X}} * D^{\prime \mathrm{T}}$. The derived alignment of the summation aligned decomposition, $D$, equals that of the skeletal contingent reduction and the sum of the contingent derived alignments,

$$
\operatorname{algn}\left(A * D^{\mathrm{T}}\right)=\operatorname{algn}\left(A * D^{\prime \mathrm{T}}\right)+\sum_{(C, T) \in \operatorname{cont}(D)} \operatorname{algn}(A * C * T)
$$

The summation alignment must be positive, alignmentSum $(A, D)=\sum(\operatorname{algn}(A *$ $C * T):(C, T) \in \operatorname{cont}(D)) \geq 0$, because of contingent diagonalisation. Hence the derived alignment of a multiple transform summation aligned decomposition must be at least the formal alignment of the corresponding skeletal contingent reduction, $\operatorname{algn}\left(A * D^{\mathrm{T}}\right) \geq \operatorname{algn}\left(A^{\mathrm{X}} * D^{\prime \mathrm{T}}\right)>0$. This is true even if the summation alignment is zero, $\sum(\operatorname{algn}(A * C * T):(C, T) \in \operatorname{cont}(D))=0$. This constraint tends to reduce the correlation of the derived alignment summation aligned inducer, $I_{z, \mathrm{a}, \mathrm{D}, \Sigma}^{\prime}$, with the literal derived alignment decomposition inducer, $I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime}$.

Although the slices are contingently formal-abstract equal, $A^{\mathrm{X}} * C * T=$ $(A * C * T)^{\mathrm{x}}$, and therefore contingently independent-formal, $A^{\mathrm{x}} * C * T=$ $\left(A^{\mathrm{X}} * C * T\right)^{\mathrm{x}}$, they are not necessarily independent-formal slices, $(A * C)^{\mathrm{X}} * T=$ $\left((A * C)^{\mathrm{X}} * T\right)^{\mathrm{X}}$, and so the formal alignment, $\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)$, may be
higher than would otherwise be the case. That is, an independent slice, $(A * C)=(A * C)^{\mathrm{X}}$, may have a transform $T$ where the derived alignment is purely formal, $\operatorname{algn}(A * C * T)=\operatorname{algn}\left((A * C)^{\mathrm{X}} * T\right)>0$. The overall formal alignment, $\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)$, is higher in the cases where the slices have formal alignment, not just where the skeletal contingent reduction has formal alignment.

Furthermore, given a substrate summation aligned decomposition $D \in \mathcal{D}_{U_{A}, V_{A}} \cap$ $\mathcal{D}_{\Sigma}(A)$ that is ideal, $A=A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}$, there may exist a super substrate summation aligned decomposition $E \in \mathcal{D}_{U_{A}, V_{A}} \cap \mathcal{D}_{\Sigma}(A)$, where $D \in \operatorname{subtrees}(E)$, having higher derived alignment, $\operatorname{algn}\left(A * E^{\mathrm{T}}\right)>\operatorname{algn}\left(A * D^{\mathrm{T}}\right)$. This is because the independent components of the partition, $D^{\mathrm{P}}$, are allowed purely formal transforms, $\operatorname{algn}(A * C * T)=\operatorname{algn}\left((A * C)^{\mathrm{X}} * T\right)>0$, where $C^{\mathrm{S}} \in D^{\mathrm{P}}$.

Conversely, given a substrate summation aligned decomposition $D \in \mathcal{D}_{U_{A}, V_{A}} \cap$ $\mathcal{D}_{\Sigma}(A)$ that is ideal, $A=A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}$, there may exist a super substrate summation aligned decomposition $E \in \mathcal{D}_{U_{A}, V_{A}} \cap \mathcal{D}_{\Sigma}(A)$, where $D \in$ $\operatorname{subtrees}(E)$, having the same summation alignment, alignmentSum $(A, E)=$ alignmentSum $(A, D)$, but higher derived alignment, $\operatorname{algn}\left(A * E^{\mathrm{T}}\right)>\operatorname{algn}(A *$ $\left.D^{\mathrm{T}}\right)$, because of higher skeletal formal alignment, $\operatorname{algn}\left(A^{\mathrm{X}} * E^{\mathrm{T}}\right)>\operatorname{algn}\left(A^{\mathrm{X}} *\right.$ $D^{\prime \mathrm{T}}$ ). For example, if the super-decomposition, $E$, is an immediate superdecomposition having additional slice $\{(C, T)\}=\operatorname{cont}(E) \backslash \operatorname{cont}(D)$ which is such that $\operatorname{algn}(A * C * T)=0$. Therefore these cases also reduce the correlation of the derived alignment summation aligned inducer, $I_{z, \mathrm{a}, \mathrm{D}, \Sigma}^{\prime}$, with the literal derived alignment decomposition inducer, $I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime}$.

Therefore consider the set of idealising summation aligned decompositions, $\mathcal{D}_{\Sigma, \mathrm{k}}(A) \subset \mathcal{D}_{\Sigma}(A)$, which are summation aligned decompositions that are subject to two additional constraints, (iii) non-independent contingent derived histograms, $\forall(C, T) \in \operatorname{cont}(D)\left(A * C * T \neq(A * C * T)^{\mathrm{X}}\right)$ and (iv) independent formal slice, $\forall(C, T) \in \operatorname{cont}(D)\left((A * C)^{\mathrm{x}} * T=\left((A * C)^{\mathrm{x}} * T\right)^{\mathrm{x}}\right)$. Define the derived alignment integral-independent substrate idealising summation aligned decomposition inducer $I_{z, \mathrm{a}, \mathrm{D}, \mathrm{\Sigma}, \mathrm{k}}^{\prime} \in \operatorname{inducers}(z)$ such that the application to a non-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}} \backslash\left\{A^{\mathrm{X}}\right\}$ is the nullable transform alignment approximation function of the substrate idealising summation aligned decompositions,

$$
I_{z, \mathrm{a}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime *}(A)=\left\{\left(D, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}\left(A * D^{\mathrm{T}}\right)\right)\right): D \in \mathcal{D}_{U_{A}, V_{A}} \cap \mathcal{D}_{\Sigma, \mathrm{k}}(A)\right\}
$$

There are no idealising summation aligned decompositions of an independent substrate histogram, $\mathcal{D}_{\Sigma, \mathrm{k}}\left(A^{\mathrm{X}}\right)=\emptyset$, but the definition of an inducer requires
a domain of at least the integral-independent substrate histograms, $\mathcal{A}_{z, \mathrm{xi}}$, so define

$$
I_{z, \mathrm{a}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime *}\left(A^{\mathrm{X}}\right)=\left\{\left(D_{\mathrm{u}}, 0\right)\right\}
$$

where $D_{\mathrm{u}}=\left\{\left(\left(\emptyset, T_{\mathrm{u}}\right), \emptyset\right)\right\}$ and $T_{\mathrm{u}}=\left\{V_{A}^{\mathrm{CS}}\right\}^{\mathrm{T}}$.
An idealising substrate summation aligned decomposition $D \in \mathcal{D}_{U_{A}, V_{A}} \cap$ $\mathcal{D}_{\Sigma, \mathrm{k}}(A)$ that is ideal, $A=A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}$, has no super idealising substrate summation aligned decomposition, $\forall E \in \mathcal{D}_{U_{A}, V_{A}} \cap \mathcal{D}_{\Sigma, \mathrm{k}}(A)(D \notin \operatorname{subtrees}(E))$. Conjecture that the derived alignment idealising summation aligned inducer, $I_{z, \mathrm{a}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime}$, is positively, but not perfectly, correlated with the literal derived alignment decomposition inducer, $I_{z, \mathrm{a}, \mathrm{D}, \mathrm{l}}^{\prime}$

$$
\begin{aligned}
& \forall z \in \mathbf{N}_{>0} \\
& \begin{aligned}
\left(\operatorname{var}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime *}\right)\right. & >0 \wedge \operatorname{var}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime *}\right)>0 \Longrightarrow \\
& \left.1>\operatorname{corr}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, \mathrm{l}}^{\prime *} \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime}\right) \geq 0\right)
\end{aligned}
\end{aligned}
$$

and that the correlation is greater than that for the derived alignment summation aligned inducer, $I_{z, \mathrm{a}, \mathrm{D}, \Sigma}^{\prime}$,

$$
\begin{aligned}
& \forall z \in \mathrm{~N}_{>0} \\
& \qquad\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, \Sigma}^{\prime *}\right) \leq\right. \\
& \left.\qquad \operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, \Sigma, \mathrm{k}, \mathrm{k}}^{\prime *}\right)\right)
\end{aligned}
$$

The correlation is increased by the additional idealising constraints which, while they do not increase the cardinality of the literal intersection, $\mid \mathcal{D}_{\Sigma, \mathrm{k}}(A) \cap$ $\mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A)\left|\leq\left|\mathcal{D}_{\Sigma}(A) \cap \mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A)\right|\right.$, remove decompositions from the maximum set, $\operatorname{maxd}\left(I_{z, \mathrm{a}, \mathrm{D}, \Sigma}^{*}(A)\right) \subset \mathcal{D}_{U_{A}, V_{A}} \cap \mathcal{D}_{\Sigma}(A)$, that are there because of unnecessary formal alignment. That is, $\operatorname{maxr}\left(I_{z, \mathrm{a}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime *}(A)\right) \leq \operatorname{maxr}\left(I_{z, \mathrm{a}, \mathrm{D}, \Sigma}^{\prime}(A)\right)$.

Now define the content alignment integral-independent substrate idealising summation aligned decomposition inducer $I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime} \in \operatorname{inducers}(z)$ such that the application to a non-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}} \backslash\left\{A^{\mathrm{X}}\right\}$ is the summation alignment approximation function of the substrate idealising summation aligned decompositions,

$$
I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime}(A)=\left\{\left(D, I_{\approx \ln \mathbf{Q}}^{*}(\operatorname{algnSum}(A, D))\right): D \in \mathcal{D}_{U_{A}, V_{A}} \cap \mathcal{D}_{\Sigma, \mathbf{k}}(A)\right\}
$$

where algnSum $=$ alignmentSum. Define $I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime *}\left(A^{\mathrm{X}}\right)=\left\{\left(D_{\mathrm{u}}, 0\right)\right\}$. Note that the computation of summation alignment, $\operatorname{algnSum}(A, D)$, does not require the computation of non-integral factorials because the abstract histogram of the slices is integral, $\left(A^{\mathrm{X}} \in \mathcal{A}_{\mathfrak{i}}\right) \wedge\left(A^{\mathrm{X}} * C * T=(A * C * T)^{\mathrm{X}}\right) \Longrightarrow$
$(A * C * T)^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$. Therefore the alignmenter, $I_{\mathrm{a}}$, need not be implemented by means of an implementation of the unit-translated gamma function, $\Gamma_{!}$, such as in the $\log$ factorialer, $I_{\approx \ln !}$. The log-rational approxer, $I_{\approx \ln \mathbf{Q}}$, can therefore be used in preference to the real approxer, $I_{\approx \mathbf{R}}$.

The content alignment idealising summation aligned inducer, $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{\Sigma}, \mathrm{k}}^{\prime}$, avoids the computation of the nullable transform, $D^{\mathrm{T}}$, but compromises by computing only the content alignment, $\operatorname{algn}\left(A * D^{\mathrm{T}}\right)-\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)=\operatorname{algnSum}(A, D)$, instead of the derived alignment, $\operatorname{algn}\left(A * D^{\mathrm{T}}\right)$. Of course, the literal substrate decompositions, $\mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A)$, of the literal derived alignment decomposition inducer, $I_{z, \mathrm{a}, \mathrm{D}, \mathrm{l}}^{\prime}$, have no formal alignment, $\forall E \in \mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A)\left(\operatorname{algn}\left(A^{\mathrm{X}} * E^{\mathrm{T}}\right)=0\right)$, because formal-abstract equality implies independent formal, $A^{\mathrm{X}} * E^{\mathrm{T}}=$ $\left(A * E^{\mathrm{T}}\right)^{\mathrm{X}} \Longrightarrow A^{\mathrm{X}} * E^{\mathrm{T}}=\left(A^{\mathrm{X}} * E^{\mathrm{T}}\right)^{\mathrm{X}}$. Thus the intersecting summation aligned decompositions, $\mathcal{D}_{\Sigma}(A) \cap \mathcal{D}_{\mathrm{fa}, \mathrm{j}}(A)$, are such that content alignment equals derived alignment. So the reduction in correlation is not necessarily as great as would otherwise be the case. Conjecture that the content alignment idealising summation aligned inducer, $I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime}$, is positively correlated with the literal derived alignment decomposition inducer, $I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime}$

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime *}\right) \geq 0\right)
$$

but that the correlation is lower than that for the derived alignment idealising summation aligned inducer, $I_{z, \mathrm{a}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime}$,

$$
\begin{aligned}
& \forall z \in \mathbf{N}_{>0} \\
& \qquad\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, \Sigma, \mathrm{k}, \mathrm{k}}^{\prime *}\right) \geq\right. \\
& \\
& \left.\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime *}\right)\right)
\end{aligned}
$$

An idealising substrate summation aligned decomposition $D \in \mathcal{D}_{U_{A}, V_{A}} \cap$ $\mathcal{D}_{\Sigma, \mathrm{k}}(A)$ that is ideal, $A=A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}$, has no super idealising substrate summation aligned decomposition, $\forall E \in \mathcal{D}_{U_{A}, V_{A}} \cap \mathcal{D}_{\Sigma, \mathrm{k}}(A)(D \notin \operatorname{subtrees}(E))$. All of its sub idealising substrate summation aligned decompositions have lower content alignment, $\forall E \in \mathcal{D}_{U_{A}, V_{A}} \cap \mathcal{D}_{\Sigma, \mathrm{k}}(A)(E \in \operatorname{subtrees}(D) \Longrightarrow$ $\operatorname{algnSum}(A, E)<\operatorname{algnSum}(A, D))$. Therefore, the maximum idealising substrate summation aligned decompositions in the content idealising inducer, $I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime}$, are all ideal, $\forall D \in \operatorname{maxd}\left(I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime *}(A)\right)$ (ideal $\left.\left(A, D^{\mathrm{T}}\right)\right)$. Thus the content idealising inducer, $I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime}$, is positively correlated with the literal derived alignment decomposition inducer, $I_{z, \mathrm{a}, \mathrm{D}, 1}^{\prime}$, because the maximum idealising substrate summation aligned decompositions are all ideal even if not formal-abstract equivalent.

Define the content alignment integral-independent substrate idealising summation aligned fud decomposition inducer $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \Sigma, \mathrm{k}}^{\prime} \in \operatorname{inducers}(z)$ such that the application to a non-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}} \backslash\left\{A^{\mathrm{X}}\right\}$ is the summation alignment approximation function of the substrate idealising summation aligned fud decompositions,

$$
\begin{aligned}
& I_{z, \mathrm{c}, \mathrm{D}, \mathrm{~F}, \Sigma, \mathrm{k}}^{\prime *}(A)= \\
& \quad\left\{\left(D, I_{\approx \ln \mathbf{Q}}^{*}(\operatorname{algnSum}(A, D))\right): D \in \mathcal{D}_{\mathrm{F}, U_{A}, V_{A}}, D^{\mathrm{D} V_{A}} \in \mathcal{D}_{\Sigma, \mathrm{k}}(A)\right\}
\end{aligned}
$$

where $D^{\mathrm{D} V}:=\operatorname{map}(\operatorname{expand}(U, V) \circ$ transform, $D)$. Define $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \Sigma, \mathrm{k}}^{*}\left(A^{\mathrm{X}}\right)=$ $\left\{\left(D_{\mathrm{F}, \mathrm{u}}, 0\right)\right\}$ where $D_{\mathrm{F}, \mathrm{u}}=\left\{\left(\left(\emptyset,\left\{T_{\mathrm{u}}\right\}\right), \emptyset\right)\right\}$ and $T_{\mathrm{u}}=\left\{V_{A}^{\mathrm{CS}}\right\}^{\mathrm{T}}$.

The maximum transform function of the content alignment fud decomposition inducer $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \Sigma, \mathrm{k}}^{\prime}$, equals the maximum transform function of the content alignment decomposition inducer $I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime}$, maxro $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \Sigma, \mathrm{k}}^{*}=\operatorname{maxro} I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime}$, because the applications of the inducers can be mapped, $\left\{\left(D^{D V_{A}}, c\right):(D, c) \in\right.$ $\left.I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \Sigma, \mathrm{k}}^{\prime}(A)\right\}=I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime *}(A)$.

### 4.21.3 Intractabilities

Although the computation time of the literal derived alignment integralindependent substrate ideal formal-abstract transform inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, is lower than that of the intractable literal alignment-bounded iso-transform space ideal transform inducer, $I_{z, \mathrm{y}, \mathrm{l}}, \forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(I_{z, \mathrm{a}, \mathrm{l}}^{\mathrm{t}}(A)<I_{z, \mathrm{y}, \mathrm{l}}^{\mathrm{t}}(A)\right)$, the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, is also an intractable inducer. That is, either or both of (a) the computational time complexity, or (b) the representational encoding space complexity, is greater than polynomial with respect to some parameter. There are several reasons why this is the case, (i) intractable substrate volume, (ii) intractable derived volume, (iii) intractable search set domain, (iv) intractable partition variables, and (v) intractable literal substrate model inclusion.

### 4.21.4 Intractable substrate volume

The literal substrate transforms $\mathcal{T}_{\text {fa, },}(A) \subset \mathcal{T}_{U_{A}, V_{A}}$ of integral-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$, are not tractably computable. The application of the transformer $I_{* \mathrm{~T}}$, in the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, to the substrate histogram, $A$, and any literal substrate transform, $T \in \mathcal{T}_{\text {fa, }}(A)$, is $I_{* \mathrm{~T}}^{*}((T, A))=A * T$. The representation encoding space complexity of the one functional transform, $T$, in the transformer, $I_{* \mathrm{~T}}$, varies as the underlying volume $v=\left|V_{A}^{\mathrm{C}}\right|$. This is because the histogram, $\operatorname{his}(T) \in \mathcal{A}_{\mathrm{i}}$, of
a one functional transform, $T \in \mathcal{T}_{U_{A}, \mathrm{f}, 1}$, has cardinality equal to the underlying volume, $|\operatorname{his}(T)|=v$. Hence the representation space of the transform in the transformer must be at least as large as the underlying volume, $I_{* \mathrm{~T}}^{\mathrm{S}}((T, A))>v$. All substrate transforms have the same underlying volume, $\forall T \in \mathcal{T}_{U_{A}, V_{A}}(|\operatorname{his}(T)|=v)$. The volume grows exponentially with underlying dimension $n=\left|V_{A}\right|$, and so the space complexity of the transformer, $I_{* \mathrm{~T}}$, is exponential with respect to underlying dimension, $n$. For example, a regular substrate of valency $d$ has volume $v=d^{n}$.

Although the space complexity of substrate transforms in the transformer is intractable, the time complexity of the application of the transformer, $I_{* T}^{*}((T, A))$, is tractable. If the transforms are implemented in a binary map histogram representation, a lookup implemented by a binary map getter, $I_{\mathrm{B}, \mathrm{g}}$, has time complexity of only $\ln v$. The overall time complexity of the application is then $b \ln v$ where $b=\left|A^{\mathrm{F}}\right|$, assuming that the substrate histogram, $A$, representation excludes ineffective states, for example in a binary map histogram representation.

Overall, intractable substrate volume, $v$, implies intractable transformer, $I_{* \mathrm{~T}}$. To implement an inducer with tractable substrate models, consider subsets of the substrate, $\mathrm{P}\left(V_{A}\right)$. The cardinality of each of the substrate subsets can then be limited. For example, a maximum underlying volume limit of $\operatorname{xmax} \in \mathbf{N}_{\geq 4}$ could constrain substrate subset $K \subseteq V$ such that $\left|K^{\mathrm{C}}\right| \leq$ xmax. Another example is a maximum underlying dimension limit of $\operatorname{kmax} \in \mathbf{N}_{\geq 2}$ applied such that $|K| \leq$ kmax.

A limited-underlying subset of the functional definition sets $\mathcal{F}_{\mathrm{u}} \subset \mathcal{F}$ can be defined such that a fud $F \in \mathcal{F}_{\mathrm{u}}$ is such that its transforms, $F \subset \mathcal{T}$, are each tractably computable. Given integral-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$, a limited-underlying substrate fud $F \in \mathcal{F}_{U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}}$ has possibly complete coverage of the substrate, $|\operatorname{und}(F)| \leq n$ where $n=\left|V_{A}\right|$, but is such that its transforms, $F \subset \mathcal{T}_{U_{A}, f, 1}$, are each tractably computable. This is achieved by limiting the underlying variables of each transform. For example, a maximum underlying volume limit of xmax would constrain the fud $\forall T \in F \diamond K=\operatorname{und}(T)\left(\left|K^{\mathrm{C}}\right| \leq \mathrm{xmax}\right)$. If the fud is non-overlapping, $\neg \operatorname{overlap}(F)$, and the fud has a single layer, $\forall T \in F \diamond K=\operatorname{und}(T)\left(K \subseteq V_{A}\right)$, then the components of the partition of the substrate each obey the limit. For example, $\forall u \in \operatorname{der}(F) \diamond K=\operatorname{und}(\operatorname{dep}(F,\{u\}))\left(\left|K^{\mathrm{C}}\right| \leq \operatorname{xmax}\right)$. The limited-underlying fuds, $\mathcal{F}_{\mathbf{u}}$, represents the class of subsets of the functional definition sets such that the application of the fud is tractable. That is,
the limited-underlying fuds, $\mathcal{F}_{\mathbf{u}}$, here stands for one of the limiting methods, for example, maximum underlying volume, xmax, or maximum underlying dimension, kmax.

The literal derived alignment integral-independent substrate ideal formalabstract fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, 1}^{\prime}$, has, as its subset of the substrate models, the literal substrate fuds,

$$
\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{~F}, \mathrm{l}}^{\prime *}(A)\right)=\mathcal{F}_{\mathrm{f}, \mathrm{j}, \mathrm{j}}(A) \subset \mathcal{M}_{U_{A}, V_{A}}\right)
$$

As in the case of the literal derived alignment transform inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$, the serial time computation of the literal derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, 1}^{\prime}$, is intractable with respect to underlying volume.

Consider a limited-underlying derived alignment integral-independent substrate ideal formal-abstract fud inducer $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}}^{\prime} \in \operatorname{inducers}(z)$ which has, as its subset of the substrate models, a limited-underlying subset of the literal substrate fuds,

$$
\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{~F}, \mathrm{l}, \mathrm{u}}^{\prime *}(A)\right)=\mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A) \cap \mathcal{F}_{\mathrm{u}} \subset \mathcal{M}_{U_{A}, V_{A}}\right)
$$

The application of the limited-underlying derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}}^{\prime}$, is a subset of the application of the literal derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}}^{\prime}$. That is, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}}^{\prime *}(A) \subseteq I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}}^{\prime *}(A)$. The expanded transforms of the domain of a limited-underlying derived alignment fud inducer is a subset of the literal substrate transforms, $\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(\left\{F^{\mathrm{TV}} \mathrm{V}_{A}: F \in \mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A) \cap \mathcal{F}_{\mathrm{u}}\right\} \subseteq\right.$ $\left.\mathcal{T}_{\text {fa, }, ~}(A)\right)$. The application is implemented in a fuder, see below, but is otherwise equal to that of the derived alignment inducer, $\forall A \in \mathcal{A}_{z, \mathrm{xi}} \forall F \in$ $\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}}^{\prime}(A)\right)\left(I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}}^{\prime *}(A)(F)=I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}(A)\left(F^{\mathrm{T} V_{A}}\right)\right)$. Conjecture that the maximum transform function of the limited-underlying derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}}^{\prime}$, is positively correlated with that of the literal derived alignment transform inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, 1}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{~F}, \mathrm{l}, \mathrm{u}}^{\prime}\right) \geq 0\right)
$$

The application of the fud $F \in \mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A) \cap \mathcal{F}_{\mathrm{u}}$ consists of the tractable sequential application of its transforms, $A * F^{\mathrm{T}}=\operatorname{apply}(F, A)$, where apply $\in$ $\mathcal{F} \times \mathcal{A} \rightarrow \mathcal{A}$ is described in the section 'Functional Definition Sets'. This application is implemented in a fuder $I_{* F}=$ fuder $\in$ computers, described in the section 'Computation of functional definition sets' above. The application of the fuder is $I_{* \mathrm{~F}}^{*}((F, A))=\operatorname{apply}(F, A)$. The representation space
of the substrate fud, $F$, in the fuder, $I_{* \mathrm{~F}}$, is tractable, because each of the transformers in the application is tractable. The time complexity is at most $r y \ln y$ where $r=|\operatorname{vars}(F)|$ and $y=\left|A^{\mathrm{F}}\right|$. Therefore both the space and time complexity of the fuder are tractable. There is no need to represent the intractable expanded transform of the fud, $F^{\mathrm{TV}} \mathrm{V}_{A} \in \mathcal{T}_{U_{A}, \mathrm{f}, 1}$, in order to compute the application.

Thus the computation of the transformed histogram in a limited-underlying derived alignment fud inducer is tractable despite intractable substrate volume, but at the cost of searching only the subset of the literal substrate transforms for which corresponding tractable fuds exist. The excluded intractable part of the literal substrate transforms is $\mathcal{T}_{\text {fa, }, ~}(A) \backslash\left\{F^{T V_{A}}: F \in \mathcal{F}_{U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}}\right\}$. The exact composition of the subset of literal substrate transforms, $\left\{F^{T V_{A}}\right.$ : $\left.F \in \mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A) \cap \mathcal{F}_{\mathrm{u}}\right\}$, of a particular implementation of a limited-underlying derived alignment fud inducer depends on its definition of the limitations on the underlying variables in $\mathcal{F}_{\mathrm{u}}$. Thus there are multiple implementations of limited-underlying derived alignment fud inducers, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}}^{\prime}$, for any given implementation of the literal derived alignment transform inducer, $I_{z, \mathrm{a}, 1}^{\prime}$.

### 4.21.5 Intractable derived volume

Given integral-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$ and literal substrate transform $T \in \mathcal{T}_{\text {fa, }}(A)$, both the computation time and computation space of the alignmenter applied to the transformed sample histogram, $I_{\mathrm{a}}^{*}(A * T) \approx \operatorname{algn}(A * T)$, in the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l},}^{\prime}$, vary with the derived volume, $w=\left|W^{\mathrm{C}}\right|$, where $W=\operatorname{der}(T)$. That is, $I_{\mathrm{a}}^{\mathrm{t}}(A * T)>w$ and $I_{\mathrm{a}}^{\mathrm{s}}(A * T)>w$. This is because the calculation of alignment requires that the independent derived be computed by an independenter, $I_{\mathrm{X}}^{*}(A * T)=(A * T)^{\mathrm{X}}$, which has time and space complexities of at least $w$. Although the formal histogram is independent, $A^{\mathrm{X}} * T=$ $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, and so the derived volume is no greater than the underlying volume, $w \leq v$, the substrate histogram, $A \in \mathcal{A}_{z, \mathrm{xi}}$, has a completely effective independent, $A^{\mathrm{XF}}=A^{\mathrm{C}}$, and the formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$. Hence the independent derived is also completely effective, $\left(A^{\mathrm{F}} * T\right)^{\mathrm{XF}}=\left(A^{\mathrm{XF}} * T\right)^{\mathrm{XF}}=\left(A^{\mathrm{C}} * T\right)^{\mathrm{XF}}=W^{\mathrm{C}}$, and so both the computation time and space of the alignmenter, $I_{\mathrm{a}}$, must be at least $w$. The derived volume, $w$, grows exponentially with derived dimension $m=|W|$ and so the time and space complexities are exponential, and therefore intractable, with respect to derived dimension, $m$. In the case of the value full functional transform, $T_{\mathrm{s}}=\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in V_{A}\right\}^{\mathrm{T}} \in \mathcal{T}_{\text {fa, },}(A)$, the derived dimension equals the underlying dimension, $m=n$. In this case both complexities of
the alignmenter, $I_{\mathrm{a}}$, are also intractable with respect to underlying dimension, $n$.

So an implementation of the literal derived alignment integral-independent substrate ideal formal-abstract transform inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, that uses the alignmenter, $I_{\mathrm{a}}$, or any other computer that applies the independenter, $I_{\mathrm{X}}$, to the derived histogram, $I_{\mathrm{X}}^{*}(A * T)$, must be intractable with respect to derived dimension, $m$. The value full functional transform, $T_{\mathrm{s}}$, is a literal substrate transform, $T_{\mathrm{s}} \in \mathcal{T}_{\text {fa, }}(A)$, and so the literal derived alignment integralindependent substrate ideal formal-abstract transform inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, is also intractable with respect to underlying dimension, $n$.

This is also the case for an implementation of a limited-underlying derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}}^{\prime}$. Although the fuder, $I_{* \mathrm{~F}}$, in the limitedunderlying derived alignment fud inducer is tractable despite intractable substrate volume, because of the use of a tractable fud, $F \in \mathcal{F}_{U_{A}, V_{A}} \cap \mathcal{F}_{\mathbf{u}}$, which allows tractable application, $A * F^{\mathrm{T}}$, the limited-underlying derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}}^{\prime}$, must still compute $\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}$ in an independenter, $I_{\mathrm{X}}$, in order to compute derived alignment, $\operatorname{algn}\left(A * F^{\mathrm{T}}\right)$. Thus limitedunderlying derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}}^{\prime}$, is intractable with respect to derived dimension, $m$. The value full functional fud is in the substrate models of the limited-underlying derived alignment fud inducer application, $F_{\mathrm{s}}=\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in V_{A}\right\} \in \operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}}^{\prime *}(A)\right)=\mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A) \cap \mathcal{F}_{\mathrm{u}}$, because it is practicable in the fuder. Hence the limited-underlying derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}}^{\prime}$, is also intractable with respect to underlying dimension, $n$.

One possibility is to consider a further subset of the literal substrate transforms, $\mathcal{T}_{\text {fa }, j}(A)$, which limits the derived dimension, $m$. For example, a maximum derived volume limit of wmax $\in \mathbf{N}_{\geq 4}$ could constrain the subset to $\left\{T: T \in \mathcal{T}_{\text {fa }, \mathrm{j}}(A), W=\operatorname{der}(T),\left|W^{\mathrm{C}}\right| \leq \mathrm{wmax}\right\}$. Another example is a maximum derived dimension limit of $\max \in \mathbf{N}_{\geq 2}$ which could constrain the subset to $\left\{T: T \in \mathcal{T}_{\text {fa, }}(A), W=\operatorname{der}(T),|W| \leq \operatorname{jmax}\right\}$. Such a limit would exclude the value full functional transform, $T_{\mathrm{s}}$, if, for example, $\operatorname{jmax}<n$.

A limited-derived subset of the functional definition sets $\mathcal{F}_{\mathrm{d}} \subseteq \mathcal{F}$ can be defined such that a fud $F \in \mathcal{F}_{\mathrm{d}}$ has tractably computable independent derived. Given integral-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$, a limitedderived substrate fud $F \in \mathcal{F}_{U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{d}}$ has tractably computable independent derived. This is achieved by limiting the derived variables of the fud. For example, a maximum derived volume limit of wmax would constrain the fud
$\left|W^{\mathrm{C}}\right| \leq$ wmax where $W=\operatorname{der}(F)$. The limited-derived fuds, $\mathcal{F}_{\mathrm{d}}$, represents the class of subsets of the fuds such that the independent derived of the fud is tractable. That is, the limited-derived fuds here stands for one of the limiting methods, for example, maximum derived volume, wmax, or maximum derived dimension, jmax.

Consider a limited-variables derived alignment integral-independent substrate ideal formal-abstract fud inducer $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}, \mathrm{d}}^{\prime} \in \operatorname{inducers}(z)$, which has, as its subset of the substrate models, a limited-underlying and limited-derived subset of the literal substrate fuds,

$$
\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{~F}, \mathrm{l}, \mathrm{u}, \mathrm{~d}}^{\prime *}(A)\right)=\mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A) \cap \mathcal{F}_{\mathbf{u}} \cap \mathcal{F}_{\mathrm{d}} \subset \mathcal{M}_{U_{A}, V_{A}}\right)
$$

Then (i) the fud, $F$, in the fuder, $I_{* \mathrm{~F}}$, is tractable because of the limited underlying variables of the transforms of the fud, and (ii) the independent transformed histogram, $\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}$, in the independenter, $I_{\mathrm{X}}$, is tractable because of the limited derived variables of the fud.

The application of the limited-variables derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}, \mathrm{d}}^{\prime}$, is a subset of the application of the literal derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, 1}^{\prime}$. That is, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}, \mathrm{d}}^{\prime *}(A) \subseteq I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}}^{\prime *}(A)$. The excluded intractable part of the literal substrate transforms is $\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A) \backslash\left\{F^{T V_{A}}: F \in \mathcal{F}_{U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{d}}\right\}$. The excluded set is a superset of the less limited limited-underlying derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}}^{\prime}$. Conjecture that the maximum transform function of the limited-variables derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}, \mathrm{d}}^{\prime}$, is positively correlated with that of the literal derived alignment transform inducer, $I_{z, \mathrm{a}, \mathrm{l},}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{~F}, \mathrm{l}, \mathrm{u}, \mathrm{~d}}^{\prime *}\right) \geq 0\right)
$$

but that the correlation is lower than that for the limited-underlying derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}}^{\prime}$,

```
\(\forall z \in \mathbf{N}_{>0}\)
    \(\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}}^{\prime *}\right) \geq \operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}, \mathrm{d}}^{\prime *}\right)\right)\)
```

The exact composition of the subset of literal substrate transforms, $\left\{F^{\mathrm{T} V_{A}}\right.$ : $\left.F \in \mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A) \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{d}}\right\}$, of a particular implementation of a limited-variables derived alignment fud inducer depends on its definition of the limitations on the underlying variables, $\mathcal{F}_{\mathbf{u}}$, and the limitations on the derived variables, $\mathcal{F}_{\mathrm{d}}$. Thus there are multiple implementations of limited-variables derived alignment fud inducers, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}, \mathrm{d}}^{\prime}$, for any given implementation of the literal
derived alignment transform inducer, $I_{z, \mathrm{a}, \mathrm{l},}^{\prime}$.
The computation of alignment in such a limited-variables derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}, \mathrm{d}}^{\prime}$, is therefore tractable despite both intractable substrate volume and intractable derived volume, because of tractable fuder, $I_{* \mathrm{~F}}$, and independenter, $I_{\mathrm{X}}$, respectively. However, although the coverage of the inducer, $\operatorname{und}(F) \subseteq V_{A}$, where $F \in \mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A) \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{d}}$, is not constrained, and hence the underlying volume, $v=\left|V_{A}^{\mathrm{C}}\right|$, is not constrained, the derived volume, $w=\left|W^{\mathrm{C}}\right|$ where $W=\operatorname{der}(F)$, must be less than the underlying volume, $w<v$, if the underlying volume is impracticable. That is, the underlying freedoms are unlimited, but the derived freedoms are limited.

Another approach to the problem of intractable derived volume is to consider an inducer which has, as its subset of the substrate models, the set of substrate summation aligned decompositions, $\mathcal{D}_{U_{A}, V_{A}} \cap \mathcal{D}_{\Sigma}(A)$, where $A \in$ $\mathcal{A}_{z, \mathrm{xi}}$. Summation aligned decompositions are well behaved distinct decompositions having no variable symmetries that are subject to the constraints of (i) contingent diagonalisation and (ii) contingent formal-abstract equivalence, with respect to the histogram, A. As described in section 'Summation aligned decomposition inducers', above, the computation of the content alignment, $\operatorname{algn}\left(A * D^{\mathrm{T}}\right)-\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)$ where $D \in \mathcal{D}_{\Sigma}(A)$, does not require the computation of the nullable transform, $D^{\mathrm{T}}$, because the content alignment equals the summation alignment, $\operatorname{algn}\left(A * D^{\mathrm{T}}\right)-\operatorname{algn}\left(A^{\mathrm{x}} * D^{\mathrm{T}}\right)=$ $\operatorname{alignmentSum}(A, D)$, where alignmentSum $(A, D)=\sum \operatorname{algn}(A * C * T)$ : $(C, T) \in \operatorname{cont}(D)$ and cont $=$ elements o contingents. Thus the intractable derived volume, $w=\left|N^{\mathrm{C}}\right|$ where $N=\operatorname{der}\left(D^{\mathrm{T}}\right)$, need not be computed.

Define the content alignment integral-independent substrate summation aligned decomposition inducer $I_{z, \mathrm{c}, \mathrm{D}, \Sigma}^{\prime} \in \operatorname{inducers}(z)$ such that the application to a substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$ is the summation alignment approximation function of the substrate summation aligned decompositions,

$$
I_{z, \mathrm{c}, \mathrm{D}, \Sigma}^{\prime *}(A)=\left\{\left(D, I_{\approx \ln \mathbf{Q}}^{*}(\operatorname{algnSum}(A, D))\right): D \in \mathcal{D}_{U_{A}, V_{A}} \cap \mathcal{D}_{\Sigma}(A)\right\}
$$

where algnSum $=$ alignmentSum .
The computation of summation alignment in the content summation aligned decomposition inducer, $I_{z, \mathrm{c}, \mathrm{D}, \Sigma}^{\prime}$, is not tractable because there is no constraint that the contingent slice sizes decrease. For example, a summation aligned decomposition $D \in \operatorname{dom}\left(I_{z, \mathrm{c}, \mathrm{D}, \Sigma}^{\prime *}(A)\right)$ could consist of mono-derivedvariate transforms, $\forall T \in \operatorname{transforms}(D)(|\operatorname{der}(T)|=1)$. The computation of
the summation alignment requires the contingent application of the transformer and alignmenter to each of the transforms requiring time of at least $\sum I_{* \mathrm{~T}}^{\mathrm{t}}((T, A * C))+I_{\mathrm{a}}^{\mathrm{t}}(A * C * T):(C, T) \in \operatorname{cont}(D)$.

If the contingent slice size is constrained to decrease, then the longest path of the decomposition must be less or equal to the size, $\forall L \in \operatorname{paths}(D)(|L| \leq z)$, and the cardinality of the leaves must be less than the size, leaves $(D)<z$. The cardinality of the transforms is, in this case, less than the square of the size, $|\operatorname{transforms}(D)|<z^{2}$, which has polynomial complexity.

Therefore consider the set of idealising summation aligned decompositions, $\mathcal{D}_{\Sigma, \mathrm{k}}(A) \subset \mathcal{D}_{\Sigma}(A)$, which are summation aligned decompositions that are subject to two additional constraints, (iii) non-independent contingent derived histograms, and (iv) independent formal slice. The content alignment integral-independent substrate idealising summation aligned decomposition inducer $I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime} \in \operatorname{inducers}(z)$ is defined above such that the application to a non-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}} \backslash\left\{A^{\mathrm{X}}\right\}$ is the summation alignment approximation function of the substrate idealising summation aligned decompositions,

$$
I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime *}(A)=\left\{\left(D, I_{\approx \ln \mathbf{Q}}^{*}(\operatorname{algnSum}(A, D))\right): D \in \mathcal{D}_{U_{A}, V_{A}} \cap \mathcal{D}_{\Sigma, \mathrm{k}}(A)\right\}
$$

The content alignment idealising summation aligned inducer, $I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime}$, is conjectured to be positively correlated with the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, 1}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime *}\right) \geq 0\right)
$$

The subset of substrate models, $\mathcal{M}_{U_{A}, V_{A}}$, of an implementation of an idealising summation aligned decomposition inducer cannot be substrate decompositions of substrate transforms, $\mathcal{D}_{U_{A}, V_{A}} \subset \operatorname{trees}\left(\mathcal{S} \times \mathcal{T}_{U_{A}, V_{A}}\right)$, because the substrate volume, $v$, is still intractable even if the derived volume, $w$, is (indirectly) tractable. To be tractable with limited-variables methods the subset of substrate models must at least be a subset of substrate fud decompositions, $\mathcal{D}_{\mathrm{F}, U_{A}, V_{A}}$. Define the limited-variables content alignment integralindependent substrate idealising summation aligned fud decomposition inducer $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F},, \mathrm{k}, \mathrm{k}, \mathrm{u}, \mathrm{d}}^{\prime} \in \operatorname{inducers}(z)$ such that the application to a non-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}} \backslash\left\{A^{\mathrm{X}}\right\}$ is the summation alignment function of the limited-variables substrate idealising summation aligned fud decompo-
sitions,

$$
\begin{aligned}
& I_{z, \mathrm{c}, \mathrm{D}, \mathrm{~F}, \Sigma, \mathrm{k}, \mathrm{u}, \mathrm{~d}}^{\prime *}(A)= \\
& \quad\left\{\left(D, I_{\approx \ln \mathbf{Q}}^{*}(\operatorname{algnSum}(A, D))\right):\right. \\
& \left.\quad D \in \mathcal{D}_{\mathrm{F}, U_{A}, V_{A}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathbf{u}} \cap \mathcal{F}_{\mathrm{d}}\right)\right), D^{\mathrm{DV} V_{A}} \in \mathcal{D}_{\Sigma, \mathrm{k}}(A)\right\}
\end{aligned}
$$

Define $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \Sigma, \mathrm{k}, \mathrm{u}, \mathrm{d}}^{\prime *}\left(A^{\mathrm{X}}\right)=\left\{\left(D_{\mathrm{F}, \mathrm{u}}, 0\right)\right\}$ where $D_{\mathrm{F}, \mathrm{u}}=\left\{\left(\left(\emptyset,\left\{T_{\mathrm{u}}\right\}\right), \emptyset\right)\right\}$ and unary partition transform $T_{\mathrm{u}}=\left\{V_{A}^{\mathrm{VC}}\right\}^{\mathrm{T}}$. Note that in the special case of independent substrate histogram, $A=A^{\mathrm{X}}$, the dummy unary decomposition, $D_{\mathrm{F}, \mathrm{u}}$, is intractable because of intractable substrate volume, but, of course, the given independent substrate histogram, $A=A^{\mathrm{X}}$, is itself intractably computable for the same reason.

Here the $\mathcal{D}_{\mathrm{F}, U_{A}, V_{A}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{d}}\right)\right)$ stands for the class of subsets of the substrate fuds, the definitions of which depend in turn on the definitions of the limited-underlying substrate fuds, $\mathcal{F}_{\mathrm{u}}$, and the limited-derived substrate fuds, $\mathcal{F}_{\mathrm{d}}$.

Conjecture that the limited-variables content alignment fud decomposition inducer, $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \Sigma, \mathrm{k}, \mathrm{u}, \mathrm{d}}^{\prime}$, is positively correlated with the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{c}, \mathrm{D}, \mathrm{~F}, \Sigma, \mathrm{k}, \mathrm{u}, \mathrm{~d}}^{\prime *}\right) \geq 0\right)
$$

but that the correlation is lower than that for the content content alignment fud decomposition inducer, $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \Sigma, \mathrm{k}}^{\prime}$, defined in section 'Summation aligned decomposition inducers', above,

$$
\begin{aligned}
& \forall z \in \mathbf{N}_{>0} \\
& \quad\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime}, \operatorname{maxr} \circ I_{z, \mathrm{c}, \mathrm{D}, \mathrm{~F}, \Sigma, \mathrm{k}}^{\prime *}\right) \geq\right. \\
& \left.\quad \operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{c}, \mathrm{D}, \mathrm{~F}, \Omega, \mathrm{k}, \mathrm{u}, \mathrm{~d}}^{\prime *}\right)\right)
\end{aligned}
$$

The idealising summation aligned decomposition $D \in \operatorname{dom}\left(I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \mathrm{L}, \mathrm{k}, \mathrm{u}, \mathrm{d}}^{\prime *}(A)\right)$ may have multiple fuds, so the derived volume, $w=\left|N^{\mathrm{C}}\right|$ where $N=$ $\operatorname{der}\left(D^{\mathrm{T}}\right)$, is not limited by the derived dimension of a fud such as is the case in the limited-variables derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}, \mathrm{d}}^{\prime}$. However, because the correlation of the unlimited content content alignment fud decomposition inducer, $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \mathrm{L}, \mathrm{k}}^{\prime}$, with the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$, is not perfect, for the reasons described in section 'Summation aligned decomposition inducers', above, it is not obvious whether or
not the correlation of the limited-variables content alignment fud decomposition inducer, $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \Sigma, \mathrm{k}, \mathrm{u}, \mathrm{d}}^{\prime}, \operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxro} I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \Sigma, \mathrm{k}, \mathrm{u}, \mathrm{d}}^{\prime *}\right)$, is greater than that for the limited-variables derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}, \mathrm{d}}^{\prime}$, $\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}, \mathrm{d}}^{\prime *}\right)$.

### 4.21.6 Intractable search set elements

Given an integral-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$, the literal substrate transforms,

$$
\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)=\operatorname{dom}\left(X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)\right)=\operatorname{dom}\left(X_{z, \mathrm{x}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}(A)\right)
$$

is defined

$$
\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)=\left\{T: T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}
$$

The computation time of the literal derived alignment integral-independent substrate ideal formal-abstract transform inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, must be at least as great as the cardinality of the literal substrate transforms, $I_{z, \mathrm{a}, 1}^{\prime \mathrm{t}}(A)>$ $\left|\mathcal{T}_{\text {fa, }}(A)\right|$, if the computation of each transform is performed serially. If the computation is parallel, then it is the computation space which is at least as great as the cardinality of the literal substrate transforms, $I_{z, \mathrm{a}, 1}^{\prime \mathrm{s}}(A)>$ $\left|\mathcal{T}_{\text {fa, }}(A)\right|$. Consider the serial computation. In the alignmenter implementation of the literal derived alignment inducer, the computation time is such that

$$
I_{z, \mathrm{a}, \mathrm{l}}^{\prime \mathrm{t}}(A)>\sum\left(I_{* \mathrm{~T}}^{\mathrm{t}}((T, A))+I_{\mathrm{a}}^{\mathrm{t}}(A * T): T \in \mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)\right)>\left|\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)\right|
$$

However, to compute the literal substrate transforms, $\mathcal{T}_{\text {fa, }}(A)$, it is necessary to compute the entire superset of substrate transforms, $\mathcal{T}_{U_{A}, V_{A}} \supset \mathcal{T}_{\text {fa, } j}(A)$, where $\mathcal{T}_{U_{A}, V_{A}}=\left\{F^{\mathrm{T}}: F \subseteq\left\{P^{\mathrm{T}}: P \in \mathrm{~B}\left(V_{A}^{\mathrm{CS}}\right)\right\}\right\}$. This is because tests of (i) formal-abstract equality, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, and (ii) ideality, ideal $(A, T)$, depend on the application of a transform, $T$, to the substrate histogram, $A$, and so all of the substrate transforms, $\mathcal{T}_{U_{A}, V_{A}}$, must be constructed before testing. Conjecture that there is no subset of the multi-partition transforms, $\mathcal{T}_{U, \mathrm{P}^{*}}$, that may be excluded for all substrate histograms, $\neg\left(\exists Q \in \mathrm{P}\left(\mathcal{T}_{U, \mathrm{P}^{*}}\right) \backslash\{\emptyset\} \forall A \in\right.$ $\left.\mathcal{A}_{z, \mathrm{xi}} \forall T \in Q \cap \mathcal{T}_{U_{A}, V_{A}}\left(\left(A^{\mathrm{X}} * T=(A * T)^{\mathrm{x}}\right) \wedge\left(A=A * T * T^{\dagger A}\right)\right)\right)$. Therefore the computation time of the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, must be at least as great as the cardinality of the substrate histograms, $I_{z, \mathrm{a}, 1}^{\mathrm{t}}(A)>$ $\left|\mathcal{T}_{U_{A}, V_{A}}\right|$. The cardinality of the substrate transforms is $\left|\mathcal{T}_{U_{A}, V_{A}}\right|=2^{\text {bell }(v)}$ where $v=\left|V_{A}^{\mathrm{C}}\right|$. Thus $I_{z, \mathrm{a}, \mathrm{l}}^{\prime \mathrm{t}}(A)>2^{\mathrm{bell}(v)}$. So the serial computation time complexity of the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, is intractable with respect to underlying volume, $v$.

Consider the derived alignment integral-independent substrate ideal formalabstract non-overlapping transform inducer $I_{z, \mathrm{a}, \mathrm{l}, \mathrm{n}}^{\prime} \in \operatorname{inducers}(z)$ which is defined such that its application to an integral-independent substrate histogram $A \in \mathcal{A}_{z, \text { xi }}$ is a subset of the application of the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}, \mathrm{n}}^{\prime \prime}(A)=\left\{(T, a):(T, a) \in I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}(A), \neg \operatorname{overlap}(T)\right\} \subset I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}(A)$. Thus the domain of the application is the non-overlapping subset of the literal substrate transforms, $\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{l}, \mathrm{n}}^{\prime *}(A)\right)=\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A) \cap \mathcal{T}_{U_{A}, V_{A}, \mathrm{n}}$ where $\mathcal{T}_{U, V, \mathrm{n}}=\{T$ : $\left.T \in \mathcal{T}_{U, V}, \neg \operatorname{overlap}(T)\right\}$. A non-overlapping transform implies that the formal histogram is independent, $\neg \operatorname{overlap}(T) \Longrightarrow A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, which is also implied by formal-abstract equality, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}} \Longrightarrow A^{\mathrm{X}} * T=$ $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, so the domain of the application is not empty, $\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{l}, \mathrm{n}}^{\prime *}(A)\right) \neq \emptyset$.

The non-overlapping transform limitation means that only the non-overlapping substrate transforms set, $\mathcal{T}_{U_{A}, V_{A}, \mathrm{n}} \subset \mathcal{T}_{U_{A}, V_{A}}$ need be constructed. This subset is independent of the substrate histogram, $A$. The serial computation time of the non-overlapping derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}, \mathrm{n}}^{\prime}$, is constrained $I_{z, \mathrm{a}, \mathrm{l}, \mathrm{n}}^{\prime \mathrm{n}}(A)>\left|\mathcal{T}_{U_{A}, V_{A}, \mathrm{n}}\right|$. The non-overlapping substrate transforms set can be constructed explicitly,

$$
\mathcal{T}_{U_{A}, V_{A}, \mathrm{n}}=\left\{N^{\mathrm{TV} V_{A}}: Y \in \mathrm{~B}^{\prime}\left(V_{A}\right), N \in \prod_{K \in Y} \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\} \cup\{(\emptyset, \emptyset)\}
$$

As shown above, in section 'Substrate structures', the cardinality of this set is conjectured to be constrained $\operatorname{bell}(v) \leq\left|\mathcal{T}_{U_{A}, V_{A}, \mathrm{n}}\right| \leq 2 \times \operatorname{bell}(n) \times \operatorname{bell}(v)+1$, where $n=\left|V_{A}\right|$ and $v=\left|V_{A}^{\mathrm{C}}\right|$. The complexity of the cardinality of the non-overlapping substrate transforms set, $\mathcal{T}_{U_{A}, V_{A}, \mathrm{n}}$, is therefore factorial on the underlying volume, bell $\in \mathrm{O}(!)$. The serial computation time complexity of the non-overlapping derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}, \mathrm{n}}^{\prime}$, is still intractable with respect to underlying volume, $v$. Note that the non-overlapping derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}, \mathrm{n}}^{\prime}$, not only limits the search set, but also limits the derived dimension, $\neg \operatorname{overlap}(T) \Longrightarrow m \leq n$, where $m=|\operatorname{der}(T)|$.

Consider the literal derived alignment integral-independent substrate ideal formal-abstract fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, 1}^{\prime}$, which has, as its subset of the substrate models, the literal substrate fuds, $\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{F}, 1}^{\prime *}(A)\right)=\mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A)$ where $A \in \mathcal{A}_{z, \mathrm{xi}}$. The serial time computation of the literal derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}}^{\prime}$, is intractable with respect to underlying volume. Similarly to the case of the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, above, the entire set of substrate fuds, $\mathcal{F}_{U_{A}, V_{A}}$, must be constructed before testing for (i) formal-abstract equality, $A^{\mathrm{X}} * F^{\mathrm{T}}=\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}$, and (ii) ideality, ideal $\left(A, F^{\mathrm{T}}\right)$. The cardinality of the substrate fuds is greater than that of the substrate transforms, $\left|\mathcal{F}_{U_{A}, V_{A}}\right|>\left|\mathcal{T}_{U_{A}, V_{A}}\right|$, so $I_{z, \mathrm{a}, \mathrm{F}, 1}^{\prime \mathrm{t}}(A)>2^{\operatorname{bell}(v)}$ where $v=\left|V_{A}^{\mathrm{C}}\right|$.

Compare (i) the literal derived alignment integral-independent substrate ideal formal-abstract fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, 1}^{\prime}$, which has, as its subset of the substrate models, the literal substrate fuds, $\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}}^{\prime}(A)\right)=\mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A)$, to (ii) the limited-variables derived alignment integral-independent substrate ideal formal-abstract fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}, \mathrm{d}}^{\prime}$, which has, as its subset of the substrate models, a limited-underlying and limited-derived subset of the literal substrate fuds, $\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}, \mathrm{d}}^{\prime *}(A)\right)=\mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A) \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{d}}$. In the limited-variables case the definitions of the limited-underlying, $\mathcal{F}_{\mathbf{u}}$, and limited-derived, $\mathcal{F}_{\mathrm{d}}$, allow an explicit construction of a subset of substrate fuds, $\mathcal{F}_{U_{A}, V_{A}} \cap \mathcal{F}_{\mathbf{u}} \cap \mathcal{F}_{\mathrm{d}}$, because they are independent of the substrate histogram, $A$. Thus the complexity of the cardinality of the inducer's search models is reduced by the limits, in a similar fashion to the reduction in complexity of the non-overlapping transform limitation, above. However, the limited-variables derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}, \mathrm{d}}^{\prime}$, is still intractable with respect to underlying dimension, $n$, where $n=\left|V_{A}\right|$. This is for two reasons, (i) fud flattening, and (ii) layer variables cardinality.

The definition of the substrate fud set, $\mathcal{F}_{U_{A}, V_{A}}$, described in section 'Substrate structures', above, explicitly excludes duplicate nested partitions within the fud, $\forall F \in \mathcal{F}_{U_{A}, V_{A}} \forall u \in \operatorname{vars}(F) \backslash V_{A} \diamond G=\operatorname{depends}(F,\{u\}) \forall w \in$ $\operatorname{vars}(G) \backslash V_{A} \backslash\{u\} \diamond H=\operatorname{depends}(F,\{w\})\left(G^{\mathrm{TP} V_{A}} \neq H^{\mathrm{TP} V_{A}}\right)$. The substrate fud set is a set of subsets of the power fud, $\mathcal{F}_{U_{A}, V_{A}} \subset \mathrm{P}\left(\operatorname{power}\left(U_{A}\right)\left(V_{A}\right)\right) \subset$ $\mathcal{F}_{U_{A}, \mathrm{P}}$. The power fud is constructed recursively from the bottom substrate layer upwards by adding layer partition transforms which do not flatten to an existing partition. Without flattening, the power fud recursion would not terminate and so the power fud would have infinite layers and hence infinite cardinality. The substrate fud set, $\mathcal{F}_{U_{A}, V_{A}}$, is the set of subsets of the power fud such that the fuds have the same underlying substrate variables, $\mathcal{F}_{U_{A}, V_{A}}=\left\{F: F \subseteq \operatorname{power}\left(U_{A}\right)\left(V_{A}\right)\right.$, und $\left.(F) \subseteq V_{A}\right\}$, so the cardinality of the substrate fud set $\mathcal{F}_{U_{A}, V_{A}}$, would also be infinite without flattening. The explicit construction of the substrate fud set, $\mathcal{F}_{U_{A}, V_{A}}$, in an inducer application, such as in the literal derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, 1}^{\prime}$, above, requires the computation of the power fud, and thus the flattened partition of each new variable must be computed. However this would imply intractable underlying volume. That is, the space of a flattened partition transform in substrate fud $F$ would be at least equal to the underlying volume, $\left|\operatorname{his}\left(G^{\mathrm{TV}}{ }^{A}\right)\right|=v$ where $G=\operatorname{depends}(F,\{u\}), u \in \operatorname{vars}(F) \backslash V_{A}$ and $v=\left|V_{A}^{\mathrm{C}}\right|$, even in the serial case. So, for example, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}}^{\mathrm{s}}(A)>v$. The space complexity is therefore intractable because it is exponential with respect to underlying dimension, $n$. Even an inducer that has, as its subset of the substrate models, the limited-underlying
subset of the substrate fuds, $\mathcal{F}_{U_{A}, V_{A}} \cap \mathcal{F}_{\mathbf{u}}$, such as the limited-variables derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{d}, \mathrm{d}}^{\prime}$, above, must compute the flattened partition transform, $G^{\mathrm{T} V_{A}}$, and so must still have intractable space complexity, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}, \mathrm{d}}^{\prime}(A)>v$. If the definition of the search set is relaxed to allow fuds containing duplicate flattened partitions, and thus doing away with the need to compute the flattened partition transform, some other method of limiting the cardinality of layers in the fud is required to prevent intractable infinite recursion.

Define the infinite-layer substrate fud set $\mathcal{F}_{\infty, U, V} \subset \mathcal{F}_{U, \mathrm{P}}$ as

$$
\mathcal{F}_{\infty, U, V}=\{F: F \subseteq \operatorname{powinf}(U)(V, \emptyset), \quad \operatorname{und}(F) \subseteq V\}
$$

where $U$ is the infinite implied system, $U=\operatorname{implied}(f i l t e r(V, U))$, and the infinite power fud powinf $(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{F}_{U, \mathrm{P}} \rightarrow \mathcal{F}_{U, \mathrm{P}}$ is defined without termination

$$
\begin{aligned}
& \operatorname{powinf}(U)(V, F):=F \cup G \cup \operatorname{powinf}(U)(V, F \cup G): \\
& G=\left\{T: K \subseteq \operatorname{vars}(F) \cup V, T \in F_{U, K}\right\}
\end{aligned}
$$

or explicitly,

$$
\begin{aligned}
& \operatorname{powinf}(U)(V, F):=F \cup G \cup \operatorname{powinf}(U)(V, F \cup G): \\
& \\
& \quad G=\left\{P^{\mathrm{T}}: K \subseteq \operatorname{vars}(F) \cup V, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}
\end{aligned}
$$

The cardinality of the infinite-layer substrate fud set is infinite, $\left|\mathcal{F}_{\infty, U, V}\right|=\infty$. To implement an inducer with a tractable finite subset of the infinite-layer substrate fud set, $\mathcal{F}_{\infty, U_{A}, V_{A}}$, where $A \in \mathcal{A}_{z, \mathrm{x}}$, consider a limit on the cardinality of the layers $l$, where $l=\operatorname{layer}(F, \operatorname{der}(F))$ and $F \in \mathcal{F}_{\infty, U_{A}, V_{A}}$. For example, a maximum layer limit of $\operatorname{lmax} \in \mathbf{N}_{>0}$ applied such that $l \leq \operatorname{lmax}$. Define a limited-layer subset of the functional definition sets $\mathcal{F}_{\mathrm{h}} \subset \mathcal{F}$ which represents the class of subsets of the functional definition sets such that the layer of the fud is limited. The cardinality of limited-layer substrate fud set is finite, $\left|\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{h}}\right|<\infty$. The limited-layer substrate fud set allows fuds containing duplicate flattened partitions and so is a superset of the intersection of the substrate fud set and the limited-layer fuds, $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{h}} \supseteq \mathcal{F}_{U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{h}}$.

Let the literal substrate histogram search infinite-layer fuds $\mathcal{F}_{\infty, \mathrm{fa}, \mathrm{j}}(A) \subset$ $\mathcal{F}_{\infty, U_{A}, V_{A}}$ be defined
$\mathcal{F}_{\infty, \mathrm{fa}, \mathrm{j}}(A)=\left\{F: F \in \mathcal{F}_{\infty, U_{A}, V_{A}}, A^{\mathrm{X}} * F^{\mathrm{T}}=\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}, A=A * F^{\mathrm{T}} * F^{\mathrm{T} \dagger A}\right\}$

The cardinality of the literal substrate histogram search infinite-layer fuds is infinite, $\left|\mathcal{F}_{\infty, \mathrm{fa}, \mathrm{j}}(A)\right|=\infty$. The literal substrate histogram search infinitelayer fuds map to the literal substrate transforms, $\left\{F^{\mathrm{T} V_{A}}: F \in \mathcal{F}_{\infty, \mathrm{fa}_{\mathrm{a}, \mathrm{j}}}(A)\right\}=$ $\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)$, and so is a subset of the substrate models, $\mathcal{F}_{\infty, \mathrm{fa}, \mathrm{j}}(A) \subset \mathcal{M}_{U_{A}, V_{A}}$.

Define the limited-layer limited-variables derived alignment integral-independent substrate ideal formal-abstract infinite-layer fud inducer $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{l}, \mathrm{u}, \mathrm{d}, \mathrm{h}}^{\prime} \in \operatorname{inducers}(z)$, which has, as its subset of the substrate models, a limited-layer, limitedunderlying and limited-derived subset of the literal substrate histogram search infinite-layer fuds,

$$
\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{~F}, \infty, \mathrm{l}, \mathrm{u}, \mathrm{~d}, \mathrm{~h}}^{\prime *}(A)\right)=\mathcal{F}_{\infty, \mathrm{fa}, \mathrm{j}}(A) \cap \mathcal{F}_{\mathrm{u}, \mathrm{~d}, \mathrm{~h}} \subset \mathcal{M}_{U_{A}, V_{A}}\right)
$$

where $\mathcal{F}_{\mathrm{u}, \mathrm{d}, \mathrm{h}}=\mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{d}} \cap \mathcal{F}_{\mathrm{h}}$. The domain of the limited-layer limitedvariables derived alignment fud inducer is finite, $\left|\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{l}, \mathrm{u}, \mathrm{d}, \mathrm{h}}^{\prime *}(A)\right)\right|=$ $\left|\mathcal{F}_{\infty, \mathrm{fa}, \mathrm{j}}(A) \cap \mathcal{F}_{\mathrm{u}, \mathrm{d}, \mathrm{h}}\right|<\infty$. The space complexity of the serially computed limited-layer limited-variables derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{l}, \mathrm{u}, \mathrm{d}, \mathrm{h}}^{\prime}$, is tractable with respect to flattening because the flattened partition transforms are not computed.

The space required to construct a substrate fud depends on the sequence of the computation. If the computation is from the top layer downwards and definitions of (i) the limited-derived, $\mathcal{F}_{\mathrm{d}}$, is a maximum derived dimension limit of jmax $\in \mathbf{N}_{\geq 2}$, (ii) the limited-underlying, $\mathcal{F}_{\mathbf{u}}$, is a maximum underlying dimension limit of $\mathrm{kmax} \in \mathbf{N}_{\geq 2}$, and (iii) the limited-layer, $\mathcal{F}_{\mathrm{h}}$, is a maximum layer limit of $\operatorname{lmax} \in \mathbf{N}_{>0}$, then there exists a fud $F \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}, \mathrm{d}, \mathrm{h}}$ having lmax layers, layer $(F, \operatorname{der}(F))=\operatorname{lmax}$, and such that the cardinality of the $i$-th layer from the top is

$$
|\{u: u \in \operatorname{vars}(F), \operatorname{layer}(F,\{u\})=\operatorname{lmax}-i\}|=\operatorname{jmax} \times \operatorname{kmax}^{i}
$$

where $0 \leq i<\operatorname{lmax}$. If the partition transforms of the $i$-th layer of the fud are such that the volume equals the maximum underlying volume limit of $\operatorname{xmax} \in \mathbf{N}_{\geq 4}$, then the space of the limited-variables derived alignment fud inducer is such that,

$$
I_{z, \mathrm{a}, \mathrm{~F}, \infty, \mathrm{l}, \mathrm{u}, \mathrm{~d}, \mathrm{~h}}^{\prime \mathrm{s}}(A)>\sum\left(\mathrm{xmax} \times \mathrm{jmax} \times \operatorname{kmax}^{i}: i \in\{0 \ldots \operatorname{lmax}-1\}\right)
$$

which is tractable.
Similarly, if the implementation of the computation of the fud is from the
bottom layer upwards with the same definitions of limited-layer and limitedvariables, there exists a fud $F \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}, \mathrm{d}, \mathrm{h}}$ such that the cardinality of the $i$-th layer from the bottom is

$$
|\{u: u \in \operatorname{vars}(F), \operatorname{layer}(F,\{u\})=i\}|=n^{\mathrm{kmax}^{i}}
$$

where $n=\left|V_{A}\right|$ and $0 \leq i<\operatorname{lmax}$. The space of the limited-layer limitedvariables derived alignment fud inducer in the upwards sequence computation is such that,

$$
I_{z, \mathrm{a}, \mathrm{~F}, \infty, \mathrm{l}, \mathrm{u}, \mathrm{~d}, \mathrm{~h}}^{\prime}(A)>\sum\left(\operatorname{xmax} \times n^{\mathrm{kmax}^{i}}: i \in\{1 \ldots \operatorname{lmax}\}\right)
$$

which is tractable because it is only polynomial in underlying dimension, $n$. In the non-overlapping case where the underlying variables are partitioned, there exists a fud $F$ such that the cardinality of the $i$-th layer from the bottom is, with a certain abuse of notation,

$$
|\{u: u \in \operatorname{vars}(F), \operatorname{layer}(F,\{u\})=i\}|<n^{\underline{\operatorname{kmax}^{i}}}
$$

Although in this implementation of the inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, 1, \mathrm{u}, \mathrm{d}, \mathrm{h}}^{\prime}$, the space complexity is tractable, the time complexity remains intractable with respect to underlying dimension, $n$. The cardinality of fuds having space as defined in the upwards computation above, and such that the partition transforms of the $i$-th layer each have underlying volume of xmax is

$$
(\operatorname{bell}(\mathrm{xmax}))^{n^{k \max }{ }^{i}}
$$

Thus the time complexity is at least exponential in underlying dimension, $n$,

$$
\left|\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}, \mathrm{~d}, \mathrm{~h}}\right|>(\operatorname{bell}(\operatorname{xmax}))^{n} \Longrightarrow I_{z, \mathrm{a}, \mathrm{~F}, \infty, \mathrm{l}, \mathrm{u}, \mathrm{~d}, \mathrm{~h}}^{\prime \mathrm{h}}(A)>(\operatorname{bell}(\mathrm{xmax}))^{n}
$$

To implement an inducer with tractable time complexity, consider limits on the cardinality of the variables in the layers. For example, a maximum layer breadth limit of bmax $\in \mathbf{N}_{>0}$ could constrain a fud such that $\forall i \in\{1 \ldots l\}(\mid\{u: u \in \operatorname{vars}(F)$, layer $(F,\{u\})=i\} \mid \leq \operatorname{bmax})$ where $l=\operatorname{layer}(F, \operatorname{der}(F))$. Define a limited-breadth subset of the functional definition sets $\mathcal{F}_{\mathrm{b}} \subset \mathcal{F}$ which represents the class of subsets of the functional definition sets such that the cardinality of the variables in any layer is limited.

Then define the limited-models derived alignment integral-independent substrate ideal formal-abstract infinite-layer fud inducer $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{l}, \mathrm{q}}^{\prime} \in \operatorname{inducers}(z)$,
which has, as its subset of the substrate models, a limited-breadth, limitedlayer, limited-underlying and limited-derived subset of the literal substrate histogram search infinite-layer fuds,

$$
\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{~F}, \infty, \mathrm{l}, \mathrm{q}}^{\prime *}(A)\right)=\mathcal{F}_{\infty, \mathrm{fa}, \mathrm{j}}(A) \cap \mathcal{F}_{\mathrm{q}} \subset \mathcal{M}_{U_{A}, V_{A}}\right)
$$

where $\mathcal{F}_{\mathrm{q}}=\mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{d}} \cap \mathcal{F}_{\mathrm{h}} \cap \mathcal{F}_{\mathrm{b}}$. The substrate models of the limited-models derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{l}, \mathrm{q}}^{\prime}$, are a subset of the literal substrate histogram search infinite-layer fuds, $\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{l}, \mathrm{q}}^{\prime}(A)\right) \subset \mathcal{F}_{\infty, \mathrm{fa}, \mathrm{j}}(A)$, but are not necessarily a subset of the literal substrate fuds, $\mid \operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{l}, \mathrm{q}}^{\prime *}(A)\right) \backslash$ $\mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A) \mid \geq 0$. This is because an infinite-layer fud $F \in \operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{l}, \mathrm{q}}^{\prime *}(A)\right)$ may contain duplicate expanded partitions. However, the corresponding substate transforms are all in the literal substrate transforms, $\left\{F^{\mathrm{TV}} \mathrm{V}_{A}: F \in\right.$ $\left.\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{l}, \mathrm{q}}^{\prime *}(A)\right)\right\} \subset \mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)$.

Conjecture that the limited-models derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{l}, \mathrm{q}}^{\prime}$, is positively correlated with the literal derived alignment transform inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{~F}, \infty, \mathrm{l}, \mathrm{q}}^{\prime}\right) \geq 0\right)
$$

but that the correlation is lower than that for the limited-variables derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{l}, \mathrm{u}, \mathrm{d}}^{\prime}$,
$\forall z \in \mathbf{N}_{>0}$

$$
\begin{aligned}
& \left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{~F}, \mathrm{l}, \mathrm{~d}, \mathrm{~d}}^{\prime *}\right) \geq\right. \\
& \left.\qquad \operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{~F}, \infty, \mathrm{l}, \mathrm{q}}^{\prime *}\right)\right)
\end{aligned}
$$

The limited-models derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{l}, \mathrm{q}}^{\prime}$, has tractable time and space complexity with respect to the search set elements.

Similarly, a tractable inducer, with respect to the search set domain, may be defined for idealising summation aligned decompositions. The substrate infinite-layer fud decompositions $\mathcal{D}_{\mathrm{F}, \infty, U, V}$ is defined, similarly to the substrate fud decompositions $\mathcal{D}_{\mathrm{F}, U, V}$, in section 'Substrate structures', above, as

$$
\begin{aligned}
& \mathcal{D}_{\mathrm{F}, \infty, U, V}=\left\{D: D \in \mathcal{D}_{\mathrm{F}, \mathrm{~d}}, \operatorname{fuds}(D) \subseteq \mathcal{F}_{\infty, U, V},\right. \\
& \quad \forall L \in \operatorname{paths}(D)(\operatorname{maxr}(\operatorname{count}(\{(F, i):(i,(\cdot, F)) \in L\}))=1)\}
\end{aligned}
$$

Now define the limited-models content alignment integral-independent substrate idealising summation aligned infinite-layer fud decomposition inducer
$I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime} \in \operatorname{inducers}(z)$ such that the application to a non-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}} \backslash\left\{A^{\mathrm{X}}\right\}$ is the summation alignment function of the limited-models substrate idealising summation aligned fud decompositions,

$$
\begin{aligned}
& I_{z, \mathrm{c}, \mathrm{D}, \mathrm{~F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime *}(A)= \\
& \quad\left\{\left(D, I_{\approx \ln \mathbf{Q}}^{*}(\operatorname{algnSum}(A, D))\right):\right. \\
& \left.\quad D \in \mathcal{D}_{\mathrm{F}, \infty, U_{A}, V_{A}} \cap \operatorname{trees}\left(\mathcal{S} \times \mathcal{F}_{\mathrm{q}}\right), D^{\mathrm{D} V_{A}} \in \mathcal{D}_{\Sigma, \mathrm{k}}(A)\right\}
\end{aligned}
$$

Define $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime *}\left(A^{\mathrm{X}}\right)=\left\{\left(D_{\mathrm{F}, \mathrm{u}}, 0\right)\right\}$ where $D_{\mathrm{F}, \mathrm{u}}=\left\{\left(\left(\emptyset,\left\{T_{\mathrm{u}}\right\}\right), \emptyset\right)\right\}$ and unary partition transform $T_{\mathrm{u}}=\left\{V_{A}^{\mathrm{VC}}\right\}^{\mathrm{T}}$.

Conjecture that the limited-models content alignment infinite-layer fud decomposition inducer, $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime}$, is positively correlated with the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime}, \operatorname{maxr} \circ I_{z, \mathrm{c}, \mathrm{D}, \mathrm{~F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime *}\right) \geq 0\right)
$$

but that the correlation is lower than that for the limited-variables content alignment fud decomposition inducer, $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \Sigma, \mathrm{k}, \mathrm{u}, \mathrm{d}}^{\prime}$,

$$
\begin{aligned}
& \forall z \in \mathbf{N}_{>0} \\
& \quad\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{c}, \mathrm{D}, \mathrm{~F}, \Sigma, \mathrm{k}, \mathrm{u}, \mathrm{~d}}^{\prime *}\right) \geq\right. \\
& \\
& \left.\quad \operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{c}, \mathrm{D}, \mathrm{~F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime *}\right)\right)
\end{aligned}
$$

The limited-models content alignment integral-independent substrate idealising summation aligned infinite-layer fud decomposition inducer $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime}$, has tractable time and space complexity with respect to the search set elements.

### 4.21.7 Intractable partition variables

Given integral-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$, the literal substrate transforms, $\mathcal{T}_{\text {fa, } j}(A)$, are the substrate models of the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$. The literal substrate transforms are a subset of the substrate transforms, $\mathcal{T}_{\text {fa, }}(A) \subset \mathcal{T}_{U_{A}, V_{A}}$. The substrate transforms are defined in terms of partition variables of the substrate, $\mathcal{T}_{U, V}=\left\{F^{\mathrm{T}}: F \subseteq\right.$ $\left.\left\{P^{\mathrm{T}}: P \in \mathrm{~B}\left(V^{\mathrm{CS}}\right)\right\}\right\}$. The encoding space of a substrate transform partition variable is at least maximum $(\ln \operatorname{bell}(v), v)$ where $v=\left|V_{A}^{\mathrm{C}}\right|$. Other ways of encoding the partition variable must require greater space. For example, a nested binary map representation of sets of sets would have space complexity of at least $v \ln v$.

Furthermore, the values of partition variables are components of the partition, $(P, P) \in U_{A}$ where $P \in \mathrm{~B}\left(V_{A}^{\mathrm{CS}}\right)$, and so have space complexities equal to the variables. Of course, the values could be encoded as an index $i$ of the cardinality of the partition variable, $1 \leq i \leq|P|$, which would have space of $\ln |P|$, but some order $M \in$ enums $(P)$ would then be required to list the components, $\operatorname{flip}(M) \in \mathcal{L}(P)$, and so either the time or space complexity to compute the index would be just as large.

Similarly, the literal substrate fuds, $\mathcal{F}_{\text {fa, } \mathrm{j}}(A)$, which are the substrate models of the literal derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, 1}^{\prime}$, are a subset of the substrate fuds, $\mathcal{F}_{\mathrm{fa}, \mathrm{j}}(A) \subset \mathcal{F}_{U_{A}, V_{A}}$. The substrate fud set is a set of subsets of the power fud, $\mathcal{F}_{U_{A}, V_{A}} \subset \mathrm{P}\left(\operatorname{power}\left(U_{A}\right)\left(V_{A}\right)\right) \subset \mathcal{F}_{U_{A}, \mathrm{P}}$, and so the substrate fuds consist of partition transforms. The substrate fud set contains the base partition functional definition set, $F_{U_{A}, V_{A}} \in \mathcal{F}_{U_{A}, V_{A}}$ where $F_{U, V}=\left\{P^{\mathrm{T}}: P \in \mathrm{~B}\left(V^{\mathrm{CS}}\right)\right\} \in \mathcal{F}_{U, \mathrm{P}}$. The space complexity of the partitions of the partition functional definition set, $F_{U_{A}, V_{A}}$, is, like the space complexity of the substrate transform partition variables, at least $\ln \operatorname{bell}(v)$. The partition variables in layers higher than the first are partitions of states of partition variables. For example, a bivariate partition variable $R \in \mathrm{~B}\left(\{P, Q\}^{\mathrm{CS}}\right)$ where $P, Q \in \mathrm{~B}\left(V^{\mathrm{CS}}\right)$, or a partition of the self partition, $R \in \mathrm{~B}\left(\left\{V^{\mathrm{CS}\{ \}}\right\}^{\mathrm{CS}}\right)$. The space of partition variables therefore increases exponentially with layer.

Therefore both the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$ and the literal derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, 1}^{\prime}$, are intractable because of exponential space complexity with respect to dimension $n$, where $n=\left|V_{A}\right|$. In addition, an unlimited infinite-layer fud inducer would be intractable because of exponential space complexity with respect to fud layer. However, the limited-models infinite-layer fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{l}, \mathrm{q}}^{\prime}$, which has, as its subset of the substrate models, a limited-breadth, limited-layer, limited-underlying and limited-derived subset of the literal substrate histogram search infinitelayer fuds, $\mathcal{F}_{\infty, \mathrm{f}, \mathrm{j}}(A) \cap \mathcal{F}_{\mathrm{q}}$, is tractable with respect to partition variables. That is, the partition variables of limited-models fuds, $\mathcal{F}_{\mathbf{q}}$, must have no more than polynomial complexity for either time or space. This is because, as shown in section 'Intractable search set elements', above, (i) the space and time complexities of a fud $F$, considered separately from its partition variables, in the limited-models substrate fuds, $F \in \mathcal{F}_{\infty, \mathrm{fa}, \mathrm{j}}(A) \cap \mathcal{F}_{\mathrm{q}}$, are tractable, and (ii) the complexity of the cardinality of limited-models substrate fuds, $\left|\mathcal{F}_{\infty, \text { fa, },}(A) \cap \mathcal{F}_{\mathrm{q}}\right|$ is tractable and therefore the time complexity of the serial limited-models fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{l}, \mathrm{q}}^{\prime}$, is also tractable. Tractable fuds imply
tractable partition variables because the partition variables depend only on the fuds.

Note that a first layer partition variable space of at least xmax $\ln x m a x$, where the maximum underlying volume limit is $\mathrm{xmax} \in \mathbf{N}_{\geq 4}$, while tractable, may be impracticable. See section 'Practicable partition variables', below, for consideration of the cardinal number representation of variables in monadic system inducers.

### 4.21.8 Intractable literal substrate model inclusion

The computation of the set of limited-models substrate infinite-layer fuds, $\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{q}}$, in the limited-models derived alignment integral-independent substrate ideal formal-abstract infinite-layer fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{l}, \mathrm{q}}^{\prime}$, has tractable time and space complexity. Given an integral-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$, the computation of the derived alignment for each of the fuds, $\left\{\left(F, \operatorname{algn}\left(A * F^{\mathrm{T}}\right)\right): F \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}\right\}$, would also be tractable. In fact, only the derived alignments of the literal subset of the limited-models substrate infinite-layer fuds, $\mathcal{F}_{\infty, \mathrm{fa}, \mathrm{j}}(A) \cap \mathcal{F}_{\mathrm{q}} \subset \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}$, need be computed in the inducer, after testing for inclusion under the constraints of (i) formalabstract equality, $A^{\mathrm{X}} * F^{\mathrm{T}}=\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}$, and (ii) ideality, ideal $\left(A, F^{\mathrm{T}}\right)$. That is, if the computation is parallel, the process is (i) the limited-models substrate infinite-layer fuds, $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}$, are computed, (ii) the inclusion tests are applied to construct the limited-models literal substrate histogram search infinite-layer fuds, $\mathcal{F}_{\infty, \mathrm{f}, \mathrm{j}, \mathrm{j}}(A) \cap \mathcal{F}_{\mathrm{q}}=\left\{F: F \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}, A^{\mathrm{X}} * F^{\mathrm{T}}=\right.$ $\left.\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}, A=A * F^{\mathrm{T}} * F^{\mathrm{T} \dagger A}\right\}$, and (iii) the derived alignment is computed for each, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{l}, \mathrm{q}}^{\prime *}(A)=\left\{\left(F, \operatorname{algn}\left(A * F^{\mathrm{T}}\right)\right): F \in \mathcal{F}_{\infty, \mathrm{fa}, \mathrm{j}}(A) \cap \mathcal{F}_{\mathrm{q}}\right\}$. If the computation is serial, the process of (i) construction, (ii) inclusion testing, and (iii) derived alignment computation of each fud is performed one fud at a time.

However, both of these inclusion tests are intractable because of intractable substrate volume. The computation of the independent histogram, $A^{\mathrm{X}}$, by an independenter, $I_{\mathrm{X}}^{*}(A)=A^{\mathrm{X}}$, requires time and space of at least $v$, where $v=\left|V_{A}^{\mathrm{CS}}\right|$, because the substrate histogram, $A$, has completely effective independent, $A^{\mathrm{XF}}=V_{A}^{\mathrm{C}}$. Thus the computation of the independent histogram, $A^{\mathrm{X}}$, in the computation of the formal histogram, $A^{\mathrm{X}} * F^{\mathrm{T}}$, in the formal-abstract equality inclusion test, $A^{\mathrm{X}} * F^{\mathrm{T}}=\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}$, is intractable with respect to underlying dimension, $n$, where $n=\left|V_{A}\right|$. Similarly, in the case where the fud, $F$, is equivalent to the unary partition transform, $F^{\mathrm{T} V_{A}}=T_{\mathrm{u}}$, where $T_{\mathrm{u}}=\left\{V_{A}^{\mathrm{CS}}\right\}^{\mathrm{T}}$, then the idealisation equals the indepen-
dent, $A * F^{\mathrm{T}} * F^{\mathrm{T} \dagger A}=A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger A}=A^{\mathrm{X}}$, and so the computation time and space of the idealisation in an idealiser $I_{\dagger} \in$ computers must be at least as great as that of the independent in the independenter, $I_{\dagger}^{\mathrm{s}}\left(\left(A, T_{\mathrm{u}}\right)\right)>I_{\mathrm{X}}^{\mathrm{s}}(A)$ and $I_{\dagger}^{\mathrm{t}}\left(\left(A, T_{\mathrm{u}}\right)\right)>I_{\mathrm{X}}^{\mathrm{t}}(A)$. Of course, the limits of the limited-models fuds, $\mathcal{F}_{\mathrm{q}}$, may exclude the unary partition transform, $T_{\mathrm{u}} \notin\left\{F^{\mathrm{T} V_{A}}: F \in \mathcal{F}_{\mathrm{q}}\right.$, und $(F) \subseteq$ $\left.V_{A}\right\}$, and so the computation of the space and time required by the ideality inclusion test depends on the definition of the limits.

Consider the formal-abstract equality inclusion test in the literal derived alignment integral-independent substrate ideal formal-abstract transform inducer, $I_{z, \mathrm{a}, 1}^{\prime}$. Given an integral-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}}$, the application of the inducer is defined

$$
\begin{aligned}
& I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}(A)= \\
& \quad\left\{\left(T, I_{\approx \ln \mathbf{Q}}^{*}(\operatorname{algn}(A * T))\right): T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}
\end{aligned}
$$

Now replace the formal-abstract equality inclusion test, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, with the less strict independent-formal constraint, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, which is implied by formal-abstract equality, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}} \Longrightarrow A^{\mathrm{X}} * T=$ $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, to define the derived alignment substrate ideal independent-formal transform inducer $I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime} \in \operatorname{inducers}(z)$, given substrate histogram $A \in \mathcal{A}_{z}$, as

$$
\begin{aligned}
& I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime *}(A)= \\
& \quad\left\{\left(T, I_{\approx \mathbf{R}}^{*}(\operatorname{algn}(A * T))\right): T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{x}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}}, A=A * T * T^{\dagger A}\right\}
\end{aligned}
$$

The independent-formal inducer, $I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}$, is defined with the real approxer, $I_{\approx \mathbf{R}}$, rather than the log-rational approxer, $I_{\approx \ln \mathbf{Q}}$, because in some cases the abstract alignment is not integral, $(A * T)^{\mathrm{X}} \notin \mathcal{A}_{\mathrm{i}}$. Also, there is no longer any need to constrain the domain of the inducer to the subset integralindependent substrate histograms, $\mathcal{A}_{z, \mathrm{xi}} \subset \mathcal{A}_{z}$.

The weaker constraint means that the application of the independent-formal inducer, $I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}$, is a superset of that of the formal-abstract inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, $I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime *}(A) \supseteq I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}(A)$, in the case where the substrate histogram has integral independent, $A \in \mathcal{A}_{z, \mathrm{xi}}$. The substrate models are no longer constrained to be a subset of the literal substrate models, so that in some cases $\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}(A)\right) \backslash \mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A) \neq \emptyset$. Conjecture that the maximum transform function of the independent-formal inducer, $I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}$, is positively correlated with that of the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime *}\right) \geq 0\right)
$$

The independent-formal inclusion test, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, may be dropped altogether by altering the range of the application to be content alignment, $\operatorname{algn}(A * T)-\operatorname{algn}\left(A^{\mathrm{X}} * T\right)$, instead of derived alignment. Define the content alignment substrate ideal transform inducer $I_{z, \mathrm{c}, \mathrm{j}}^{\prime} \in \operatorname{inducers}(z)$, given substrate histogram $A \in \mathcal{A}_{z}$, as

$$
\begin{aligned}
& I_{z, \mathrm{c}, \mathrm{j}}^{\prime *}(A)= \\
& \quad\left\{\left(T, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}(A * T)-\operatorname{algn}\left(A^{\mathrm{x}} * T\right)\right)\right): T \in \mathcal{T}_{U_{A}, V_{A}}, A=A * T * T^{\dagger A}\right\}
\end{aligned}
$$

This still weaker constraint means that the set of substrate models of the content inducer, $I_{z, \mathrm{c}, \mathrm{j}}^{\prime}$, is a superset of that of those of the independent-formal inducer, $I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}$. That is, $\operatorname{dom}\left(I_{z, \mathrm{c}, \mathrm{j}}^{\prime *}(A)\right) \supseteq \operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime *}(A)\right) \supseteq \operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}(A)\right)$. So the subset that is disjoint with the literal substrate models, $\operatorname{dom}\left(I_{z, \mathrm{c}, \mathrm{j}}^{\prime}(A)\right) \backslash$ $\mathcal{T}_{\text {fa, }}(A)$, has possibly greater cardinality.

The formal alignment, $\operatorname{algn}\left(A^{\mathrm{X}} * T\right)$, is zero when the formal histogram is independent, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}} \Longrightarrow \operatorname{algn}\left(A^{\mathrm{X}} * T\right)=0$. The formal alignment is always greater than or equal zero, where the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}} \Longrightarrow A^{\mathrm{X}} * T \in \mathcal{A}_{\mathrm{i}} \Longrightarrow \operatorname{algn}\left(A^{\mathrm{X}} * T\right) \geq 0$. Conjecture that the content alignment inducer, $I_{z, \mathrm{c}, \mathrm{j}}^{\prime}$, is positively correlated with the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{c}, \mathrm{j}}^{\prime *}\right) \geq 0\right)
$$

but that the correlation is lower than that for the independent-formal inducer, $I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}$,

$$
\begin{aligned}
& \forall z \in \mathbf{N}_{>0} \\
& \quad\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, 1}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}\right) \geq \operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, 1}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{c}, \mathrm{j}}^{\prime *}\right)\right)
\end{aligned}
$$

This is because in some cases the maximum transforms, $\operatorname{maxd}\left(I_{z, \mathrm{c}, \mathrm{j}}^{\prime}(A)\right) \subset$ $\mathcal{T}_{U_{A}, V_{A}}$, are such that the formal histogram is not independent. That is, $A^{\mathrm{X}} * T_{\mathrm{c}} \neq\left(A^{\mathrm{X}} * T_{\mathrm{c}}\right)^{\mathrm{X}}$, where $T_{\mathrm{c}} \in \operatorname{maxd}\left(I_{z, \mathrm{c}, \mathrm{j}}^{\prime}(A)\right)$.

However, both (i) the independent-formal inclusion test, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} *\right.$ $T)^{\mathrm{X}}$, in the independent-formal inducer, $I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}$, and (ii) the formal alignment, $\operatorname{algn}\left(A^{\mathrm{X}} * T\right)$, in the content alignment inducer, $I_{z, \mathrm{c}, \mathrm{j}}^{\prime}$, remain intractable because of intractable substrate volume. The independent histogram, $A^{\mathrm{X}}$, must still be computed by the independenter, $I_{\mathrm{X}}^{*}(A)=A^{\mathrm{X}}$, requiring time and space of at least $v$, where $v=\left|V^{\mathrm{CS}}\right|$. The independent-formal constraint in the derived alignment independent-formal inducer, $I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}$, may be
made more tractable by constraining the domain of the application more strictly to the non-overlapping transforms, $\mathcal{T}_{U_{A}, V_{A}, \mathrm{n}}$, where $\mathcal{T}_{U, V, \mathrm{n}}=\{T: T \in$ $\left.\mathcal{T}_{U, V}, \neg \operatorname{overlap}(T)\right\}$. A non-overlapping transform implies that the formal histogram is independent, $\neg \operatorname{overlap}(T) \Longrightarrow A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$. Define the derived alignment substrate ideal non-overlapping transform inducer $I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime} \in \operatorname{inducers}(z)$, given substrate histogram $A \in \mathcal{A}_{z}$, as

$$
\begin{aligned}
& I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime \prime}(A)= \\
& \quad\left\{\left(T, I_{\approx \mathbf{R}}^{*}(\operatorname{algn}(A * T))\right): T \in \mathcal{T}_{U_{A}, V_{A}, \mathrm{n}}, A=A * T * T^{\dagger A}\right\}
\end{aligned}
$$

The set of substrate models of the derived alignment non-overlapping inducer, $I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime}$, is a subset of that of the derived alignment independent-formal inducer, $\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime *}(A)\right)=\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime *}(A)\right) \cap \mathcal{T}_{U_{A}, V_{A}, \mathrm{n}}$. The set of substrate models is neither a superset nor a subset of the set of the literal substrate mod$e l s,\left|\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime *}(A)\right) \backslash \mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)\right| \geq 0$ and $\left|\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A) \backslash \operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime *}(A)\right)\right| \geq 0$. This is because independent-formal transforms are not necessarily non-overlapping, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}} \Longleftarrow \neg \operatorname{overlap}(T)$, and therefore transforms that are subject to formal-abstract equality, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}} \Longrightarrow A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, are not necessarily non-overlapping. However, the intersection with the literal substrate models is not empty, $\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime *}(A)\right) \cap \mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A) \neq \emptyset$.

Conjecture that the derived alignment non-overlapping inducer, $I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime}$, is positively correlated with the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime *}\right) \geq 0\right)
$$

but that the correlation is lower than that for the derived alignment independentformal inducer, $I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}$,

$$
\begin{aligned}
& \forall z \in \mathbf{N}_{>0} \\
& \quad\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime *}\right) \geq \operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{n},}^{\prime *}\right)\right)
\end{aligned}
$$

because the intersection with the literal substrate models is sometimes smaller, $\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime *}(A)\right) \cap \mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A) \subseteq \operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime *}(A)\right) \cap \mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)$.

In the derived alignment non-overlapping inducer, $I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime}$, the inclusion test for independent-formal, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, is replaced by a test for non-overlapping transform, $\neg \operatorname{overlap}(T)$. However, determining whether a substrate transform is non-overlapping or not requires contracting each of the derived variables, and then checking to see if the contracted partition transforms are disjoint, $\left\{\operatorname{vars}\left(P^{\%}\right): w \in \operatorname{der}(T), P=(\operatorname{his}(T) \%(\operatorname{und}(T) \cup\right.$
$\left.\{w\}),\{w\})^{\mathrm{P}}\right\} \in \mathrm{B}(\operatorname{und}(T))$. The representation space of the transform, $T$, in the inducer must be at least as large as the underlying volume, $I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\mathrm{s}}(A)>v$, and is therefore intractable. In section 'Intractable substrate volume', above, a similar intractability is addressed in the application of the transform to the histogram by the transformer, $I_{* T}^{\mathrm{s}}((T, A))>v$. Define the derived alignment substrate ideal non-overlapping fud inducer $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{n}, \mathrm{j}}^{\prime} \in \operatorname{inducers}(z)$, given substrate histogram $A \in \mathcal{A}_{z}$, as

$$
\begin{aligned}
& I_{z, \mathrm{a}, \mathrm{~F}, \mathrm{n}, \mathrm{j}}^{\prime *}(A)= \\
& \quad\left\{\left(F, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}\left(A * F^{\mathrm{T}}\right)\right)\right): F \in \mathcal{F}_{U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}}, A=A * F^{\mathrm{T}} * F^{\mathrm{T} \dagger A}\right\}
\end{aligned}
$$

where $\mathcal{F}_{\mathrm{n}}:=\{F: F \in \mathcal{F}, \neg \operatorname{overlap}(F)\}$.
A fud can be tractably tested for overlap by following the depends tree of the partition transforms, $\neg \operatorname{overlap}(F) \Longleftrightarrow\{\operatorname{und}(\operatorname{depends}(F,\{w\})): w \in$ $\operatorname{der}(F)\} \in \mathrm{B}(\operatorname{und}(F))$.

The application of the derived alignment ideal non-overlapping fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \mathrm{n}, \mathrm{j}}^{\prime}$, maps to that of the derived alignment ideal non-overlapping inducer, $I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime}$, above, $\left\{\left(F^{\mathrm{T} V_{A}}, a\right):(F, a) \in I_{z, \mathrm{a}, \mathrm{F}, \mathrm{n}, \mathrm{j}}^{\prime *}(A)\right\}=I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime *}(A)$, so the correlations to the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, are equal

$$
\begin{aligned}
& \forall z \in \mathbf{N}_{>0} \\
& \quad\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime *}\right)=\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{~F}, \mathrm{n}, \mathrm{j}}^{\prime *}\right)\right)
\end{aligned}
$$

Now constrain the fud inducer by limited models. Define the limited-models derived alignment substrate ideal non-overlapping infinite-layer fud inducer $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, \mathrm{j}}^{\prime} \in \operatorname{inducers}(z)$, given substrate histogram $A \in \mathcal{A}_{z}$, as
$I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, \mathrm{j}}^{\prime *}(A)=$

$$
\left\{\left(F, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}\left(A * F^{\mathrm{T}}\right)\right)\right): F \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}, A=A * F^{\mathrm{T}} * F^{\mathrm{T} \dagger A}\right\}
$$

Similarly to the derived alignment ideal non-overlapping inducer, $I_{z, a, \mathrm{n}, \mathrm{j}}^{\prime}$, above, the set of substrate transforms corresponding to the substrate models of the limited-models derived alignment ideal non-overlapping fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, \mathrm{j}}^{\prime}$, is neither a superset nor a subset of the set of the literal substrate transforms, $\left|\left\{F^{\mathrm{TV} V_{A}}: F \in \operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, \mathrm{j}}^{\prime *}(A)\right)\right\} \backslash \mathcal{T}_{\text {fa, }}(A)\right| \geq 0$ and $\mid \mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A) \backslash\left\{F^{\mathrm{T} V_{A}}: F \in\right.$ $\left.\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, \mathrm{j}}^{\prime}(A)\right)\right\} \mid \geq 0$. Therefore conjecture that the limited-models derived alignment ideal non-overlapping fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, \mathrm{j}}^{\prime}$, is positively correlated with the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, 1}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}, \mathrm{j}}^{\prime *}\right) \geq 0\right)
$$

but that the correlation is lower than that for the limited-models derived alignment ideal formal-abstract fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{l}, \mathrm{q}}^{\prime}$,

$$
\begin{aligned}
& \forall z \in \mathbf{N}_{>0} \\
& \quad\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, 1}^{\prime}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{~F}, \infty, \mathrm{l}, \mathrm{q}}^{\prime *}\right) \geq\right. \\
& \left.\qquad \operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}, \mathrm{j}}^{\prime *}\right)\right)
\end{aligned}
$$

As shown in section 'Transform alignment', above, in the case of a histogramtransform pair $(A, T) \in \mathcal{O}_{U, z+y}$, where the histogram, $A$, is the sum of a diagonal histogram of size $z$ and a cartesian histogram of size $y$, the idealisation alignment is approximately equal to the derived alignment, $\operatorname{algn}\left(A * T * T^{\dagger A}\right) \approx$ $\operatorname{algn}(A * T)$. It is also conjectured that the idealisation alignment is always less than or equal to the alignment of the histogram, where the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}} \Longrightarrow \operatorname{algn}\left(A * T * T^{\dagger A}\right) \leq \operatorname{algn}(A)$. The histogram alignment, $\operatorname{algn}(A)$, is constant, so at the maximum idealisation alignment the transform is ideal, $\operatorname{algn}\left(A * T * T^{\dagger A}\right)=\operatorname{algn}(A) \Longrightarrow A \equiv A * T * T^{\dagger}$. Therefore conjecture that the maximisation of the derived alignment, $\operatorname{algn}(A * T)$, weakly maximises the idealisation alignment, $\operatorname{algn}\left(A * T * T^{\dagger A}\right)$, idealising the transform, ideal $(A, T)$. In order to make an inducer computation tractable, the ideality inclusion test must be removed. Dropping the ideality inclusion test, $A=A * F^{\mathrm{T}} * F^{\mathrm{T} \dagger A}$, define the limited-models derived alignment substrate non-overlapping infinite-layer fud inducer $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime} \in \operatorname{inducers}(z)$, given substrate histogram $A \in \mathcal{A}_{z}$, as

$$
\begin{aligned}
& I_{z, \mathrm{a}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)= \\
& \quad\left\{\left(F, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}\left(A * F^{\mathrm{T}}\right)\right)\right): F \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right\}
\end{aligned}
$$

Conjecture that the derived alignment non-overlapping fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is positively correlated with the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}\right) \geq 0\right)
$$

but that the correlation is lower than that for the derived alignment ideal non-overlapping fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, \mathrm{j}}^{\prime}$,

$$
\begin{aligned}
& \forall z \in \mathbf{N}_{>0} \\
& \quad\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}, \mathrm{j}}^{\prime}\right) \geq\right. \\
& \left.\quad \operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}\right)\right)
\end{aligned}
$$

because the intersection of the set of substrate transforms corresponding to the substrate models of the limited-models derived alignment non-overlapping
fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, with the literal substrate transforms, $\left\{F^{\mathrm{T} V_{A}}: F \in\right.$ $\left.\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}(A)\right)\right\} \cap \mathcal{T}_{\text {fa, }, ~}$, equals that of the derived alignment ideal nonoverlapping fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, \mathrm{j}}^{\prime}$, but the set of substrate models is a superset, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{*}(A) \supseteq I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, \mathrm{j}}^{\prime *}(A)$. That is, the cardinality of the set of non-literal substrate models, $\left\{F: F \in \operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)\right), F^{\mathrm{TV} V_{A}} \notin \mathcal{T}_{\mathrm{f}, \mathrm{j}, \mathrm{j}}(A)\right\}$, is at least that of the ideal inducer.

The derived alignment non-overlapping fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is tractable in all respects.

Although the derived alignment non-overlapping fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is tractable, the non-overlapping constraint, $\neg \operatorname{overlap}(F)$, is weaker than a formal-abstract equality inclusion test of the fud, $A^{\mathrm{X}} * F^{\mathrm{T}}=\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}$. To see how the formal-abstract equality condition might be adhered to more strictly, consider the abstract-non-formal entropy substrate ideal independent-formal transform inducer $I_{z, \mathrm{e}, \mathrm{fx}, \mathrm{j}}^{\prime} \in \operatorname{inducers}(z)$. Given a substrate histogram $A \in \mathcal{A}_{z}$, the abstract-non-formal entropy inducer is defined as

$$
\begin{aligned}
& I_{z, \mathrm{e}, \mathrm{fx}, \mathrm{j}}^{\prime *}(A)= \\
& \quad\left\{\left(T, I_{\approx \ln \mathbf{Q}}^{*}\left(\operatorname{entropy}\left((A * T)^{\mathrm{X}}\right)-\operatorname{entropy}\left(\left(A^{\mathrm{x}} * T\right)^{\mathrm{X}}\right)\right)\right):\right. \\
& \left.\quad T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{x}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}
\end{aligned}
$$

The abstract-non-formal entropy inducer, $I_{z, \mathrm{e}, \mathrm{fx}, \mathrm{j}}^{\prime}$, relaxes the formal-abstract equality inclusion test to constrain the search transforms to those that are such that the formal histogram is independent, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, which is implied by formal-abstract equality, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}} \Longrightarrow A^{\mathrm{X}} * T=$ $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$. The set of substrate models of the abstract-non-formal entropy inducer, $I_{z, \mathrm{e}, \mathrm{fx}, \mathrm{j}}^{\prime}$, is the same as those of the independent-formal inducer, $I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}$, and therefore a superset of the literal substrate models, $\mathcal{T}_{\text {fa, } j}(A)$. That is, $\operatorname{dom}\left(I_{z, \mathrm{e}, \mathrm{fx}, \mathrm{j}}^{\prime *}(A)\right)=\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime *}(A)\right) \supseteq \operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}(A)\right)$. To compensate, the range of the application is the difference in the entropy of the abstract histogram and the entropy of the formal histogram, entropy $\left((A * T)^{\mathrm{X}}\right)-$ entropy $\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right)$. Although both the formal histogram, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, and the abstract histogram, $(A * T)^{\mathrm{X}}$, are independent, it is conjectured that the abstract histogram tends to have lower entropy than the doubly independent formal histogram

$$
\begin{aligned}
& \operatorname{average}\left(\left\{\left(T, \text { entropy }\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right)-\operatorname{entropy}\left((A * T)^{\mathrm{X}}\right)\right):\right.\right. \\
& \left.\left.\qquad T \in \mathcal{T}_{U_{A}, V_{A}}, \quad A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right\}\right) \geq 0
\end{aligned}
$$

In particular, the formal histogram is completely effective, $\left(A^{\mathrm{XF}} * T\right)^{\mathrm{XF}}=$ $\left(V_{A}^{\mathrm{C}} * T\right)^{\mathrm{XF}}=W^{\mathrm{C}}$, where $W=\operatorname{der}(T)$, whereas the abstract histogram is not
necessarily completely effective, $(A * T)^{\mathrm{XF}} \leq W^{\mathrm{C}}$. For example, the abstract histogram, $(A * T)^{\mathrm{X}}$, may be a cartesian sub-volume.

Overall, the maximisation, maxr $\circ I_{z, \mathrm{e}, \mathrm{fx}, \mathrm{j}}^{\prime *} \in \mathcal{A}_{z} \rightarrow \mathbf{Q}$, tends to equalise the formal histogram, $A^{\mathrm{X}} * T$ and the abstract histogram, $(A * T)^{\mathrm{X}}$.

The abstract-non-formal entropy inducer, $I_{z, \mathrm{e}, \mathrm{fx}, \mathrm{j}}^{\prime}$, is properly considered to be an inducer because it is conjectured to obey the constraint on inducers that the maximum of the inducer application, maxro $I_{z, \mathrm{e}, \mathrm{fx}, \mathrm{j}, \mathrm{e}}^{\prime *}$, is positively correlated with the finite alignment-bounded iso-transform space ideal transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}$. That is,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j},}, \operatorname{maxr} \circ I_{z, \mathrm{e}, \mathrm{f}, \mathrm{j}, \mathrm{j}}^{\prime}\right) \geq 0\right)
$$

The abstract-non-formal entropy inducer, $I_{z, \mathrm{e}, \mathrm{fx}, \mathrm{j}}^{\prime}$, is positively correlated with the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l},}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{e}, \mathrm{f}, \mathrm{j}, \mathrm{j}}^{\prime *}\right) \geq 0\right)
$$

because, as shown in section 'Minimum alignment', above, the derived alignment approximates to the scaled difference between the entropy of the abstract histogram and the entropy of the derived histogram,

$$
\operatorname{algn}(A * T) \approx z \times \operatorname{entropy}\left((A * T)^{\mathrm{x}}\right)-z \times \operatorname{entropy}(A * T)
$$

The abstract-non-formal entropy inducer, $I_{z, \mathrm{e}, \mathrm{fx}, \mathrm{j}}^{\prime}$, tends to maximise the first term, entropy $\left((A * T)^{\mathrm{X}}\right)$, relative, at least, to the formal independent histogram entropy, entropy $\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right)$, thereby weakly maximising the derived alignment, $\operatorname{algn}(A * T)$. The positive correlation with the literal derived alignment inducer maximum function, maxro $I_{z, \mathrm{a}, 1}^{\prime *}$, implies, transitively, a positive correlation with the alignment-bounded iso-transform space ideal transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{f}, \mathrm{j}, \mathrm{j}}$.

A variation that more directly maximises the derived alignment is to replace the sized abstract entropy with the derived alignment,

$$
\begin{aligned}
& \quad \operatorname{algn}(A * T)-z \times \operatorname{entropy}\left(\left(A^{\mathrm{x}} * T\right)^{\mathrm{X}}\right) \\
& \approx \quad \operatorname{algn}(A * T)-\operatorname{algn}\left(A^{\mathrm{x}} * T\right)+z \times \operatorname{entropy}\left(A^{\mathrm{x}} * T\right)
\end{aligned}
$$

That is, the maximisation of the content alignment, $\operatorname{algn}(A * T)-\operatorname{algn}\left(A^{\mathrm{X}} * T\right)$, plus the sized formal entropy, $z \times$ entropy $\left(A^{\mathrm{X}} * T\right)$.

This attempt to strengthen the formal-abstract equality may be taken a step further by considering the actualisations. If the formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, and the derived histogram is completely effective, $(A * T)^{\mathrm{F}}=W^{\mathrm{C}}$, then the contentisation equals the surrealisation, $A^{\mathrm{X}} * T * T^{\odot A}=(A * T)^{\mathrm{X}} * T^{\odot A}$. Conjecture that if the inclusion tests are relaxed to constrain the search transforms to those that are such that the formal histogram is independent, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, which is implied by formal-abstract equality, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}} \Longrightarrow A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, then the expected difference in the alignments of the contentisation and the surrealisation is negative,

$$
\begin{aligned}
& \operatorname{average}\left(\left\{\left(T, \operatorname{algn}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}} * T^{\odot A}\right)-\underset{\left.\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)\right):}{ } \quad \mathrm{T} \in \mathcal{T}_{U_{A}, V_{A}}, \quad A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right\}\right) \leq 0\right.
\end{aligned}
$$

This is because the abstract histogram, $(A * T)^{\mathrm{X}}$, tends to have lower entropy than the doubly independent formal histogram, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, as noted above. The lower entropy of the abstract histogram in general means higher alignment of the actualisation. Thus the surrealisation alignment tends to be higher than the contentisation alignment.

Now weaken the inclusion testing by replacing the formal-abstract equality inclusion test, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, with the less strict independent-formal constraint, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, but compensate by altering the range of the application to be the difference in the alignments of the contentisation and the surrealisation, $\operatorname{algn}\left(A^{\mathrm{X}} * T * T^{\odot A}\right)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)$, to define the contentised non-surrealised alignment substrate ideal independent-formal transform inducer $I_{z, \mathrm{~g}, \mathrm{fx}, \mathrm{j}} \in \operatorname{inducers}(z)$, given substrate histogram $A \in \mathcal{A}_{z}$, as

$$
\begin{aligned}
& I_{z, \mathrm{~g}, \mathrm{fx}, \mathrm{j}}^{*}(A)= \\
& \qquad \begin{array}{l}
\left\{\left(T, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}\left(A^{\mathrm{X}} * T * T^{\odot A}\right)-\operatorname{algn}\left((A * T)^{\mathrm{x}} * T^{\odot A}\right)\right)\right):\right. \\
\left.\quad T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}
\end{array}
\end{aligned}
$$

Note that the contentisation is not necessarily size-conserving. It is only size-conserving if the derived histogram is as effective as the formal histogram, $(A * T)^{\mathrm{F}} \geq\left(A^{\mathrm{X}} * T\right)^{\mathrm{F}}$, which requires that the derived histogram be completely effective, $(A * T)^{\mathrm{F}}=W^{\mathrm{C}}$. The formal histogram is completely effective because the independent is completely effective and formal histogram is independent, $\left(A^{\mathrm{XF}}=V_{A}^{\mathrm{C}}\right) \wedge\left(A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \Longrightarrow$ $\left(A^{\mathrm{X}} * T\right)^{\mathrm{F}}=\left(A^{\mathrm{XF}} * T\right)^{\mathrm{XF}}=\left(V_{A}^{\mathrm{C}} * T\right)^{\mathrm{XF}}=W^{\mathrm{C}}$. That is, the contentisation is size-conserving if the derived histogram is completely effective, $(A * T)^{\mathrm{F}}=$
$W^{\mathrm{C}} \Longrightarrow \operatorname{size}\left(A^{\mathrm{X}} * T * T^{\odot A}\right)=z$. Similarly, the surrealisation is only size-conserving if the derived histogram is as effective as the abstract histogram, $(A * T)^{\mathrm{F}} \geq(A * T)^{\mathrm{XF}} \Longrightarrow \operatorname{size}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)=z$. However, the formal histogram is at least as effective as the abstract histogram, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{F}}=W^{\mathrm{C}} \geq(A * T)^{\mathrm{XF}}$. So in the cases where the abstract histogram is not completely effective, the contentisation alignment is sometimes less than the surrealisation alignment because the contentisation size is less than the surrealisation size.

Note, also, that the range of the application, $\operatorname{ran}\left(I_{z, \mathrm{~g}, \mathrm{fx}, \mathrm{j}}^{*}(A)\right)$, is not derived or lifted, unlike that, for example, of the abstract-non-formal entropy inducer, $I_{z, \mathrm{e}, \mathrm{fx}, \mathrm{j}}^{\prime}$, so the contentised non-surrealised derived alignment inducer, $I_{z, \mathrm{~g}, \mathrm{fx}, \mathrm{j}}$, is denoted without the prime embellishment.

As in the case of substrate models of the abstract-non-formal entropy inducer, $I_{z, \mathrm{e}, \mathrm{fx}, \mathrm{j}}^{\prime}$, above, the set of substrate models of the contentised non-surrealised derived alignment inducer, $I_{z, \mathrm{~g}, \mathrm{fx}, \mathrm{j}}$, is the same as those of the independentformal inducer, $I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}$, and therefore a superset of the literal substrate models, $\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)$. That is, $\operatorname{dom}\left(I_{z, \mathrm{~g}, \mathrm{fx}, \mathrm{j}}^{*}(A)\right)=\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}(A)\right) \supseteq \operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}(A)\right)$. Conjecture that the maximum transform function of the contentised nonsurrealised derived alignment inducer, $I_{z, \mathrm{~g}, \mathrm{fx}, \mathrm{j},}$, is positively correlated with that of the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{~g}, \mathrm{f}, \mathrm{j}}^{*}\right) \geq 0\right)
$$

Overall, the maximisation, maxr $\circ I_{z, \mathrm{~g}, \mathrm{fx}, \mathrm{j}}^{*} \in \mathcal{A}_{z} \rightarrow \mathbf{Q}$, tends to equalise the formal histogram, $A^{\mathrm{X}} * T$ and the abstract histogram, $(A * T)^{\mathrm{X}}$, while still weakly maximising the derived alignment, algn $(A * T)$, as in the abstract-non-formal entropy inducer, $I_{z, \mathrm{e}, \mathrm{f}, \mathrm{j}, \mathrm{j}}^{\prime}$, above.

In section 'Transform alignment', above, it is conjectured that the midisation alignment varies with (a) the difference between the alignments of the contentisation and the surrealisation, and (b) the midisation pseudoalignment,

$$
\begin{aligned}
\operatorname{algn}\left(A^{\mathrm{M}(T)}\right) & \sim \operatorname{algn}\left(A^{\mathrm{X}} * T * T^{\odot A}\right)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right) \\
& \sim \operatorname{algn}(A)-\operatorname{algn}\left(A * T * T^{\odot A^{\dagger A}}\right)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)
\end{aligned}
$$

Define the midisation pseudo-alignment substrate ideal independent-formal transform inducer $I_{z, \mathrm{~m}, \mathrm{fx}, \mathrm{j}} \in \operatorname{inducers}(z)$, given substrate histogram $A \in \mathcal{A}_{z}$,

$$
\begin{aligned}
& I_{z, \mathrm{~m}, \mathrm{fx}, \mathrm{j}}^{*}(A)= \\
& \quad\left\{\left(T, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}(A)-\operatorname{algn}\left(A * T * T^{\dagger A}\right)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)\right)\right):\right. \\
& \left.\quad T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}
\end{aligned}
$$

Note that the midisation pseudo-alignment inducer, $I_{z, \mathrm{~m}, \mathrm{fx}, \mathrm{j}}$, need not compute the histogram alignment, algn $(A)$, because it is constant with regard to maximisation.

As in the case of substrate models of the abstract-non-formal entropy inducer, $I_{z, \mathrm{e}, \mathrm{fx}, \mathrm{j}}$, and the contentised non-surrealised derived alignment inducer, $I_{z, \mathrm{~g}, \mathrm{fx}, \mathrm{j}}$, above, the set of substrate models of the midisation pseudo-alignment ideal inducer, $I_{z, \mathrm{~m}, \mathrm{fx}, \mathrm{j}}$, is the same as those of the independent-formal inducer, $I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}$, and therefore a superset of the literal substrate models, $\mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)$. That is, $\operatorname{dom}\left(I_{z, \mathrm{~m}, \mathrm{fx}, \mathrm{j}}^{*}(A)\right)=\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{*}(A)\right) \supseteq \operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{l}}^{*}(A)\right)$. Conjecture that the maximum transform function of the midisation ideal alignment inducer, $I_{z, \mathrm{~m}, \mathrm{fx}, \mathrm{j}}$, is positively correlated with that of the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{~m}, \mathrm{fx}, \mathrm{j}}^{*}\right) \geq 0\right)
$$

However, the ideality inclusion test, $A=A * T * T^{\dagger}$, implies that the idealisation alignment equals the histogram alignment, $\operatorname{algn}\left(A * T * T^{\dagger}\right)=\operatorname{algn}(A)$, so in the case of ideal transform, the midisation pseudo-alignment equals the negative surrealisation alignment, $-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)$. In order to (i) improve the degree to which maximisation of midisation pseudo-alignment corresponds to the formal-abstract equality constraint and (ii) make the computation tractable, drop the ideality inclusion test, which constrains the midisation pseudo-alignment, defining the midisation pseudo-alignment substrate independent-formal transform inducer $I_{z, \mathrm{~m}, \mathrm{fx}} \in \operatorname{inducers}(z)$, given substrate histogram $A \in \mathcal{A}_{z}$, as

$$
\begin{aligned}
& I_{z, \mathrm{~m}, \mathrm{fx}}^{*}(A)= \\
& \quad \begin{array}{l}
\left\{\left(T, I_{\approx \mathrm{R}}^{*}\left(\operatorname{algn}(A)-\operatorname{algn}\left(A * T * T^{\dagger A}\right)-\operatorname{algn}\left((A * T)^{\mathrm{x}} * T^{\odot A}\right)\right)\right):\right. \\
\\
\left.\quad T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right\}
\end{array}
\end{aligned}
$$

This weaker constraint means that the set of substrate models of the midisation pseudo-alignment inducer, $I_{z, \mathrm{~m}, \mathrm{fx}}$, is a superset of those of the midisation pseudo-alignment ideal inducer, $I_{z, \mathrm{~m}, \mathrm{fx}, \mathrm{j}}$, which equals those of the independent-formal inducer, $I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}$. That is, $\operatorname{dom}\left(I_{z, \mathrm{~m}, \mathrm{fx}}^{*}(A)\right) \supseteq \operatorname{dom}\left(I_{z, \mathrm{~m}, \mathrm{fx}, \mathrm{j}}^{*}(A)\right)=$
$\operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime *}(A)\right) \supseteq \operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}(A)\right)$. So the subset that is disjoint with the literal substrate models, $\operatorname{dom}\left(I_{z, \mathrm{~m}, \mathrm{fx}}^{*}(A)\right) \backslash \mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)$, has possibly greater cardinality. Conjecture that the maximum transform function of the midisation pseudo-alignment inducer, $I_{z, \mathrm{~m}, \mathrm{fx}}$, is positively correlated with that of the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{~m}, \mathrm{fx}}^{*}\right) \geq 0\right)
$$

Although the non-literal substrate models, $\operatorname{dom}\left(I_{z, \mathrm{~m}, \mathrm{fx}}^{*}(A)\right) \backslash \mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)$, may have greater cardinality, it is not obvious whether or not the midisation pseudoalignment inducer, $I_{z, \mathrm{~m}, \mathrm{fx}}$, has a lower correlation with the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$, than the midisation ideal alignment inducer, $I_{z, \mathrm{~m}, \mathrm{fx}, \mathrm{j}}$. The cost of dropping the ideality inclusion test may be outweighed by the closer approximation to the formal-abstract equality inclusion test, in some cases.

In section 'Likely histograms', it is conjectured that there exists an intermediate mid substrate transform $T_{\mathrm{m}} \in \mathcal{T}_{U_{A}, V_{A}}$ which is neither self nor unary, $T_{\mathrm{m}} \notin\left\{T_{\mathrm{s}}, T_{\mathrm{u}}\right\}$, where the formal is independent and the midisation entropy is minimised,

$$
T_{\mathrm{m}} \in \operatorname{mind}\left(\left\{\left(T, \operatorname{entropy}\left(A^{\mathrm{M}(T)}\right)\right): T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right\}\right)
$$

Section 'Transform alignment', goes on to conjecture that an approximation to the mid transform may also be obtained by a maximisation of the midisation pseudo-alignment,

$$
\begin{aligned}
T_{\mathrm{m}} \in \operatorname{maxd}(\{(T, \operatorname{algn}(A)-\operatorname{algn}(A * T * & \left.\left.T^{\dagger A}\right)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)\right): \\
T & \left.\left.\in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right\}\right)
\end{aligned}
$$

With the removal of the ideality inclusion test, the maximum transform function of the midisation pseudo-alignment inducer, $I_{z, \mathrm{~m}, \mathrm{fx}}$, is the mid transform, $T_{\mathrm{m}} \in \operatorname{maxd}\left(I_{z, \mathrm{~m}, \mathrm{fx}}^{*}(A)\right)$. At the mid transform the formal tends to the abstract, $A^{\mathrm{X}} * T_{\mathrm{m}} \approx\left(A * T_{\mathrm{m}}\right)^{\mathrm{X}}$, and the mid component size cardinality relative entropy is small,

$$
\operatorname{entropyRelative}\left(A * T_{\mathrm{m}}, V_{A}^{\mathrm{C}} * T_{\mathrm{m}}\right) \approx 0
$$

The computation of the midisation pseudo-alignment, $\operatorname{algn}(A)-\operatorname{algn}((A *$ $\left.T)^{\mathrm{X}} * T^{\odot A}\right)-\operatorname{algn}\left(A * T * T^{\dagger A}\right)$, requires at least the computation of the idealisation, $A * T * T^{\dagger A}$, and the surrealisation, $(A * T)^{\mathrm{X}} * T^{\odot A}$, at least one of which is intractable. Consider replacing midisation pseudo-alignment with
derived alignment valency density. Section 'Transform alignment', above, describes the properties of midisation. Maximisation of midisation tends to move component alignments from off-diagonal states to on-diagonal states, balancing the high derived alignment of longer diagonals with the high ondiagonal component alignments of shorter diagonals. Thus the midisation pseudo-alignment varies with the derived alignment valency density,

$$
\begin{aligned}
\operatorname{algn}(A)-\operatorname{algn}\left((A * T)^{\mathrm{X}} *\right. & \left.T^{\odot A}\right)-\operatorname{algn}\left(A * T * T^{\dagger A}\right) \sim \\
& \operatorname{algn}(A * T) / \operatorname{capacity} \operatorname{Valency}(U)\left((A * T)^{\mathrm{FS}}\right)
\end{aligned}
$$

where the valency capacity, capacityValency $(U) \in$ capacities, is defined in terms of geometry as capacityValency $(U)\left((A * T)^{\mathrm{FS}}\right)=w^{1 / m}$, and $m=|W|$, $w=\left|W^{\mathrm{C}}\right|$ and $W=\operatorname{der}(T)$.

Define the derived alignment valency-density substrate independent-formal transform inducer $I_{z, \mathrm{ad}, \mathrm{fx}}^{\prime} \in \operatorname{inducers}(z)$, given substrate histogram $A \in \mathcal{A}_{z}$, as

$$
\begin{aligned}
& I_{z, \mathrm{ad}, \mathrm{fx}}^{\prime *}(A)= \\
& \quad\left\{\left(T, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}(A * T) / w^{1 / m}\right)\right): T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{x}} * T=\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}\right\}
\end{aligned}
$$

where $m=|W|, w=\left|W^{\mathrm{C}}\right|$ and $W=\operatorname{der}(T)$.
The set of substrate models of the derived alignment valency-density inducer, $I_{z, \mathrm{ad}, \mathrm{fx}}^{\prime}$, equals those of the midisation pseudo-alignment inducer, $I_{z, \mathrm{~m}, \mathrm{fx}}$. That is, $\operatorname{dom}\left(I_{z, \mathrm{ad}, \mathrm{fx}}^{\prime *}(A)\right)=\operatorname{dom}\left(I_{z, \mathrm{~m}, \mathrm{fx}}^{*}(A)\right) \supseteq \operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{*}(A)\right) \supseteq \operatorname{dom}\left(I_{z, \mathrm{a}, \mathrm{l}}^{\prime}(A)\right)$. Conjecture that the maximum transform function of the derived alignment valency-density inducer, $I_{z, \text { ad, fx }}^{\prime}$, is positively correlated with that of the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{ad}, \mathrm{fx}}^{\prime *}\right) \geq 0\right)
$$

In section 'Derived alignment and conditional probability', above, the alignment-bounded lifted iso-transform error is defined as the difference between the alignment-bounded lifted iso-transform space and the derived alignment

$$
\ln \sum_{B^{\prime} \in \mathcal{A}^{\prime}, \dot{\mathrm{i}, \mathrm{y}, T, z}} \frac{\prod_{R \in(A * T)^{\mathrm{xS}}}(A * T)_{R}^{\mathrm{X}}!}{\prod_{R \in B^{\prime \mathrm{S}}} B_{R}^{\prime}!}
$$

The alignment-bounded lifted iso-transform error ratio is the error per derived alignment. Given substrate histogram $A \in \mathcal{A}_{z}$, let $\operatorname{erra}(A) \in \mathrm{P}\left(\mathcal{T}_{U_{A}, V_{A}}\right) \rightarrow$
$\left(\mathcal{T}_{U_{A}, V_{A}} \rightarrow \mathbf{R}\right)$ be defined as the alignment-bounded lifted iso-transform error ratios of a set of substrate transforms,

$$
\begin{aligned}
& \operatorname{erra}(A)(Q):= \\
& \left.\begin{array}{l}
\left\{\left(T,\left(\ln \sum_{B^{\prime} \in \mathcal{A}^{\prime} U_{A}, i, y, T, z} \frac{\prod_{R \in(A * T)^{\mathrm{xS}}}(A * T)_{R}^{\mathrm{X}!}}{\prod_{R \in B^{\prime} \mathrm{S}} B_{R}^{\prime}!}\right) / \operatorname{algn}(A * T)\right):\right. \\
\quad\{(T, 0): T \in Q, \operatorname{algn}(A * T)=0\}
\end{array} \quad T \in Q, \operatorname{algn}(A * T) \neq 0\right\} \cup
\end{aligned}
$$

In that section it was shown that the error ratio varies as $\bar{w} \ln z / \operatorname{algn}(A * T)$ where the size is greater than the derived volume, $z>w$. This may be compared to the derived alignment valency-density, $\operatorname{algn}(A * T) / w^{1 / m}$. Thus the error ratio varies against the derived alignment valency-density. Higher capacities such as volume capacity, capacityVolume $(U)\left((A * T)^{\mathrm{FS}}\right):=w$, would vary inversely even more closely. In that case, the derived alignment volumedensity would be algn $(A * T) / w$. Therefore conjecture that the expected error ratio of the derived alignment valency-density inducer, $I_{z, \mathrm{da}, \mathrm{fx}}^{\prime}$, is less than that of the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$,

$$
\begin{aligned}
& \forall z \in \mathbf{N}_{>0}\left(\operatorname{ex}(z)\left(\text { maxr } \circ \operatorname{erra} \circ \operatorname{maxd} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime}\right) \geq\right. \\
& \left.\quad \operatorname{ex}(z)\left(\operatorname{maxr} \circ \operatorname{erra} \circ \operatorname{maxd} \circ I_{z, \mathrm{ad}, \mathrm{fx}}^{\prime}\right)\right)
\end{aligned}
$$

Therefore conjecture that the valency capacity tends to increase the correlation of the maximum function of the derived alignment valency-density inducer, maxro $I_{z, \mathrm{dad}, \mathrm{fx}}^{\prime *}$, to the alignment-bounded lifted iso-transform space ideal transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}^{\prime}$, and thence transitively to the alignment-bounded iso-transform space ideal transform maximum function, maxro $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}$. In other words, the derived alignment valency-density inducer, $I_{z, \mathrm{ad}, \mathrm{fx}}^{\prime}$, has a higher inducer correlation, $\operatorname{cov}(z)\left(\operatorname{maxro} X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}\right.$, maxro $\left.I_{z, \mathrm{ad}, \mathrm{fx}}^{\prime}\right)$, than might be expected, because maximisation of the derived alignment valency-density, $\operatorname{algn}(A * T) / w^{1 / m}$, tends to shorten the diagonals, $w^{1 / m}$, and reduce the derived volume, $w$, minimising the alignment-bounded lifted iso-transform error ratio. Note that the correlation is improved even though the overall derived alignments of the valency-density inducer are lower than the literal inducer. The correlation increases as the size exceeds the derived volume, $z>w$, because of the decreasing error ratio between the expected alignment, $\bar{w} \ln z / w \approx 1$, and the maximum alignment, $\bar{w} \ln z / z \ln w<1$.

As is the case for the derived alignment independent-formal inducer, $I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}$, above, the independent-formal inclusion test, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, in the
valency-density inducer, $I_{z, \text { ad, fx }}^{\prime}$, is intractable because of intractable substrate volume. Therefore replace the independent-formal inclusion test with the non-overlapping transform constraint, $\neg \operatorname{overlap}(T) \Longrightarrow A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} *\right.$ $T)^{\mathrm{X}}$. Define the derived alignment valency-density substrate non-overlapping transform inducer $I_{z, \mathrm{ad}, \mathrm{n}}^{\prime} \in \operatorname{inducers}(z)$, given substrate histogram $A \in \mathcal{A}_{z}$, as

$$
\begin{aligned}
& I_{z, \mathrm{ad}, \mathrm{n}}^{\prime *}(A)= \\
& \quad\left\{\left(T, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}(A * T) / w^{1 / m}\right)\right): T \in \mathcal{T}_{U_{A}, V_{A}, \mathrm{n}}\right\}
\end{aligned}
$$

where $m=|W|, w=\left|W^{\mathrm{C}}\right|$ and $W=\operatorname{der}(T)$.
Conjecture that the maximum transform function of the derived alignment non-overlapping valency-density inducer, $I_{z, \text { ad, }, ~}^{\prime}$, is positively correlated with that of the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{ad}, \mathrm{n}}^{\prime *}\right) \geq 0\right)
$$

but that the correlation is lower than that for the derived alignment independentformal valency-density inducer, $I_{z, \mathrm{ad}, \mathrm{fx}}^{\prime}$,

```
\(\forall z \in \mathbf{N}_{>0}\)
    \(\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, 1}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{ad}, \mathrm{fx}}^{\prime *}\right) \geq \operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{ad}, \mathrm{n}}^{\prime *}\right)\right)\)
```

because the intersection with the literal substrate models is sometimes smaller, $\operatorname{dom}\left(I_{z, \mathrm{ad}, \mathrm{n}}^{*}(A)\right) \cap \mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A) \subseteq \operatorname{dom}\left(I_{z, \mathrm{ad}, \mathrm{fx}}^{\prime *}(A)\right) \cap \mathcal{T}_{\mathrm{fa}, \mathrm{j}}(A)$.

Again, as is the case for the derived alignment non-overlapping inducer, $I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime}$, above, determining whether a substrate transform is non-overlapping or not remains intractable. Also, the limited-models constraints are required for tractability. Define the limited-models derived alignment valencydensity substrate non-overlapping infinite-layer fud inducer $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime} \in$ inducers $(z)$, given substrate histogram $A \in \mathcal{A}_{z}$, as

$$
\begin{aligned}
& I_{z, \mathrm{ad}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)= \\
& \quad\left\{\left(F, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}\left(A * F^{\mathrm{T}}\right) / w^{1 / m}\right)\right): F \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathbf{n}} \cap \mathcal{F}_{\mathrm{q}}\right\}
\end{aligned}
$$

where $m=|W|, w=\left|W^{\mathrm{C}}\right|$ and $W=\operatorname{der}(F)$.
Conjecture that the derived alignment valency-density non-overlapping fud
inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is positively correlated with the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{ad}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}\right) \geq 0\right)
$$

but that the correlation is lower than that for the derived alignment nonoverlapping valency-density inducer, $I_{z, \mathrm{ad}, \mathrm{n}}^{\prime}$,
$\forall z \in \mathbf{N}_{>0}$
$\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{ad}, \mathrm{n}}^{\prime *}\right) \geq\right.$

$$
\left.\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{ad}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}\right)\right)
$$

because of the additional limited-models constraints, $\mathcal{F}_{\mathrm{q}}$.
It is not obvious whether or not the derived alignment valency-density nonoverlapping fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, has a lower correlation, $\operatorname{cov}(z)($ maxr $\circ$ $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}, \operatorname{maxro} I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}$ ), with the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l},}^{\prime}$, than the derived alignment non-overlapping fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}, \operatorname{cov}(z)($ maxro $\left.I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}\right)$.

More importantly, it is not obvious whether or not the derived alignment valency-density non-overlapping fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, has a lower inducer correlation, $\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{*}\right)$, than the derived alignment non-overlapping fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}, \operatorname{cov}(z)($ maxr $\circ$ $\left.X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j},}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}\right)$.

Like the derived alignment non-overlapping fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, the derived alignment valency-density non-overlapping fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is tractable in all respects.

### 4.21.9 Tractable decomposition inducers

Both the derived alignment non-overlapping fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, and the derived alignment valency-density non-overlapping fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, are tractable. The derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, tends to be more ideal, $A \approx A * T * T^{\dagger A}$, than the derived alignment valency-density inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, which tends to be more formal-abstract equivalent, $A^{\mathrm{X}} * T \approx$ $(A * T)^{\mathrm{X}}$. However, the lost ideality of the valency-density fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, can be partly recovered in a valency-density decomposition inducer. The search set of the valency-density decomposition inducer consists
of substrate fud decompositions similar to idealising summation aligned decompositions, $\mathcal{D}_{\Sigma, \mathrm{k}}(A)$, but without the idealising summation aligned decomposition constraints in order to avoid intractable inclusion tests.

In section 'Intractable search set elements', above, the limited-models content alignment integral-independent substrate idealising summation aligned infinite-layer fud decomposition inducer, $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime}$, is defined such that the application to a non-independent integral-independent substrate histogram $A \in \mathcal{A}_{z, \mathrm{xi}} \backslash\left\{A^{\mathrm{X}}\right\}$ is the summation alignment function of the limited-models substrate idealising summation aligned fud decompositions,

$$
\begin{aligned}
& I_{z, \mathrm{c}, \mathrm{D}, \mathrm{~F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime *}(A)= \\
& \left\{\left(D, I_{\approx \ln \mathbf{Q}}^{*}(\operatorname{algnSum}(A, D))\right):\right. \\
& \left.\quad D \in \mathcal{D}_{\mathrm{F}, \infty, U_{A}, V_{A}} \cap \operatorname{trees}\left(\mathcal{S} \times \mathcal{F}_{\mathrm{q}}\right), D^{\mathrm{D} V_{A}} \in \mathcal{D}_{\Sigma, \mathrm{k}}(A)\right\}
\end{aligned}
$$

Define $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime *}\left(A^{\mathrm{X}}\right)=\left\{\left(D_{\mathrm{F}, \mathrm{u}}, 0\right)\right\}$ where $D_{\mathrm{F}, \mathrm{u}}=\left\{\left(\left(\emptyset,\left\{T_{\mathrm{u}}\right\}\right), \emptyset\right)\right\}$ and unary partition transform $T_{\mathrm{u}}=\left\{V_{A}^{\mathrm{CS}}\right\}^{\mathrm{T}}$.

The limited-models idealising fud decomposition inducer, $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime}$, has tractable time and space complexity with respect to the search set elements. The non-unary idealising summation aligned substrate infinite-layer fud decomposition $D \in \operatorname{dom}\left(I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime *}(A)\right) \backslash\left\{D_{\mathrm{F}, \mathrm{u}}\right\}$ is constrained (a) to be well behaved, $D \in \mathcal{D}_{\mathrm{F}, \mathrm{w}, U_{A}}$, (b) such that the infinite-layer substrate fuds appear no more than once in any path, $\forall L \in \operatorname{paths}(D)(\{(i, F):(i,(\cdot, F)) \in$ $\left.L\} \in \mathbf{N} \leftrightarrow \mathcal{F}_{\infty, U_{A}, V_{A}}\right)$, (c) to have no variable symmetries, $\{(w,(C, F))$ : $(C, F) \in \operatorname{cont}(D), w \in \operatorname{der}(F)\} \in \operatorname{der}(\bigcup G) \rightarrow \operatorname{cont}(D)$, which implies (b), and (d) such that the fuds have (i) contingent diagonalisation, $\forall(C, F) \in$ cont $(D)$ (diagonal $\left(A * C * F^{\mathrm{T}}\right)$ ), (ii) contingent formal-abstract equivalence, $\forall(C, F) \in \operatorname{cont}(D)\left(A^{\mathrm{X}} * C * F^{\mathrm{T}}=\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{X}}\right)$, (iii) non-independent contingent derived histograms, $\forall(C, F) \in \operatorname{cont}(D)\left(A * C * F^{\mathrm{T}} \neq\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{x}}\right)$, and (iv) independent formal slices, $\forall(C, F) \in \operatorname{cont}(D)\left((A * C)^{\mathrm{X}} * F^{\mathrm{T}}=\right.$ $\left.\left((A * C)^{\mathrm{X}} * F^{\mathrm{T}}\right)^{\mathrm{X}}\right)$, where $G=$ fuds $(D)$ and cont $=$ elements $\circ$ contingents.

The contingent formal-abstract equality inclusion test, $A^{\mathrm{X}} * C * F^{\mathrm{T}}=(A *$ $\left.C * F^{\mathrm{T}}\right)^{\mathrm{X}}$, is intractable because of intractable substrate volume. This is for the same reason that the formal-abstract equality inclusion test, $A^{\mathrm{X}} * F^{\mathrm{T}}=$ $\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}$, is intractable, as described in section 'Intractable literal substrate model inclusion', above. That is, the computation of the independent histogram, $A^{\mathrm{X}}$, by an independenter, $I_{\mathrm{X}}^{*}(A)=A^{\mathrm{X}}$, requires time and space of at least $v$, where $v=\left|V_{A}^{\mathrm{CS}}\right|$, because the substrate histogram, $A$, has completely effective independent, $A^{\mathrm{XF}}=V_{A}^{\mathrm{C}}$. Thus the computation of the
independent histogram, $A^{\mathrm{X}}$, in the computation of the contingent formal histogram, $A^{\mathrm{X}} * C * F^{\mathrm{T}}$, in the contingent formal-abstract equality inclusion test, $A^{\mathrm{X}} * C * F^{\mathrm{T}}=\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{X}}$, is intractable with respect to underlying dimension, $n$, where $n=\left|V_{A}\right|$.

The independent formal slice inclusion test, $(A * C)^{\mathrm{X}} * F^{\mathrm{T}}=\left((A * C)^{\mathrm{X}} * F^{\mathrm{T}}\right)^{\mathrm{X}}$, also requires the computation of the independent slice histogram, $(A * C)^{\mathrm{X}}$, by an independenter, $I_{\mathrm{X}}^{*}(A * C)=(A * C)^{\mathrm{X}}$, in the same substrate variables, $V_{A}$, and hence is subject to the same intractability in the root slice at least.

Just as in the case of the derived alignment valency-density non-overlapping fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, above, the intractability of the formal-abstract equality inclusion test and independent formal slice inclusion test in the limitedmodels idealising summation aligned infinite-layer fud decomposition inducer, $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime}$, can be addressed by replacing them with (i) a non-overlapping fud constraint, $\neg \operatorname{overlap}(F)$, and (ii) the computation of the summed derived alignment valency density. Define the summed derived alignment valency density as algnValDensSum $(U) \in \mathcal{A} \times \mathcal{D} \rightarrow \mathbf{R}$ as

$$
\begin{aligned}
& \operatorname{algnValDensSum}(U)(A, D):= \\
& \qquad \sum_{(C, T) \in \operatorname{cont}(D)} \operatorname{algn}(A * C * T) / \text { capacityValency }(U)\left((A * C * T)^{\mathrm{FS}}\right)
\end{aligned}
$$

where the valency capacity, capacityValency $(U) \in$ capacities, is defined in terms of geometry as capacityValency $(U)\left((A * C * T)^{\mathrm{FS}}\right)=w^{1 / m}$, and $m=$ $|W|, w=\left|W^{\mathrm{C}}\right|$ and $W=\operatorname{der}(T)$. Then define the limited-models summed alignment valency-density substrate aligned non-overlapping infinite-layer fud decomposition inducer, given non-independent substrate histogram $A \in \mathcal{A}_{z} \backslash$ $\left\{A^{\mathrm{X}}\right\}$,

$$
\begin{aligned}
& I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)= \\
& \qquad \begin{array}{l}
\left\{\left(D, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algnValDensSum}\left(U_{A}\right)\left(A, D^{\mathrm{D}}\right)\right)\right):\right. \\
\quad D \in \mathcal{D}_{\mathrm{F}, \infty, U_{A}, V_{A}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right), \\
\left.\forall(C, F) \in \operatorname{cont}(D)\left(\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)>0\right)\right\}
\end{array}
\end{aligned}
$$

Define $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}\left(A^{\mathrm{X}}\right)=\left\{\left(D_{\mathrm{F}, \mathrm{u}}, 0\right)\right\}$.
The summed alignment valency-density aligned fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, constrains each of the slices $(C, F) \in \operatorname{cont}(D)$ such that the application of the fud, $A * C * F^{\mathrm{T}}$, has derived alignment, $\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)>0$,
where $A \neq A^{\mathrm{x}}$. Thus the slice derived histogram, $A * C * F^{\mathrm{T}}$, cannot be independent and the idealising summation aligned decomposition nonindependent contingent derived histograms constraint, $\forall(C, F) \in \operatorname{cont}(D)(A *$ $\left.C * F^{\mathrm{T}} \neq\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{X}}\right)$, is satisfied by the inducer. In addition, fuds are prevented from appearing more than once in any path of the decomposition, $\forall L \in \operatorname{paths}(D)(\{(i, F):(i,(\cdot, F)) \in L\} \in \mathbf{N} \leftrightarrow G)$ where $G=$ fuds $(D)$, because a fud has zero derived alignment when constrained to its child slice. For example, if $\left(C_{1}, F\right),\left(C_{2}, F\right) \in \operatorname{steps}(\operatorname{contingents}(D))$ then $\operatorname{algn}\left(A * C_{2} * F^{\mathrm{T}}\right)=0$.

Variable symmetries are avoided only so far as the fuds are not repeated in a path, so in this respect the definition of the substate models of the summed alignment valency-density non-overlapping fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is less strict than the definition of the substrate idealising fud decompositions, $\left|\operatorname{dom}\left(I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{*}(A)\right) \backslash \operatorname{dom}\left(I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime *}(A)\right)\right| \geq 0$.

The valency-density decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, does not test explicitly for well behaved decomposition, $\mathcal{D}_{\mathrm{F}, \mathrm{w}, U_{A}}$. Each of the slices has derived alignment, $\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)>0$, and must therefore have non-zero size, $\operatorname{size}(A * C)>0$ and so correspond to a non-empty component, $\operatorname{ran}(\operatorname{cont}(D)) \leftrightarrow$ elements(components $(U)(D)) \backslash \operatorname{partition}(U)(D)$. That is, the decomposition, $D$, does not contain any contradictions and is therefore well behaved, $D \in \mathcal{D}_{\mathrm{F}, \mathrm{w}, U_{A}}$.

The valency-density decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, does not test explicitly for contingent diagonalisation, $\forall(C, F) \in \operatorname{cont}(D)$ (diagonal $(A * C *$ $\left.F^{\mathrm{T}}\right)$ ). The maximum transform function, maxr $\circ I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}$, optimises the summed alignment valency density, algnValDensSum $\left(U_{A}\right)(A, D)$, which varies as the derived alignments of the slices, $\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)$. As described in section 'Maximum alignment', above, maximum alignment is conjectured to occur when the derived histogram is fully diagonalised, diagonalFull $\left(U_{A}\right)(A *$ $\left.C * F^{\mathrm{T}}\right)$. Therefore higher derived alignment tends to diagonalise the slice derived histogram, $A * C * F^{\mathrm{T}}$, approximately satisfying the summation aligned decomposition contingent diagonalisation constraint.

In addition, valency-density tends to shorten diagonals and therefore the derived slice has fewer ineffective states, $\left|\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{C}}-\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{F}}\right| \approx(d-1)^{m}$ where $d=w^{1 / m}$. Although the cardinality of strong compositions of the $d i-$
agonal times the cardinality of subsets of the volume that are diagonalised,

$$
\frac{(z-1)!}{(d-1)!(z-d)!}(d!)^{m-1}=d z^{\underline{d}}\left(d^{\underline{d}}\right)^{m-2} / z
$$

which is dominated by $z^{\underline{d}}$, increases with the diagonal, $d$, given size $z$, the ratio of this cardinality of the diagonals to the cardinality of weak compositions of the volume, $w=d^{m}$,

$$
\frac{(z-1)!}{(d-1)!(z-d)!}(d!)^{m-1} \frac{(w-1)!z!}{(z+w-1)!}=d z^{\underline{d}}\left(d^{\underline{d}}\right)^{m-2} w^{w} / w z^{\bar{w}}
$$

which is dominated by $1 / z^{\bar{w}}$, decreases with the diagonal, $d$, where $d<w<z$. That is, the fraction of derived histograms of a given derived geometry that are diagonalised increases as the diagonals shorten.

This is in line with the maximisation of midisation of a slice, $\operatorname{algn}(A * C)-$ $\operatorname{algn}\left(\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{X}} * F^{\mathrm{T} \odot A * C}\right)-\operatorname{algn}\left(A * C * F^{\mathrm{T}} * F^{\mathrm{T} \dagger A * C}\right)$, for which slice derived valency-density, $\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w^{1 / m}$, is a proxy. Maximisation of midisation tends to move component alignments within the slice, $A * C$, from off-diagonal states, $\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{CS}} \backslash\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{FS}}$, to on-diagonal states, $\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{FS}}$, balancing the high derived alignment of longer diagonals with the high on-diagonal component alignments of shorter diagonals. The lower component alignments of the off-diagonal states tend to make them less effective, while conversely the higher component alignments of on-diagonal states tend to make them more effective.

The fuds $G=$ fuds $(D)$ of the decomposition $D$ are non-overlapping, $G \subset$ $\mathcal{F}_{\mathrm{n}}$. So all slices have independent formal, $\forall(C, F) \in \operatorname{cont}(D)(\neg \operatorname{overlap}(F) \Longrightarrow$ $\left.(A * C)^{\mathrm{X}} * F^{\mathrm{T}}=\left((A * C)^{\mathrm{X}} * F^{\mathrm{T}}\right)^{\mathrm{X}}\right)$, satisfying the idealising summation aligned decomposition independent formal slices constraint. However, as noted for the derived alignment non-overlapping inducer, $I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime}$, in section 'Intractable literal substrate model inclusion', above, independent-formal transforms are not necessarily non-overlapping, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}} \Longleftarrow \neg \operatorname{overlap}(T)$, and so the strict non-overlapping constraint sometimes excludes some independentformal overlapping fuds. The set of substrate models of the valency-density decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is therefore neither a superset nor a subset of the set of the substrate idealising summation aligned infinite-layer fud decompositions, $\left|\operatorname{dom}\left(I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)\right) \backslash \operatorname{dom}\left(I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime *}(A)\right)\right| \geq 0$ and $\left|\operatorname{dom}\left(I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime *}(A)\right) \backslash \operatorname{dom}\left(I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)\right)\right| \geq 0$.

Although both the (i) non-overlapping fud constraint, $\neg \operatorname{overlap}(F)$, and the
(ii) the summed derived alignment valency density, algnValDensSum $\left(U_{A}\right)\left(A, D^{\mathrm{D}}\right)$, maximisation, in the valency-density decomposition inducer maximum transform function, maxr $\circ I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}$, tend to increase the adherence to the formal-abstract equality of individual slices, $(A * C)^{\mathrm{X}} * F^{\mathrm{T}} \approx\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{X}}$ where $(C, F) \in \operatorname{cont}(D)$, in a decomposition $D$, it is not necessarily the case that the contingent formal-abstract equality of the slice increases, $A^{\mathrm{X}} * C *$ $F^{\mathrm{T}} \approx\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{X}}$, or that the formal-abstract equality of the nullable transform increases, $A^{\mathrm{X}} * D^{\mathrm{T}} \approx\left(A * D^{\mathrm{T}}\right)^{\mathrm{X}}$. It is only in the case where the independent slice equals the sliced independent, $(A * C)^{\mathrm{X}}=A^{\mathrm{X}} * C$, that the slice formal-abstract equality and the contingent formal-abstract equality constraints are identical. This is always the case for the root fud of the decomposition, where $C=V^{\mathrm{C}} \Longrightarrow A * C=A \Longrightarrow(A * C)^{\mathrm{X}}=\left(A^{\mathrm{X}} * C\right)$.

Note that the purpose of the (i) contingent diagonalisation and (ii) contingent formal-abstract equivalence constraints in the summation aligned decompositions, $\mathcal{D}_{\Sigma}(A)$, is merely to allow the nullable transform content alignment to be computed without instantiating the intractable nullable transform. In section 'Decomposition alignment', above, it is shown that

$$
\operatorname{algn}\left(A * D^{\mathrm{T}}\right)-\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)=\operatorname{alignmentSum}(A, D)
$$

where these conditions are met. Contrast that to the purpose of the maximisation of derived alignment valency density in the derived alignment valencydensity non-overlapping fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, which is to maximise the formal-abstract equality and hence increase the correlation, $\operatorname{cov}(z)(\operatorname{maxr} \circ$ $\left.I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}\right)$, to the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$, and thence transitively to the increase the inducer correlation to the alignmentbounded iso-transform space ideal transform maximum function, $\operatorname{cov}(z)(\operatorname{maxro}$ $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}$.

However, the goals of (a) computing the content alignment of the intractable nullable transform, $D^{\mathrm{T}}$, by means of contingent formal-abstract equivalence, and (b) increasing the correlation of summed alignment valency-density decomposition inducer, $\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{*}\right)$, attributable to formal-abstract equivalent slices, can be made to converge by (i) choosing components, $C$, with high cardinality, and (ii) minimising the formal alignment of the decomposition, $\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)$.

In the first case, high cardinality components, $C$, tend to approximate better to the cartesian volume, $C \approx V_{A}^{\mathrm{CS}}$, and hence $A^{\mathrm{X}} * C \approx A^{\mathrm{X}}$ which implies $A^{\mathrm{X}} * C \approx(A * C)^{\mathrm{X}}$ because $(A * C)^{\mathrm{X}} \approx A^{\mathrm{X}}$. That is, shorter diagonals are
preferable because the component sizes are larger. Maximisation of derived alignment valency-density, $\operatorname{algn}(A * C * T) / w^{1 / m}$, tends to shorter diagonals, and therefore higher component cardinality of child slices.

In the second case, lower formal alignment of the decomposition, $\operatorname{algn}\left(A^{\mathrm{X}} *\right.$ $\left.D^{\mathrm{T}}\right)$, implies lower contingent formal alignment of the slices, $\operatorname{algn}\left(A^{\mathrm{X}} * C *\right.$ $F^{\mathrm{T}}$ ), and hence contingent independent-formal equality, $A^{\mathrm{X}} * C * F^{\mathrm{T}} \approx$ $\left(A^{\mathrm{X}} * C * F^{\mathrm{T}}\right)^{\mathrm{X}}$, which is implied by contingent formal-abstract equality, $A^{\mathrm{X}} * C * F^{\mathrm{T}} \approx\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{X}}$. Minimisation of the formal alignment of the decomposition, $\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)$, is desirable in any case because then the summed derived alignment valency density, algnValDensSum $\left(U_{A}\right)(A, D)$, most approximates to the nullable transform derived alignment valency density rather than the nullable transform content alignment valency density

$$
\left(\operatorname{algn}\left(A * D^{\mathrm{T}}\right)-\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)\right) / y^{1 / p} \approx \operatorname{algnValDensSum}\left(U_{A}\right)(A, D)
$$

where $p=|Y|, u=\left|Y^{\mathrm{C}}\right|$ and $Y=\operatorname{der}\left(D^{\mathrm{T}}\right)$. That is, $\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)=$ $0 \Longrightarrow \operatorname{algn}\left(A * D^{\mathrm{T}}\right) / y^{1 / p} \approx \operatorname{algnValDensSum}\left(U_{A}\right)(A, D)$. Note that if the decomposition, $D$, contains more than one $f u d,|G|>1$, then the volume of the derived variables of the nullable transform, $D^{\mathrm{T}}$, is greater than the volume of the derived variables of the fuds, $\left|\operatorname{der}\left(D^{\mathrm{T}}\right)^{\mathrm{C}}\right|>\left|\operatorname{der}(\bigcup G)^{\mathrm{C}}\right|$. This is because the nullable variables that do not originate in the root transform, nullables $(U)(D)$, have an additional null value with respect to their corresponding originating variable, $\exists(u, x) \in \operatorname{originals}(U)(D)\left(\left|U_{u}\right|=\left|U_{x}\right|+1\right)$. So the incremented valencies lengthen the geometric average diagonal of the nullable transform, $y^{1 / p}$.

As described in section 'Summation aligned decomposition inducers', above, part of the formal alignment of the decomposition, $\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)$, consists of the pure formal alignment of the skeletal reduction, $\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right) \geq$ $\operatorname{algn}\left(A^{\mathrm{X}} * D^{\prime \mathrm{T}}\right)>0$ where $D^{\prime} \in \operatorname{reductions}(A, D)$, which is such that skeletal $(A *$ $D^{\prime \mathrm{T}}$ ). In section 'Skeletal alignment', above, it is shown that the alignment of a uniform full regular skeleton histogram is minimised for a given size, such that the counts are at least one, when the regular skeleton tree is a binary tree. That is, the pure formal alignment of the skeletal reduction, $\operatorname{algn}\left(A^{\mathrm{X}} * D^{\prime \mathrm{T}}\right)$, is least when bi-valent, $d=2$. Thus the shorter diagonals, $d=w^{1 / m}$, of the maximisation of summed derived alignment valency density, tends to reduce the pure formal alignment of the skeletal reduction, if not the contingent formal alignment of the slices.

The fuds $G=$ fuds $(D)$ of a decomposition $D$ are individually non-overlapping, $G \subset \mathcal{F}_{\mathrm{n}}$ or $\forall F \in G(\neg \operatorname{overlap}(F))$, but there is nothing to prevent fuds from
overlapping with eachother, overlap $\left(F_{1} \cup F_{2}\right)$ where $F_{1}, F_{2} \in G$. However, as was noted above, a fud cannot appear more than once in any path of the decomposition because it has zero derived alignment when constrained to its child slice. Similarly, if a pair of highly overlapping fuds, $F_{1}, F_{2}$, are in the same path, then the latter derived alignment, $\operatorname{algn}\left(A * C_{2} * F_{2}^{\mathrm{T}}\right)$, tends to be lower than if it were not constrained to be in a descendant slice of the former, $A * C_{2} \subset A * C_{1}$, for example where $\left(C_{1}, F_{1}\right),\left(C_{2}, F_{2}\right) \in \operatorname{steps}($ contingents $(D))$. Therefore, maximisation of derived alignment tends to reduce overlapping between fuds on the same path, and so reduces the overall formal alignment, $\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)$. In the case of fuds in separate paths of the decomposition, overlap merely allows the representation of symmetries without increasing formal alignment, albeit with creation of duplicate or highly similar fuds. For example, $\operatorname{algn}\left(A * C_{1} * F^{\mathrm{T}}\right)+\operatorname{algn}\left(A * C_{2} * F^{\mathrm{T}}\right) \approx \operatorname{algn}\left(A *\left(C_{1}+C_{2}\right) * F^{\mathrm{T}}\right)$ where $\left(C_{1}, F\right),\left(C_{2}, F\right) \in \operatorname{cont}(D)$.

Insofar as the limited-models summed alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, adheres to the constraints of the limitedmodels idealising summation aligned fud decomposition inducer, $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime}$, the search set consists of substrate fud decompositions similar to idealising summation aligned decompositions, $\mathcal{D}_{\Sigma, \mathrm{k}}(A)$. The limited-models idealising summation aligned fud decomposition inducer, $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime}$, is derived from the content alignment idealising summation aligned inducer, $I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime}$, described in section 'Summation aligned decomposition inducers', above. An idealising substrate summation aligned decomposition $D \in \mathcal{D}_{U_{A}, V_{A}} \cap \mathcal{D}_{\Sigma, \mathrm{k}}(A)$ that is ideal, $A=A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}$, has no super idealising substrate summation aligned decomposition, $\forall E \in \mathcal{D}_{U_{A}, V_{A}} \cap \mathcal{D}_{\Sigma, \mathrm{k}}(A)(D \notin \operatorname{subtrees}(E))$. All of its sub idealising substrate summation aligned decompositions have lower content alignment, $\forall E \in \mathcal{D}_{U_{A}, V_{A}} \cap \mathcal{D}_{\Sigma, \mathrm{k}}(A)(E \in \operatorname{subtrees}(D) \Longrightarrow \operatorname{algnSum}(A, E)<$ $\operatorname{algnSum}(A, D))$. Therefore, the maximum idealising substrate summation aligned decompositions in the content idealising inducer, $I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime}$, are all ideal, $\forall D \in \operatorname{maxd}\left(I_{z, \mathrm{c}, \mathrm{D}, \Sigma, \mathrm{k}}^{\prime *}(A)\right)$ (ideal $\left(A, D^{\mathrm{T}}\right)$ ). The same reasoning applies to summed alignment valency-density, $\forall E \in \mathcal{D}_{U_{A}, V_{A}} \cap \mathcal{D}_{\Sigma, \mathrm{k}}(A)(E \in$ $\left.\operatorname{subtrees}(D) \Longrightarrow \operatorname{algnValDensSum}\left(U_{A}\right)(A, E)<\operatorname{algnValDensSum}\left(U_{A}\right)(A, D)\right)$. Thus the substrate fud decompositions of the maximum function of the summed alignment valency-density fud decomposition inducer, $\operatorname{maxd}\left(I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)\right) \subset$ $\mathcal{D}_{\mathrm{F}, \infty, U_{A}, V_{A}}$, tend to be ideal, even though the non-leaf fuds of the decompositions are not themselves ideal with respect to their slices. This is the case even though the summed alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is not subject to the intractabilities of the idealising inducers. In this way, the lost ideality of the tractable derived alignment
valency-density fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, compared to the tractable derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, can be restored to some extent.

This restoration of the ideality in the limited-models summed alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, tends to increase the component size cardinality relative entropy, entropyRelative $\left(A * D^{\mathrm{T}}, V_{A}^{\mathrm{C}} * D^{\mathrm{T}}\right)$ where $D \in \operatorname{maxd}\left(I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}(A)\right)$, in the case of non-singleton decompositions, $|\operatorname{nodes}(D)|>1$.

In section 'Likely histograms', it is conjectured that there exists an intermediate mid substrate transform $T_{\mathrm{m}} \in \mathcal{T}_{U_{A}, V_{A}}$ which is neither self nor unary, $T_{\mathrm{m}} \notin\left\{T_{\mathrm{s}}, T_{\mathrm{u}}\right\}$, where the formal is independent and the midisation entropy is minimised,

$$
T_{\mathrm{m}} \in \operatorname{mind}\left(\left\{\left(T, \operatorname{entropy}\left(A^{\mathrm{M}(T)}\right)\right): T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right\}\right)
$$

At the mid transform the formal tends to the abstract, $A^{\mathrm{X}} * T_{\mathrm{m}} \approx\left(A * T_{\mathrm{m}}\right)^{\mathrm{X}}$, and the mid component size cardinality relative entropy is small,

$$
\text { entropyRelative }\left(A * T_{\mathrm{m}}, V_{A}^{\mathrm{C}} * T_{\mathrm{m}}\right) \approx 0
$$

Section 'Transform alignment', goes on to conjecture that an approximation to the mid transform may also be obtained by a maximisation of the midisation pseudo-alignment,

$$
\begin{aligned}
& T_{\mathrm{m}} \in \operatorname{maxd}\left(\left\{\left(T, \operatorname{algn}(A)-\operatorname{algn}\left(A * T * T^{\dagger A}\right)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)\right):\right.\right. \\
& T\left.\left.\in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{x}} * T=\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}\right\}\right)
\end{aligned}
$$

Then it is shown that the midisation pseudo-alignment varies with the derived alignment valency-density,

$$
\operatorname{algn}(A)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)-\operatorname{algn}\left(A * T * T^{\dagger A}\right) \sim \operatorname{algn}(A * T) / w^{1 / m}
$$

where $m=|W|, w=\left|W^{\mathrm{C}}\right|$ and $W=\operatorname{der}(T)$. So the maximisation of the $d e-$ rived alignment valency-density in the derived alignment valency-density inducer, $I_{z, \mathrm{ad}, \mathrm{fx}}^{\prime}$, tends to formal-abstract equality, $A^{\mathrm{X}} * T_{\mathrm{m}} \approx\left(A * T_{\mathrm{m}}\right)^{\mathrm{x}}$, allowing lifting and increasing the inducer correlation. Similarly, the maximisation of the summed derived alignment valency density, algnValDensSum $\left(U_{A}\right)\left(A, D^{\mathrm{D}}\right)$, in the limited-models summed alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, tends to formal-abstract equality in each slice, $(A *$ $C)^{\mathrm{X}} * F^{\mathrm{T}} \approx\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{X}}$ where $(C, F) \in \operatorname{cont}(D)$.

Section 'Likely histograms' goes on to show that the subsequent minimisation of the idealisation entropy, where the mid idealisation is integral, $A * T_{\mathrm{m}} * T_{\mathrm{m}}^{\dagger A} \in \mathcal{A}_{\mathrm{i}}$, tends to increase the mid component size cardinality relative entropy,

$$
\text { entropyRelative }\left(A * T_{\mathrm{m}}, V_{A}^{\mathrm{C}} * T_{\mathrm{m}}\right) \sim-\operatorname{entropy}\left(A * T_{\mathrm{m}} * T_{\mathrm{m}}^{\dagger A}\right)
$$

In section 'Transform alignment', it is conjectured that subsequent maximisation of the idealisation alignment also tends to increase the relative entropy,

$$
\text { entropyRelative }\left(A * T_{\mathrm{m}}, V_{A}^{\mathrm{C}} * T_{\mathrm{m}}\right) \sim \operatorname{algn}\left(A * T_{\mathrm{m}} * T_{\mathrm{m}}^{\dagger A}\right)
$$

Let $L \in \operatorname{paths}\left(\mathcal{D}_{\Sigma, \mathrm{k}}(A)\right)$ be a path of idealising summation aligned decompositions of histogram $A$ such that (i) each decomposition is an immediate super-decomposition of the previous decomposition, $\forall i \in\{2 \ldots l\}\left(L_{i-1} \in\right.$ $\operatorname{subtrees}\left(L_{i}\right) \wedge\left|\operatorname{nodes}\left(L_{i-1}\right)\right|=\left|\operatorname{nodes}\left(L_{i}\right)\right|-1$, where $l=|L|$, and (ii) the last decomposition is ideal, $A * L_{l}^{\mathrm{T}} * L_{l}^{\mathrm{T} \dagger} \neq A$. In section 'Decomposition alignment', above, it is shown that the idealisation alignment increases along the path,

$$
\forall i \in\{2 \ldots l\}\left(\operatorname{algn}\left(A * L_{i}^{\mathrm{T}} * L_{i}^{\mathrm{T} \dagger A}\right)>\operatorname{algn}\left(A * L_{i-1}^{\mathrm{T}} * L_{i-1}^{\mathrm{T} \dagger A}\right)\right)
$$

Consider the case where (i) the root transform is the mid transform, $L_{1}=$ $\left\{\left(\left(\emptyset, T_{\mathrm{m}}\right), \emptyset\right)\right\}$, and (ii) the idealisations along the path are all integral, $\forall i \in$ $\{1 \ldots l\}\left(A * L_{i}^{\mathrm{T}} * L_{i}^{\mathrm{T} \dagger A} \in \mathcal{A}_{\mathrm{i}}\right)$. In this case the relative entropy also increases along the path,
$\forall i \in\{2 \ldots l\}$

$$
\text { (entropyRelative } \left.\left(A * L_{i}^{\mathrm{T}}, V_{A}^{\mathrm{C}} * L_{i}^{\mathrm{T}}\right)>\operatorname{entropyRelative}\left(A * L_{i-1}^{\mathrm{T}}, V_{A}^{\mathrm{C}} * L_{i-1}^{\mathrm{T}}\right)\right)
$$

The first decomposition, $L_{1}$, which is a sub-decomposition of all subsequent, has the least relative entropy, entropyRelative $\left(A * L_{1}^{\mathrm{T}}, V_{A}^{\mathrm{C}} * L_{1}^{\mathrm{T}}\right) \approx 0$. The last decomposition, $L_{l}$, which is a super-decomposition of all previous, has the greatest relative entropy, entropyRelative $\left(A * L_{l}^{\mathrm{T}}, V_{A}^{\mathrm{C}} * L_{l}^{\mathrm{T}}\right)>0$.

That is, an idealising summation aligned decomposition $D \in \mathcal{D}_{\Sigma, \mathrm{k}}(A)$ that (i) is ideal, $A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}=A$, and (ii) is rooted in the mid transform, $D=\left\{\left(\left(\emptyset, T_{\mathrm{m}}\right), \cdot\right)\right\}$, tends to increase relative entropy as the cardinality of decomposition nodes increases,

$$
\text { entropyRelative }\left(A * D^{\mathrm{T}}, V_{A}^{\mathrm{C}} * D^{\mathrm{T}}\right) \sim|\operatorname{nodes}(D)|
$$

In the case where each transform is the mid transform for the component,

$$
\begin{aligned}
& \forall(C, T) \in \operatorname{cont}(D)\left(T \in \operatorname { m i n d } \left(\left\{\left(T^{\prime}, \text { entropy }\left((A * C)^{\mathrm{M}\left(T^{\prime}\right)}\right)\right):\right.\right.\right. \\
& \left.\left.\left.\qquad T^{\prime} \in \mathcal{T}_{U_{A}, V_{A}},(A * C)^{\mathrm{x}} * T^{\prime}=\left((A * C)^{\mathrm{x}} * T^{\prime}\right)^{\mathrm{x}}\right\}\right)\right)
\end{aligned}
$$

then each non-leaf decomposition node $((\cdot, T), F) \in \operatorname{nodes}(D)$, where $F \neq \emptyset$, forms a child decomposition $E=\{((\emptyset, T), F)\}$ in slice $A * C$ which is rooted in the slice mid transform, $T$, so that the slice formal approximates to the slice abstract, $(A * C)^{\mathrm{X}} * T \approx(A * C * T)^{\mathrm{X}}$, but the child decomposition relative entropy, entropyRelative $\left(A * C * E^{\mathrm{T}}, V_{A}^{\mathrm{C}} * E^{\mathrm{T}}\right)$, is not necessarily small.

Therefore, insofar as the search set of the tractable limited-models summed alignment valency-density fud decomposition inducer,

$$
\operatorname{dom}\left(I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)\right) \subset \mathcal{D}_{\mathrm{F}, \infty, U_{A}, V_{A}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right)
$$

consists of substrate fud decompositions similar to idealising summation aligned decompositions, $\mathcal{D}_{\Sigma, \mathrm{k}}(A)$, the component size cardinality relative entropy of a maximal model may be expected to be (a) greater than that of the corresponding model in the tractable derived alignment valency-density fud inducer, $I_{z, \mathrm{da}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$,

$$
\text { entropyRelative }\left(A * D^{\mathrm{T}}, V_{A}^{\mathrm{C}} * D^{\mathrm{T}}\right)>\operatorname{entropyRelative}\left(A * F_{\mathrm{ad}}^{\mathrm{T}}, V_{A}^{\mathrm{C}} * F_{\mathrm{ad}}^{\mathrm{T}}\right)
$$

where $D \in \operatorname{maxd}\left(I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)\right)$ and $F_{\mathrm{ad}} \in \operatorname{maxd}\left(I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}(A)\right)$, and (b) comparable to that of the corresponding model in the tractable derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$,

$$
\text { entropyRelative }\left(A * D^{\mathrm{T}}, V_{A}^{\mathrm{C}} * D^{\mathrm{T}}\right) \approx \operatorname{entropyRelative}\left(A * F_{\mathrm{a}}^{\mathrm{T}}, V_{A}^{\mathrm{C}} * F_{\mathrm{a}}^{\mathrm{T}}\right)
$$

where $F_{\mathrm{a}} \in \operatorname{maxd}\left(I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)\right)$.
Note that, while the idealisations of the sub-decompositions are not necessarily integral, at least the decomposition itself is generally ideal, and therefore integral, $A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}=A \in \mathcal{A}_{\mathrm{i}}$.

That is, the relative entropy lost by maximisation of midisation alignment in the fuds can be restored to some extent by subsequent maximisation of idealisation alignment in the decomposition.

Insofar as the limited-models summed alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, adheres to the constraints of the limitedmodels derived alignment valency-density fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, the alignment bounded lifted iso-transform error of the fuds of the search set substrate fud decompositions is reduced. The limited-models derived alignment valency-density fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is derived from the derived alignment valency-density inducer, $I_{z, \mathrm{ad}, \mathrm{fx}}^{\prime}$, described in section 'Intractable literal substrate model inclusion', above. There it is conjectured that the
valency capacity tends to increase the correlation of the maximum function of the derived alignment valency-density inducer, maxr $\circ I_{z, \mathrm{da}, \mathrm{fx}}^{\prime *}$, to the alignment-bounded lifted iso-transform space ideal transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}^{\prime}$, and thence transitively to increase the inducer correlation with the alignment-bounded iso-transform space ideal transform maximum function, maxr $\circ X_{z, \mathrm{x}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}$. Although the sizes and derived alignments of the slices decrease along the paths of the substrate fud decompositions of the maximum function of the summed alignment valency-density decomposition inducer, $\operatorname{maxd}\left(I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}(A)\right) \subset \mathcal{D}_{\mathrm{F}, \infty, U_{A}, V_{A}}$, the alignmentbounded lifted iso-transform error of the slice fuds may be conjectured to be reduced nonetheless. Therefore the nullable transform, $D^{\mathrm{T}}$ where $D \in$ $\operatorname{maxd}\left(I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{*}(A)\right)$, may also have lower alignment-bounded lifted isotransform error. Thus conjecture that the valency capacity tends to increase the inducer correlation of the summed alignment valency-density fud decomposition inducer, $I_{z, \mathrm{~S}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, with the alignment-bounded iso-transform space ideal transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{f}, \mathrm{j}}$.

The limited-models summed alignment valency-density substrate aligned non overlapping infinite-layer fud decomposition inducer, $I_{z, \mathrm{~S}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is tractable in all respects.

Conjecture that the summed alignment valency-density decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is positively correlated with the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}\right) \geq 0\right)
$$

but that the correlation is lower than that for the limited-models idealising fud decomposition inducer, $I_{z, \mathrm{c}, \mathrm{D}, \mathrm{F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime}$,

$$
\begin{aligned}
& \forall z \in \mathbf{N}_{>0} \\
& \quad\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{c}, \mathrm{D}, \mathrm{~F}, \infty, \Sigma, \mathrm{k}, \mathrm{q}}^{\prime}\right) \geq\right. \\
& \left.\quad \operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime}, \operatorname{maxr} \circ I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}\right)\right)
\end{aligned}
$$

However, the correlation is higher than that for the derived alignment valencydensity fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$,

```
\(\forall z \in \mathbf{N}_{>0}\)
    \(\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}\right) \leq\right.\)
                        \(\left.\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}\right)\right)\)
```

This is because (i) the application of the fud decomposition inducer is a superset of that of the fud inducer, $\left.\{(\{(\emptyset, F), \emptyset)\}, a):(F, a) \in I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}(A)\right\} \subset$ $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}(A)$, and (ii) super-decompositions must have higher summed alignment valency-density, $\forall E \in \operatorname{dom}\left(I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)\right)(D \in \operatorname{subtrees}(E) \Longrightarrow$ $\left.I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}(A)(E)>I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)(D)\right)$ where $D=\{((\emptyset, F), \emptyset)\}$ and $F \in \operatorname{dom}\left(I_{z, \mathrm{~d}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)\right)$. Therefore, in practice it is only necessary consider two tractable inducers, (i) the derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, and (ii) the summed alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$.

It is not obvious whether the summed alignment valency-density decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, has a higher or lower inducer correlation, $\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}\right)$, than the derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}, \operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}\right)$.

### 4.22 Practicable alignment-bounding

As it is defined above the summed alignment valency-density aligned fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is a computer that lacks explicit definition of (i) the limited-models constraints, $\mathcal{F}_{\mathrm{q}}$, (ii) the finite representations of the substrate models and their traversal, or (iii) the alignmenter, $I_{\mathrm{a}}$, or real approxer, $I_{\approx \mathbf{R}}$. The following section, 'Substrate models computation', considers explicit definitions so that it can be determined whether an implementation of the tractable inducer can be shown to be practicable given particular computation time and space resources.

If it is the case that the computation resources are insufficient, section 'Optimisation' then goes on to consider practicable inducers and the constraints necessary to implement them. Consideration is given to the effects of the additional constraints on the correlation of the maximum function between the practicable inducer and its corresponding tractable inducer.

The theoretic optimisation definitions are then given an explicit example implementation in the next section, 'Implementation'. There the computation definition is less elegant, but more practical, because of (i) explicit recursion, (ii) defined ordering, (iii) caching of temporary values and structures, and (iv) the assignment of variable references or identifiers to replace partition variables.

### 4.22.1 Substrate models computation

The summed alignment valency-density aligned fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is defined in section 'Tractable decomposition inducers', above, given non-independent substrate histogram $A \in \mathcal{A}_{z} \backslash\left\{A^{\mathrm{X}}\right\}$, as

$$
\begin{aligned}
& I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)= \\
& \quad\left\{\left(D, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algnValDensSum}\left(U_{A}\right)(A, D)\right)\right):\right. \\
& \quad D \in \mathcal{D}_{\mathrm{F}, \infty, U_{A}, V_{A}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathbf{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right), \\
& \left.\quad \forall(C, F) \in \operatorname{cont}(D)\left(\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)>0\right)\right\}
\end{aligned}
$$

where $\operatorname{cont}(D):=\operatorname{elements}(\operatorname{contingents}(D))$ and the summed derived alignment valency density, algnValDensSum $(U) \in \mathcal{A} \times \mathcal{D}_{\mathrm{F}} \rightarrow \mathbf{R}$, is defined

$$
\begin{aligned}
& \operatorname{algnValDensSum}(U)(A, D):= \\
& \qquad \sum\left(\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / \operatorname{cvl}(F):(C, F) \in \operatorname{cont}(D)\right)
\end{aligned}
$$

where the derived valency capacity is $\operatorname{cvl}(F):=\left(w^{1 / m}: W=\operatorname{der}(F)\right.$, w $=$ $\left.\left|W^{\mathrm{C}}\right|, m=|W|\right)$. The cardinality of the substrate models, $\mathcal{D}_{\mathrm{F}, \infty, U_{A}, V_{A}} \cap$ $\operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right)$, has tractable time and space complexities, but may yet be impracticable.

The derived alignment valency-density non-overlapping fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is defined above as

$$
\begin{aligned}
& I_{z, \mathrm{ad}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)= \\
& \quad\left\{\left(F, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}\left(A * F^{\mathrm{T}}\right) / \operatorname{cvl}(F)\right)\right): F \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right\}
\end{aligned}
$$

The fuds of the decompositions of the fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, are the substrate fuds of the derived alignment valency-density non-overlapping fud inducer, $I_{z, \text { ad,F }, \infty, \mathrm{n}, \mathrm{q}}^{\prime}, \bigcup\left\{\right.$ fuds $\left.(D): D \in \mathcal{D}_{\mathrm{F}, \infty, U_{A}, V_{A}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right)\right\}=$ $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$.

Consider various ways in which the limited-models non-overlapping infinitelayer substrate fuds, $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$, may be constructed. The infinitelayer substrate fud set $\mathcal{F}_{\infty, U, V} \subset \mathcal{F}_{U, \mathrm{P}}$ is defined as

$$
\mathcal{F}_{\infty, U, V}=\{F: F \subseteq \operatorname{powinf}(U)(V, \emptyset), \quad \operatorname{und}(F) \subseteq V\}
$$

where $U$ is the infinite implied system, $U=\operatorname{implied}($ filter $(V, U))$, and the infinite power fud powinf $(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{F}_{U, \mathrm{P}} \rightarrow \mathcal{F}_{U, \mathrm{P}}$ is defined without
termination

$$
\begin{aligned}
& \operatorname{powinf}(U)(V, F):=F \cup G \cup \operatorname{powinf}(U)(V, F \cup G): \\
& \quad G=\left\{P^{\mathrm{T}}: K \subseteq \operatorname{vars}(F) \cup V, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}
\end{aligned}
$$

A tree of non-empty infinite-layer substrate fuds may be constructed such that successive fuds in a path have incremented layer cardinality. That is, the fuds are constructed from bottom-up. Define the infinite partition infinite-layer fud tree $\operatorname{tfi}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{F}_{U, \mathrm{P}} \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}}\right)$ as

$$
\begin{aligned}
& \operatorname{tfi}(U)(V, F):= \\
& \qquad \begin{array}{l}
\{(F \cup G, \operatorname{tfi}(U)(V, F \cup G)): \\
\qquad G \subseteq\left\{P^{\mathrm{T}}: K \subseteq \operatorname{vars}(F) \cup V,(\operatorname{der}(F) \neq \emptyset \Longrightarrow K \cap \operatorname{der}(F) \neq \emptyset),\right. \\
\\
\left.\quad P \neq \mathrm{B}\left(K^{\mathrm{CS}}\right)\right\},
\end{array}
\end{aligned}
$$

Let $\mathrm{tfi}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}}\right)$ be defined $\operatorname{tfi}(U)(V)=\operatorname{tfi}(U)(V, \emptyset)$.

The fuds of the tree are the infinite-layer substrate fuds

$$
\mathcal{F}_{\infty, U, V}=\operatorname{elements}(\mathrm{tfi}(U)(V)) \cup\{\emptyset\}
$$

In this construction the fuds are cumulative along the paths. That is, successive fuds are proper supersets,

$$
\forall M \in \operatorname{subpaths}(\operatorname{tfi}(U)(V)) \forall i \in\{2 \ldots|M|\}\left(M_{i-1} \subset M_{i}\right)
$$

Moreover, the new partition transforms, $P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)$ where $K \subseteq \operatorname{vars}(F) \cup V$, that are added to the next fud of a step, are constrained such that at least one underlying variable is in the highest layer of the previous fud, $\exists x \in$ $K(x \in \operatorname{der}(F))$. Thus

$$
\forall M \in \operatorname{subpaths}(\operatorname{tfi}(U)(V)) \forall i \in\{1 \ldots|M|\}\left(\operatorname{layer}\left(M_{i}, \operatorname{der}\left(M_{i}\right)\right)=i\right)
$$

A fud, $F \in$ elements $(\operatorname{tfi}(U)(V))$, may appear more than once in the tree if there are multiple paths to its construction,

$$
\left|\left\{M: M \in \operatorname{subpaths}(\mathrm{tfi}(U)(V)), M_{|M|}=F\right\}\right| \geq 1
$$

For convenience, define the sets of partition variables in the next layer tuples $\in$ $\mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{F}_{U, \mathrm{P}^{*}} \rightarrow \mathrm{P}\left(\mathrm{P}\left(\mathcal{V}_{U}\right)\right)$ as

$$
\operatorname{tuples}(V, F):=\{K: K \subseteq \operatorname{vars}(F) \cup V,(\operatorname{der}(F) \neq \emptyset \Longrightarrow K \cap \operatorname{der}(F) \neq \emptyset)\}
$$

The sets of partition variables, $K \in \operatorname{tuples}(V, F)$, will be called tuples in the context of practicable inducers. Note that here a tuple is not an ordered list, although (i) in some implementations tuples have limited cardinalities, and (ii) when ordered they may be used to index an array histogram representation.

The partition infinite-layer fud tree may then be defined more succinctly in terms of tuples as

$$
\begin{aligned}
& \operatorname{tfi}(U)(V, F):= \\
& \qquad \begin{aligned}
&\{(F \cup G, \operatorname{tfi}(U)(V, F \cup G)): \\
& G \subseteq\left\{P^{\mathrm{T}}: K \in \operatorname{tuples}(V, F), P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}, \\
&G \neq \emptyset\}
\end{aligned}
\end{aligned}
$$

The set of next layer fuds, $\left\{G: G \subseteq\left\{P^{\mathrm{T}}: K \in \operatorname{tuples}(V, F), P \in\right.\right.$ $\left.\left.\mathrm{B}\left(K^{\mathrm{CS}}\right)\right\}, G \neq \emptyset\right\} \subset \mathcal{F}_{U, \mathrm{P}}$ may be defined in terms of a set of partitionsets, $\mathrm{P}\left(\bigcup\left\{\mathrm{B}\left(K^{\mathrm{CS}}\right): K \in \operatorname{tuples}(V, F)\right\}\right) \backslash\{\emptyset\}$. For the first layer, $F=\emptyset$, the set of next layer fuds is the set of fuds of partition transforms of the non-empty partition-sets of the substrate partition-sets set,

$$
\left\{\left\{P^{\mathrm{T}}: P \in N\right\}: N \in \mathcal{N}_{U, V}, N \neq \emptyset\right\} \subset \mathcal{F}_{U, \mathrm{P}}
$$

which has cardinality $\left|\mathcal{N}_{U, V}\right|-1$. The substrate partition-sets set is defined

$$
\mathcal{N}_{U, V}=\mathrm{P}\left(\left\{P: K \subseteq V, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}\right)
$$

The cardinality of the substrate partition-sets set is

$$
\left|\mathcal{N}_{U, V}\right|=2^{c}: c=\sum_{K \subseteq V} \operatorname{bell}\left(\left|K^{\mathrm{CS}}\right|\right)
$$

In the case of regular variables $V$, having valency $\{d\}=\left\{\left|U_{w}\right|: w \in V\right\}$ and dimension $n=|V|$, the cardinality is

$$
\left|\mathcal{N}_{U, V}\right|=2^{c}: c=\sum_{k \in\{0 \ldots n\}}\binom{n}{k} \operatorname{bell}\left(d^{k}\right)
$$

For higher layers, $F \neq \emptyset$, the set of next layer fuds corresponds to the intersecting substrate partition-sets set,

$$
\left\{\left\{P^{\mathrm{T}}: P \in N\right\}: N \in \mathcal{N}_{U, W, X}\right\} \subset \mathcal{F}_{U, \mathrm{P}}
$$

where $W=\operatorname{vars}(F) \cup V$ and $X=\operatorname{der}(F)$. Note that the partition infinitelayer fud tree, $\mathrm{tfi}(U)(V)$, cannot contain non-empty fuds having empty derived variables, $F \neq \emptyset \Longrightarrow \operatorname{der}(F) \neq \emptyset$. The cardinality of the set of higher layer fuds is $\left|\mathcal{N}_{U, W, X}\right|$. The intersecting substrate partition-sets set, $\mathcal{N}_{U, V, X}$, is defined,

$$
\mathcal{N}_{U, V, X}=\mathrm{P}\left(\left\{P: K \subseteq V, K \cap X \neq \emptyset, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}\right)
$$

The cardinality of the intersecting substrate partition-sets set is

$$
\left|\mathcal{N}_{U, W, X}\right|=2^{c}: c=\sum\left(\operatorname{bell}\left(\left|K^{\mathrm{CS}}\right|\right): K \subseteq W, K \cap X \neq \emptyset\right)
$$

In the case of regular substrate variables $V$ and regular fud variables $\operatorname{vars}(F) \backslash$ $V$, having valency $d$, dimension $q=|W|$ and intersecting dimension $x=|X|$, the cardinality is

$$
\left|\mathcal{N}_{U, W, X}\right|=2^{c}: c=\sum_{k \in\{1 \ldots q\}}\left(\binom{q}{k}-\binom{q-x}{k}\right) \operatorname{bell}\left(d^{k}\right)
$$

where the binomial coefficient is defined such that $\forall a, b \in \mathbf{N}(b>a \Longrightarrow$ $\left.\binom{a}{b}=0\right)$.

The infinite non-overlapping infinite-layer substrate fuds, $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}}$, may be similarly constructed by selecting only those fuds which are nonoverlapping,

$$
\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}}=\{F: F \in \operatorname{elements}(\operatorname{tfi}(U)(V)), \neg \operatorname{overlap}(F)\}
$$

Now consider the construction of the finite limited-models non-overlapping infinite-layer substrate fuds, $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$, with particular definitions of the limited-models constraints. The limited-models subset of the functional definition sets $\mathcal{F}_{\mathrm{q}}=\mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{d}} \cap \mathcal{F}_{\mathrm{h}} \cap \mathcal{F}_{\mathrm{b}} \subset \mathcal{F}$ represents the class of subsets of the functional definition sets that are (i) limited-underlying, $\mathcal{F}_{\mathrm{u}}$, (ii) limitedderived, $\mathcal{F}_{\mathrm{d}}$, (iii) limited-layer, $\mathcal{F}_{\mathrm{h}}$ and (iv) limited-breadth, $\mathcal{F}_{\mathrm{b}}$. Here the limited-models constraints are defined explicitly.

In order to be computable, the infinite partition infinite-layer fud tree, $\operatorname{tfi}(U)(V) \in \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}}\right)$, may be made finite by limiting the path length. Define the maximum layer limit as $\operatorname{lmax} \in \mathbf{N}_{>0}$. Define the finite limited-layer
partition infinite-layer fud tree $\operatorname{tfih}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{F}_{U, \mathrm{P}} \times \mathbf{N} \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}}\right)$ as

$$
\begin{aligned}
& \operatorname{tfih}(U)(V, F, h):= \\
& \qquad \begin{aligned}
\{(F \cup G, & \operatorname{tfih}(U)(V, F \cup G, h+1)): \\
& G \subseteq\left\{P^{\mathrm{T}}: K \in \operatorname{tuples}(V, F), P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}, \\
& G \neq \emptyset, \\
& h \leq \operatorname{lmax}\}
\end{aligned}
\end{aligned}
$$

Let $\operatorname{tfih}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}}\right)$ be defined $\operatorname{tfih}(U)(V)=\operatorname{tfih}(U)(V, \emptyset, 1)$.
The layer cardinality increments at each step in the tree's path, so the limited path length constraint, $h \leq \operatorname{lmax}$, could equally well be defined as a limited-layer constraint, layer $(F \cup G$, $\operatorname{der}(F \cup G)) \leq$ lmax, although this computation would be longer.

The fuds of the tree are the limited-layer infinite-layer substrate fuds,

$$
\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{h}}=\operatorname{elements}(\operatorname{tfih}(U)(V)) \cup\{\emptyset\}
$$

Define the finite limited-layer limited-underlying-volume limited-breadth partition infinite-layer fud tree $\operatorname{tfiubh}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{F}_{U, \mathrm{P}} \times \mathbf{N} \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}}\right)$ as

$$
\begin{aligned}
& \text { tfiubh }(U)(V, F, h):= \\
& \qquad \begin{array}{l}
\{(F \cup G, \operatorname{tfiubh}(U)(V, F \cup G, h+1)): \\
\\
\quad G \subseteq\left\{P^{\mathrm{T}}: K \in \operatorname{tuples}(V, F),\left|K^{\mathrm{C}}\right| \leq \operatorname{xmax}, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}, \\
\\
1 \leq|G| \leq \operatorname{bmax}, \\
\\
h \leq \operatorname{lmax}\}
\end{array}
\end{aligned}
$$

where the maximum underlying volume limit is $\mathrm{xmax} \in \mathbf{N}_{>0}$ and the maximum breadth limit is bmax $\in \mathbf{N}_{>0}$. Let $\operatorname{tfiubh}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}}\right)$ be defined $\operatorname{tfiubh}(U)(V)=\operatorname{tfiubh}(U)(V, \emptyset, 1)$.

The finite set of limited-models non-overlapping infinite-layer substrate fuds is

$$
\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}=\{F: F \in \operatorname{elements}(\operatorname{tfiubh}(U)(V)), \operatorname{nd}(F)\}
$$

where $\operatorname{nd} \in \mathcal{F} \rightarrow \mathbf{B}$ is defined as $\operatorname{nd}(F)=\neg \operatorname{overlap}(F) \wedge\left(\left|W^{\mathrm{C}}\right| \leq\right.$ wmax : $W=\operatorname{der}(F))$, and the maximum derived volume limit is $\operatorname{wax} \in \mathbf{N}_{>0}$.

Both the non-overlapping and limited-derived constraints must be tested after the construction of the limited-layer limited-underlying-volume limitedbreadth partition infinite-layer fud tree, tfiubh $(U)(V)$. In order to be selected only the last fud in a sublist $M \in \operatorname{subpaths}(\operatorname{tfiubh}(U)(V))$ need be non-overlapping and limited-derived, $\forall i \in\{1 \ldots|M|\}\left(M_{i} \in \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}}\right)$ and $M_{|M|} \in \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{d}}$. That is, an ancestor fud, $M_{i}$ where $i<|M|$, need not be non-overlapping nor limited-derived, so these constraints cannot be applied when constructing the tree in $\operatorname{tfiubh}(U)(V)$.

As in the case of the partition infinite-layer fud tree above, a limited-layer limited-underlying-volume limited-breadth partition infinite-layer fud tree fud $F \in$ elements $(\operatorname{tfiubh}(U)(V))$ may appear more than once in the tree if there are multiple paths to its construction,

$$
\left|\left\{M: M \in \operatorname{subpaths}(\operatorname{tfiubh}(U)(V)), M_{|M|}=F\right\}\right| \geq 1
$$

The cardinality of the finite set of limited-models non-overlapping subpaths in the tree must be greater than or equal to the cardinality of limited-models non-overlapping infinite-layer substrate fuds

$$
\left|\left\{M: M \in \operatorname{subpaths}(\operatorname{tfiubh}(U)(V)), \operatorname{nd}\left(M_{|M|}\right)\right\}\right| \geq\left|\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right|
$$

A finite computer $I_{\text {tfinq }} \in$ computers can be defined such that its application to the substrate variables, $V$, constructs the limited-models non-overlapping infinite-layer substrate fuds, $I_{\text {tfinq }}^{*}(V)=\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$, by traversing the finite limited-layer limited-underlying-volume limited-breadth partition infinitelayer fud tree, tfiubh $(U)(V)$. Let the finite traversal enumeration $P \in$ enums(subpaths $(\operatorname{tfiubh}(U)(V)))$ be such that the paths of the tree are searched in sequence, $\forall L, M \in \operatorname{subpaths}(\operatorname{tfiubh}(U)(V))\left(L \subseteq M \Longrightarrow P_{L} \leq P_{M}\right)$. An example of such an enumeration, $P$, would be a breadth-first traversal of the tree, $\forall i \in\{1 \ldots \operatorname{lmax}-1\}(\operatorname{maxr}(\{(M, j):(M, j) \in P,|M|=i\})<$ $\operatorname{minr}(\{(M, j):(M, j) \in P,|M|=i+1\}))$. Then the finite search list is $N=\left\{\left(j, M_{|M|}\right):(M, j) \in P\right\} \in \mathcal{L}\left(\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}\right)$. The finite set of limited-models non-overlapping infinite-layer substrate fuds is obtained by filtering the search list, $\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}=\operatorname{set}($ filter $(\mathrm{nd}, N)$ ). Thus the cardinality of the searched list is greater than or equal to the cardinality of the set of limited-models non-overlapping nodes which in turn is greater than or equal to the cardinality of limited-models non-overlapping infinite-layer substrate fuds, $|N| \geq|\operatorname{filter}(\mathrm{nd}, N)| \geq\left|\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right|$. The computation time is therefore greater than the cardinality of the searched list, $I_{\mathrm{tfinq}}^{\mathrm{t}}(V)>|N|$. Strictly speaking, the limited-derived non-overlapping filtering can take place during the construction of the last layer, lmax, instead of subsequent to fud
construction, because there are no descendant fuds. So cumulative computation space is only required for the fuds in all but the last layer. If the filtering takes place after searching, however, then the computation space is also greater than the cardinality of the searched list, $I_{\text {tfinq }}^{\mathrm{s}}(V)>|N|$. Also note that children fuds need not copy the transforms of their parents, so the space required for a fud and a descendant fud is less than the sum of the spaces.

The set of next layer fuds, $\left\{G: G \subseteq\left\{P^{\mathrm{T}}: K \in \operatorname{tuples}(V, F),\left|K^{\mathrm{C}}\right| \leq\right.\right.$ xmax, $\left.\left.P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}, 1 \leq|G| \leq \operatorname{bmax}\right\} \subset \mathcal{F}_{U, \mathrm{P}}$ may be defined in terms of a set of partition-sets. For the first layer, $F=\emptyset$, the set of next layer fuds is the set of fuds of partition transforms of the non-empty partition-sets of the intersection of the limited-underlying-volume substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{xmax}}$, and the limited-breadth substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{bmax}}$,

$$
\left\{\left\{P^{\mathrm{T}}: P \in N\right\}: N \in \mathcal{N}_{U, V, \mathrm{xmax}} \cap \mathcal{N}_{U, V, \mathrm{bmax}}, N \neq \emptyset\right\} \subset \mathcal{F}_{U, \mathrm{P}}
$$

which has cardinality $\left|\mathcal{N}_{U, V, \mathrm{xmax}} \cap \mathcal{N}_{U, V, \text { bmax }}\right|-1$. The limited-underlyingvolume substrate partition-sets set is defined,

$$
\mathcal{N}_{U, V, \mathrm{xmax}}=\mathrm{P}\left(\left\{P: K \subseteq V,\left|K^{\mathrm{CS}}\right| \leq \operatorname{xmax}, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}\right)
$$

The limited-breadth substrate partition-sets set is defined,

$$
\mathcal{N}_{U, V, \operatorname{bmax}}=\left\{N: N \in \mathcal{N}_{U, V},|N| \leq \operatorname{bmax}\right\}
$$

The cardinality of the intersection is

$$
\begin{aligned}
& \left|\mathcal{N}_{U, V, \mathrm{xmax}} \cap \mathcal{N}_{U, V, \mathrm{bmax}}\right|= \\
& \quad\left(\sum_{b \in\{0 \ldots \mathrm{bmax}\}}\binom{c}{b}\right): c=\sum\left(\operatorname{bell}\left(\left|K^{\mathrm{CS}}\right|\right): K \subseteq V,\left|K^{\mathrm{CS}}\right| \leq \operatorname{xmax}\right)
\end{aligned}
$$

In the case of pluri-valent regular variables $V$, having valency $d>1$ and dimension $n$, if the implied underlying-dimension limit, $\mathrm{kmax}=\ln \mathrm{xmax} / \ln d$, is integral, $\ln \mathrm{xmax} / \ln d \in \mathbf{N}$, then the cardinality is

$$
\begin{aligned}
& \left|\mathcal{N}_{U, V, \mathrm{xmax}} \cap \mathcal{N}_{U, V, \mathrm{bmax}}\right|= \\
& \left(\sum_{b \in\{0 \ldots \mathrm{bmax}\}}\binom{c}{b}\right): c=\sum_{k \in\{0 \ldots \mathrm{kmax}\}}\binom{n}{k} \operatorname{bell}\left(d^{k}\right) .
\end{aligned}
$$

For higher layers, $F \neq \emptyset$, the set of next layer fuds corresponds to the intersection of the intersecting substrate partition-sets set, $\mathcal{N}_{U, W, X}$, the limited-underlying-volume substrate partition-sets set, $\mathcal{N}_{U, W, \mathrm{xmax}}$, and the limitedbreadth substrate partition-sets set $\mathcal{N}_{U, W, \text { bmax }}$

$$
\left\{\left\{P^{\mathrm{T}}: P \in N\right\}: N \in \mathcal{N}_{U, W, X} \cap \mathcal{N}_{U, W, \mathrm{xmax}} \cap \mathcal{N}_{U, W, \mathrm{bmax}}\right\} \subset \mathcal{F}_{U, \mathrm{P}}
$$

where $W=\operatorname{vars}(F) \cup V$ and $X=\operatorname{der}(F)$. The cardinality of the set of higher layer fuds is $\left|\mathcal{N}_{U, W, X} \cap \mathcal{N}_{U, W, \mathrm{xmax}} \cap \mathcal{N}_{U, W, \text { bmax }}\right|$. The cardinality of the intersection is

$$
\begin{aligned}
& \left|\mathcal{N}_{U, W, X} \cap \mathcal{N}_{U, W, \mathrm{xmax}} \cap \mathcal{N}_{U, W, \mathrm{bmax}}\right|= \\
& \left(\sum_{b \in\{0 \ldots \mathrm{bmax}\}}\binom{c}{b}\right): \\
& \quad c=\sum\left(\operatorname{bell}\left(\left|K^{\mathrm{CS}}\right|\right): K \subseteq W, K \cap X \neq \emptyset,\left|K^{\mathrm{CS}}\right| \leq \operatorname{xmax}\right)
\end{aligned}
$$

In the case of regular substrate variables $V$ and regular fud variables $\operatorname{vars}(F) \backslash$ $V$, having valency $d$, dimension $q=|W|$ and intersecting dimension $x=$ $|X|$, such that the implied underlying-dimension limit is integral, $\mathrm{kmax}=$ $\ln \mathrm{xmax} / \ln d \in \mathbf{N}$, the cardinality is

$$
\begin{aligned}
& \left|\mathcal{N}_{U, W, X} \cap \mathcal{N}_{U, W, \mathrm{xmax}} \cap \mathcal{N}_{U, W, \mathrm{bmax}}\right|= \\
& \quad\left(\sum_{b \in\{0 \ldots \mathrm{bmax}\}}\binom{c}{b}\right): c=\sum_{k \in\{1 \ldots \mathrm{kmax}\}}\left(\binom{q}{k}-\binom{q-x}{k}\right) \operatorname{bell}\left(d^{k}\right)
\end{aligned}
$$

Consider the case where a limited-layer limited-underlying-volume limitedbreadth partition infinite-layer fud tree fud $F \in$ elements $(\operatorname{tfiubh}(U)(V))$ is such that (i) it has lmax layers, layer $(F, \operatorname{der}(F))=\operatorname{lmax}$, (ii) the first layer has breadth bmax - $n$, (iii) subsequent layers have breadth bmax, and (iv) the variables are regular, $\forall w \in \operatorname{vars}(F)\left(\left|U_{w}\right|=d\right)$. In this case the cardinality of the variables is $|\operatorname{vars}(F) \cup V|=\operatorname{lmax} \times$ bmax. The cardinality of the set of next layer fuds is

$$
\begin{aligned}
& \left|\mathcal{N}_{U, W, X} \cap \mathcal{N}_{U, W, \mathrm{xmax}} \cap \mathcal{N}_{U, W, \mathrm{bmax}}\right|= \\
& \quad\left(\sum_{b \in\{0 \ldots \mathrm{bmax}\}}\binom{c}{b}\right): \\
& \quad c=\sum_{k \in\{1 \ldots \mathrm{kmax}\}}\left(\binom{\operatorname{lmax} \times \operatorname{bmax}}{k}-\binom{(\operatorname{lmax}-1) \times \operatorname{bmax}}{k}\right) \operatorname{bell}\left(d^{k}\right)
\end{aligned}
$$

The cardinality of the selectable set, $c$, is therefore bounded

$$
c<(\operatorname{lmax} \times \operatorname{bmax})^{\mathrm{k} \max } \times \operatorname{bell}(\mathrm{xmax})
$$

This expression is dominated by the right-most term, bell(xmax), if $\operatorname{lmax} \times$ bmax $\leq$ xmax, because kmax $<$ xmax. The cardinality of the set of next layer fuds is also bounded,
$\left|\mathcal{N}_{U, W, X} \cap \mathcal{N}_{U, W, \mathrm{x} \max } \cap \mathcal{N}_{U, W, \mathrm{~b} \max }\right|<\left((\operatorname{lmax} \times \operatorname{bmax})^{\underline{\mathrm{kmax}}} \times \operatorname{bell}(\mathrm{xmax})\right)^{)^{\mathrm{bmax}}}$

In case where the maximum underlying volume equals the size, $\mathrm{xmax}=$ $z$, and the right-most term dominates, $\operatorname{lmax} \times \operatorname{bmax} \leq z$, the cardinality is comparable to $z^{z^{2}}$. Although finite and tractable, this cardinality may be impracticable if the computation time and space that it implies exceeds available resources.

In the case where the limited-layer limited-underlying-volume limited-breadth partition infinite-layer fud tree, $\operatorname{tfiubh}(U)(V)$, is additionally constrained such that the fuds have derived volume less than or equal to the maximum derived volume limit, wmax, then a subset of the limited-models nonoverlapping infinite-layer substrate fuds, $\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$, may be constructed. Define the limited-layer limited-derived-volume limited-underlyingvolume limited-breadth partition infinite-layer fud tree $\operatorname{tfiubhd}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times$ $\mathcal{F}_{U, \mathrm{P}} \times \mathbf{N} \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}}\right)$ as

$$
\begin{aligned}
& \text { tfiubhd }(U)(V, F, h):= \\
& \qquad \begin{array}{c}
\{(F \cup G, \operatorname{tfiubhd}(U)(V, F \cup G, h+1)): \\
\\
\quad G \subseteq\left\{P^{\mathrm{T}}: K \in \operatorname{tuples}(V, F),\left|K^{\mathrm{C}}\right| \leq \operatorname{xmax}, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}, \\
\\
1 \leq|G| \leq \operatorname{bmax}, \\
\\
W=\operatorname{der}(F \cup G),\left|W^{\mathrm{C}}\right| \leq \text { wmax } \\
\\
h \leq \operatorname{lmax}\}
\end{array}
\end{aligned}
$$

Again, let tfiubhd $(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}}\right)$ be defined tfiubhd $(U)(V)=$ tfiubhd $(U)(V, \emptyset, 1)$.

The limited-derived-volume constraint, $\left|W^{\mathrm{C}}\right| \leq$ wmax, is applied at every layer of the fud, so only a subset of the limited-models non-overlapping infinite-layer substrate fuds is searched

$$
\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}} \supseteq\{F: F \in \operatorname{elements}(\operatorname{tfiubhd}(U)(V)), \neg \operatorname{overlap}(F)\}
$$

For the first layer, $F=\emptyset$, the set of next layer fuds is the set of fuds of partition transforms of the non-empty partition-sets of the intersection of the limited-underlying-volume substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{xmax}}$, the limitedbreadth substrate partition-sets set, $\mathcal{N}_{U, V, b m a x}$, and the limited-derived-volume substrate partition-sets set, $\mathcal{N}_{U, V, \text { wmax }}$,

$$
\left\{\left\{P^{\mathrm{T}}: P \in N\right\}: N \in \mathcal{N}_{U, V, \mathrm{xmax}} \cap \mathcal{N}_{U, V, \mathrm{bmax}} \cap \mathcal{N}_{U, V, \mathrm{wmax}}, N \neq \emptyset\right\} \subset \mathcal{F}_{U, \mathrm{P}}
$$

which has cardinality $\left|\mathcal{N}_{U, V, \mathrm{xmax}} \cap \mathcal{N}_{U, V, \mathrm{bmax}} \cap \mathcal{N}_{U, V, \mathrm{wmax}}\right|-1$.

The computation of the cardinality of the set of fuds in the higher next layers requires that the set itself be computed, because the limited-derived-volume constraint depends on both the given $f u d, F$, and the next layer fud, $G$, for its determination. That is, in some cases the derived variables of the child fud intersect with the derived variables of the given fud, $|\operatorname{der}(F \cup G) \cap \operatorname{der}(F)| \geq 0$. However, the cardinality of the children fuds must be less than or equal to those of the limited-layer limited-underlying-volume limited-breadth partition infinite-layer fud tree, $\operatorname{tfiubh}(U)(V)$,

$$
\begin{array}{r}
\mid\left\{G: G \subseteq\left\{P^{\mathrm{T}}: K \in \operatorname{tuples}(V, F),\left|K^{\mathrm{C}}\right| \leq \operatorname{xmax}, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\},\right. \\
\left.1 \leq|G| \leq \operatorname{bmax}, W=\operatorname{der}(F \cup G),\left|W^{\mathrm{C}}\right| \leq \operatorname{wmax}\right\} \mid \\
\leq \mid\left\{G: G \subseteq\left\{P^{\mathrm{T}}: K \in \operatorname{tuples}(V, F),\left|K^{\mathrm{C}}\right| \leq \operatorname{xmax}, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\},\right. \\
1 \leq|G| \leq \operatorname{bmax}\} \mid
\end{array}
$$

The set of substrate infinite-layer fud decompositions $\mathcal{D}_{\mathrm{F}, \infty, U, V}$ is defined such that all of the fuds are infinite-layer substrate fuds and none can appear more than once in a path

$$
\begin{aligned}
& \mathcal{D}_{\mathrm{F}, \infty, U, V}=\left\{D: D \in \mathcal{D}_{\mathrm{F}, \mathrm{~d}}, \operatorname{fuds}(D) \subseteq \mathcal{F}_{\infty, U, V},\right. \\
& \quad \forall L \in \operatorname{paths}(D)(\operatorname{maxr}(\operatorname{count}(\{(F, i):(i,(\cdot, F)) \in L\}))=1)\}
\end{aligned}
$$

or equivalently,

$$
\begin{aligned}
& \mathcal{D}_{\mathrm{F}, \infty, U, V}= \\
& \quad\left\{D: D \in \mathcal{D}_{\mathrm{F}, \mathrm{~d}}, \text { fuds }(D) \subseteq \mathcal{F}_{\infty, U, V}, \forall L \in \operatorname{paths}(D)(|L|=|\operatorname{ran}(\operatorname{set}(L))|)\right\}
\end{aligned}
$$

The non-empty infinite-layer substrate fud decompositions of non-empty infinitelayer substrate fuds may be constructed by means of a tree of immediate super-decompositions. Define the infinite infinite-layer fud decomposition tree $\operatorname{tdfi}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{D}_{\mathrm{F}, \mathrm{d}} \rightarrow \operatorname{trees}\left(\mathcal{D}_{\mathrm{F}, \mathrm{d}}\right)$ as

$$
\begin{aligned}
& \operatorname{tdfi}(U)(V, D):= \\
&\{(E, \operatorname{tdfi}(U)(V, E)): \\
& Q=\operatorname{paths}(D), L \in Q, i \in\{1 \ldots|L|\}, \\
&(\cdot, F)=L_{i}, W=\operatorname{der}(F), S \in W^{\mathrm{CS}}, \\
& G \in \mathcal{F}_{\infty, U, V} \backslash\left(\operatorname{ran}\left(\operatorname{set}\left(L_{\{1 . . . i\}}\right)\right) \cup\{\emptyset\}\right), \\
& M=L_{\{1 \ldots i\}} \cup\{(i+1,(S, G))\}, \\
&\left.E=\operatorname{tree}\left(Q \backslash\left\{L_{\{1 \ldots i\}}\right\} \cup\{M\}\right), E \in \mathcal{D}_{\mathrm{F}, \mathrm{~d}}\right\}
\end{aligned}
$$

where $\operatorname{tdfi}(U)(V, \emptyset):=\left\{(E, \operatorname{tdfi}(U)(V, E)): G \in \mathcal{F}_{\infty, U, V} \backslash\{\emptyset\}, E=\{((\emptyset, G), \emptyset)\}\right\}$. Let $\operatorname{tdfi}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathcal{D}_{\mathrm{F}, \mathrm{d}}\right)$ be defined $\operatorname{tdfi}(U)(V)=\operatorname{tdfi}(U)(V, \emptyset)$.

The infinite infinite-layer fud decomposition tree is constrained to be a tree of immediate super-decompositions,

$$
\begin{aligned}
& \operatorname{tdfi}(U)(V, D)= \\
& \qquad \begin{aligned}
\{(E, \operatorname{tdfi}(U) & (V, E)): \\
& E \in \mathcal{D}_{\mathrm{F}, \mathrm{~d}}, \text { fuds }(E) \subseteq \mathcal{F}_{\infty, U, V} \backslash\{\emptyset\}, \\
& \forall L \in \operatorname{paths}(E)\left(L_{|L|} \notin \operatorname{set}\left(L_{\{1 \ldots|L|-1\}}\right)\right), \\
& D \in \operatorname{subtrees}(E),|\operatorname{nodes}(E) \backslash \operatorname{nodes}(D)|=1\}
\end{aligned}
\end{aligned}
$$

The decompositions of the tree are a subset of the infinite-layer substrate fud decompositions

$$
\mathcal{D}_{\mathrm{F}, \infty, U, V} \supset \operatorname{elements}(\operatorname{tdfi}(U)(V))
$$

The decompositions of the tree form a proper subset because the empty fud is excluded from the construction.

In this construction exactly one fud is added to the previous decomposition at each step. Thus the cardinality of the fuds equals the position in the path, $\forall L \in \operatorname{paths}(\operatorname{tdfi}(U)(V)) \forall i \in\{1 \ldots|L|\}\left(\left|f u d s\left(L_{i}\right)\right|=i\right)$.

A constructed decomposition, $D \in$ elements $(\operatorname{tdfi}(U)(V))$, may appear more than once in the tree if there are multiple paths to its construction, $\mid\{M$ : $\left.M \in \operatorname{subpaths}(\operatorname{tdfi}(U)(V)), M_{|M|}=D\right\} \mid \geq 1$, because some decompositions have multiple immediate sub-decompositions.

The limited-models infinite-layer substrate fud decompositions, $\mathcal{D}_{\mathrm{F}, \infty, U_{A}, V_{A}} \cap$ $\operatorname{trees}\left(\mathcal{S} \times \mathcal{F}_{\mathrm{q}}\right)$, may also be constructed by means of a tree of immediate super-decompositions. Define the finite limited-models infinite-layer fud decomposition tree $\operatorname{tdfiq}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{D}_{\mathrm{F}, \mathrm{d}} \rightarrow \operatorname{trees}\left(\mathcal{D}_{\mathrm{F}, \mathrm{d}}\right)$ as

$$
\begin{aligned}
& \operatorname{tdfiq}(U)(V, D):= \\
& \qquad \begin{aligned}
&\{(E, \operatorname{tdfiq}(U)(V, E)): \\
& Q=\operatorname{paths}(D), L \in Q, i \in\{1 \ldots|L|\}, \\
&(\cdot, F)=L_{i}, W=\operatorname{der}(F), S \in W^{\mathrm{CS}}, \\
& G \in \mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{q}} \backslash\left(\operatorname{ran}\left(\operatorname{set}\left(L_{\{1 \ldots i\}}\right)\right) \cup\{\emptyset\}\right), \\
& M=L_{\{1 \ldots i\}} \cup\{(i+1,(S, G))\}, \\
&\left.E=\operatorname{tree}\left(Q \backslash\left\{L_{\{1 \ldots i\}}\right\} \cup\{M\}\right), E \in \mathcal{D}_{\mathrm{F}, \mathrm{~d}}\right\}
\end{aligned}
\end{aligned}
$$

where $\operatorname{tdfiq}(U)(V, \emptyset):=\left\{(E, \operatorname{tdfiq}(U)(V, E)): G \in \mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{q}} \backslash\{\emptyset\}, E=\right.$ $\{((\emptyset, G), \emptyset)\}\}$. Let $\operatorname{tdfiq}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathcal{D}_{\mathrm{F}, \mathrm{d}}\right)$ be defined $\operatorname{tdfiq}(U)(V)=$
$\operatorname{tdfiq}(U)(V, \emptyset)$.
The decompositions of the tree are a subset of the limited-models infinitelayer substrate fud decompositions

$$
\mathcal{D}_{\mathrm{F}, \propto, U, V} \cap \operatorname{trees}\left(\mathcal{S} \times \mathcal{F}_{\mathrm{q}}\right) \supset \operatorname{elements}(\operatorname{tdfiq}(U)(V))
$$

The limited-models infinite-layer fud decomposition tree, $\operatorname{tdfiq}(U)(V)$, is finite. Therefore a computer $I_{\text {tdfiq }} \in$ computers that is defined such that its application to the substrate variables, $V$, constructs the limited-models infinitelayer substrate fud decompositions, $I_{\text {ddfiq }}^{*}(V) \subset \mathcal{D}_{\mathrm{F}, \infty, U, V} \cap \operatorname{trees}\left(\mathcal{S} \times \mathcal{F}_{\mathrm{q}}\right)$, by traversing the entire tree, $\operatorname{tdfiq}(U)(V)$, always terminates and is therefore also finite. That is, $\forall P \in \operatorname{enums}(\operatorname{tdfiq}(U)(V))(|P|<\infty)$ and so $|P|<I_{\text {tdfiq }}^{\mathrm{t}}(V)<\infty$.

Similarly, the limited-models non-overlapping infinite-layer substrate fud decompositions, $\mathcal{D}_{\mathrm{F}, \infty, U_{A}, V_{A}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right)$, may also be constructed by the tree of immediate super-decompositions to contain only non-overlapping fuds. Define the finite limited-models non-overlapping infinite-layer fud decomposition tree $\operatorname{tdfinq}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{D}_{\mathrm{F}, \mathrm{d}} \rightarrow \operatorname{trees}\left(\mathcal{D}_{\mathrm{F}, \mathrm{d}}\right)$ as

$$
\begin{aligned}
& \operatorname{tdfinq}(U)(V, D):= \\
& \qquad \begin{aligned}
&\{(E, \operatorname{tdfinq}(U)(V, E)): \\
& Q=\operatorname{paths}(D), L \in Q, i \in\{1 \ldots|L|\}, \\
&(\cdot, F)=L_{i}, W=\operatorname{der}(F), S \in W^{\mathrm{CS}}, \\
& G \in \mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}} \backslash\left(\operatorname{ran}\left(\operatorname{set}\left(L_{\{1 \ldots i\}}\right)\right) \cup\{\emptyset\}\right), \\
& M=L_{\{1 \ldots i} \cup\{(i+1,(S, G))\}, \\
&\left.E=\operatorname{tree}\left(Q \backslash\left\{L_{\{1 \ldots i\}}\right\} \cup\{M\}\right), E \in \mathcal{D}_{\mathrm{F}, \mathrm{~d}}\right\}
\end{aligned}
\end{aligned}
$$

where $\operatorname{tdfing}(U)(V, \emptyset):=\left\{(E, \operatorname{tdfinq}(U)(V, E)): G \in \mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}} \backslash\right.$ $\{\emptyset\}, E=\{((\emptyset, G), \emptyset)\}\}$. Let $\operatorname{tdfinq}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathcal{D}_{\mathrm{F}, \mathrm{d}}\right)$ be defined $\operatorname{tdfinq}(U)(V)=\operatorname{tdfinq}(U)(V, \emptyset)$.

The decompositions of the tree are a subset the limited-models non-overlapping infinite-layer substrate fud decompositions

$$
\mathcal{D}_{\mathrm{F}, \infty, U, V} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right) \supset \operatorname{elements}(\operatorname{tdfinq}(U)(V))
$$

It is also the case that the limited-models non-overlapping infinite-layer fud decomposition tree, $\operatorname{tdfinq}(U)(V)$, is finite, because it is a subset of the finite limited-models infinite-layer fud decomposition tree, $\operatorname{tdfiq}(U)(V)$. That is,
elements $(\operatorname{tdfinq}(U)(V)) \subset$ elements $(\operatorname{tdfiq}(U)(V))$.
A construction of a fud decomposition tree can be defined in terms of the finite limited-layer limited-underlying-volume limited-breadth partition infinitelayer fud tree, $\operatorname{tfiubh}(U)(V)$. Define the finite limited-derived non-overlapping limited-layer limited-underlying-volume limited-breadth infinite-layer fud decomposition tree $\operatorname{tdfiubhnd}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{D}_{\mathrm{F}, \mathrm{d}} \rightarrow \operatorname{trees}\left(\mathbf{N}_{>0} \times \mathcal{D}_{\mathrm{F}, \mathrm{d}}\right)$ as

$$
\begin{aligned}
& \operatorname{tdfiubhnd}(U)(V, D):= \\
& \qquad \begin{aligned}
&\{((j, E), \operatorname{tdfiubhnd}(U)(V, E)): \\
& Q=\operatorname{paths}(D), L \in Q, i \in\{1 \ldots|L|\}, \\
&(\cdot, F)=L_{i}, W=\operatorname{der}(F), S \in W^{\mathrm{CS}}, \\
& P \in \operatorname{order}\left(D_{\text {tfiubh }}, \operatorname{subpaths}(\operatorname{tfiubh}(U)(V))\right), \\
& N=\left\{\left(j, M_{|M|}\right):(M, j) \in P\right\}, \\
& j \in\{1 \ldots|N|\}, N_{j} \notin \operatorname{set}\left(L_{\{1 \ldots i}\right), \operatorname{nd}\left(N_{j}\right), \\
& M=L_{\{1 \ldots i\}} \cup\left\{\left(i+1,\left(S, N_{j}\right)\right)\right\}, \\
&\left.E=\operatorname{tree}\left(Q \backslash\left\{L_{\{1 \ldots i\}}\right\} \cup\{M\}\right), E \in \mathcal{D}_{\mathrm{F}, \mathrm{~d}}\right\}
\end{aligned}
\end{aligned}
$$

where

$$
\begin{aligned}
& \operatorname{tdfiubhnd}(U)(V, \emptyset):= \\
& \qquad \begin{aligned}
&\{((j, E), \operatorname{tdfiubhnd}(U)(V, E)): \\
& P \in \operatorname{order}\left(D_{\text {tfiubh }}, \operatorname{subpaths}(\operatorname{tfiubh}(U)(V))\right), \\
& N=\left\{\left(j, M_{|M|}\right):(M, j) \in P\right\}, \\
&\left.j \in\{1 \ldots|N|\}, \operatorname{nd}\left(N_{j}\right), E=\left\{\left(\left(\emptyset, N_{j}\right), \emptyset\right)\right\}\right\}
\end{aligned}
\end{aligned}
$$

Let $\operatorname{tdfiubhnd}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathcal{D}_{\mathrm{F}, \mathrm{d}}\right)$ be defined $\operatorname{tdfiubhnd}(U)(V)=$ tdfiubhnd $(U)(V, \emptyset)$.

Here search list $N \in \mathcal{L}\left(\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}}\right)$ is constructed given some order $D_{\text {tfiubh }}$ on the subpaths of the finite limited-layer limited-underlying-volume limited-breadth partition infinite-layer fud tree, $\operatorname{tfiubh}(U)(V)$, so that the search enumeration is $P \in$ enums $($ subpaths $(\operatorname{tfiubh}(U)(V)))$ and the finite search list is $N=\left\{\left(j, M_{|M|}\right):(M, j) \in P\right\}$.

Again, the decompositions of the tree are a subset of the limited-models nonoverlapping infinite-layer substrate fud decompositions

$$
\mathcal{D}_{\mathrm{F}, \infty, U, V} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right) \supset \operatorname{ran}(\operatorname{elements}(\operatorname{tdfiubhnd}(U)(V)))
$$

but the cardinality limited-derived non-overlapping limited-underlying limitedbreadth infinite-layer fud decomposition tree is greater than or equal to the cardinality of the limited-models non-overlapping infinite-layer fud decomposition tree, $|\operatorname{tdfiubhnd}(U)(V)| \geq|\operatorname{tdfinq}(U)(V)|$. Therefore a computer $I_{\text {tdfiubhnd }} \in$ computers that is defined such that its application to the substrate variables, $V$, constructs the limited-models non-overlapping infinitelayer substrate fud decompositions, $I_{\mathrm{tdfiubhnd}}^{*}(V) \subset \mathcal{D}_{\mathrm{F}, \infty, U, V} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{n}} \cap\right.\right.$ $\left.\mathcal{F}_{\mathrm{q}}\right)$ ), by traversing the limited-derived non-overlapping limited-underlying limited-breadth infinite-layer fud decomposition tree, $\operatorname{tdfiubhnd}(U)(V)$, is such that $I_{\text {tdfiubhnd }}^{\mathrm{t}}(V)>I_{\text {tdfinq }}^{\mathrm{t}}(V)$.

Instead of constructing non-overlapping infinite-layer substrate fuds, $\mathcal{F}_{\infty, U, V} \cap$ $\mathcal{F}_{\mathrm{n}}$, from the partition transforms of tuples, consider constructing them from contracted non-overlapping substrate transforms of tuples. Define the infinite contracted non-overlapping substrate transform infinite-layer fud tree $\operatorname{tfitn}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{F}_{U, \mathrm{P}^{*}} \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$ as

$$
\begin{aligned}
& \operatorname{tfitn}(U)(V, F):= \\
& \qquad \begin{aligned}
\{(F \cup G, & \operatorname{tfitn}(U)(V, F \cup G)): \\
& G \subseteq\left\{N^{\mathrm{T}}: K \in \operatorname{tuples}(V, F), N \in \mathcal{N}_{U, K, \mathrm{n}}^{\prime} \backslash\{\emptyset\}\right\}, \\
& G \neq \emptyset\}
\end{aligned}
\end{aligned}
$$

Let $\operatorname{tfitn}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$ be defined $\operatorname{tfitn}(U)(V)=\operatorname{tfitn}(U)(V, \emptyset)$.
Here the weak non-overlapping substrate partition-sets set, $\mathcal{N}_{U, K, \mathrm{n}}^{\prime}$, is defined

$$
\mathcal{N}_{U, K, \mathrm{n}}^{\prime}=\left\{N: Y \in \mathrm{~B}^{\prime}(K), N \in \prod_{J \in Y} \mathrm{~B}\left(J^{\mathrm{CS}}\right)\right\} \cup\{\emptyset\}
$$

and the non-overlapping substrate transforms set is defined in terms of the weak non-overlapping substrate partition-sets set

$$
\mathcal{T}_{U, K, \mathrm{n}}=\left\{N^{\mathrm{T} K}: N \in \mathcal{N}_{U, K, \mathrm{n}}^{\prime}\right\}
$$

The tree is a tree of multi-partition fuds. The partition fuds are a subset of the multi-partition fuds, $\mathcal{F}_{U, \mathrm{P}} \subset \mathcal{F}_{U, \mathrm{P}^{*}}$, and the non-overlapping substrate transforms are a superset of the partition transforms, $\left\{P^{\mathrm{T}}: P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\} \subseteq$ $\mathcal{T}_{U, K, \mathrm{n}}$, so the infinite non-overlapping infinite-layer substrate fuds can be constructed from the partition fuds in the tree,

$$
\begin{aligned}
& \mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}}= \\
& \quad\left\{F: F \in \operatorname{elements}(\operatorname{tfitn}(U)(V)) \cap \mathcal{F}_{U, \mathrm{P}}, \quad \neg \operatorname{overlap}(F)\right\}
\end{aligned}
$$

However, the infinite non-overlapping infinite-layer substrate fuds can also be constructed by exploding the contracted non-overlapping substrate transforms of the multi-partition fuds

$$
\begin{aligned}
& \mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}}= \\
& \quad\left\{F^{\prime}: F \in \operatorname{elements}(\operatorname{tfitn}(U)(V)), F^{\prime}=\operatorname{explode}(F), \neg \operatorname{overlap}\left(F^{\prime}\right)\right\}
\end{aligned}
$$

where $\operatorname{explode}(F):=\left\{P^{\mathrm{T}}:(\cdot, W) \in F, P \in W\right\} \in \mathcal{F}_{U, \mathrm{P}}$. Note that, although contracted non-overlapping substrate transforms are being added, it is still necessary to explicitly test that the tree exploded fuds are nonoverlapping, $ᄀ$ overlap $(\operatorname{explode}(F))$. The addition of contracted non-overlapping substrate transforms does not imply that ancestor exploded fuds are nonoverlapping.

Although the resultant set of non-overlapping infinite-layer substrate fuds, $\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}}$, is the same whether constructed with partition transforms or contracted non-overlapping substrate transforms, in the latter case more computation is required because $\left|\mathcal{T}_{U, K, \mathrm{n}}\right| \geq\left|\mathrm{B}\left(K^{\mathrm{CS}}\right)\right|$. That is, the cardinality of possible construction paths may be greater,

$$
\begin{aligned}
& \left|\left\{M: M \in \operatorname{subpaths}(\operatorname{tfitn}(U)(V)), M_{|M|}=F\right\}\right| \\
\geq & \left|\left\{M: M \in \operatorname{subpaths}(\operatorname{tfi}(U)(V)), M_{|M|}=\operatorname{explode}(F)\right\}\right|
\end{aligned}
$$

where $F \in$ elements $(\operatorname{tfitn}(U)(V))$.
The cardinality of the weak non-overlapping substrate partition-sets set is twice that of the non-overlapping substrate partition-sets set plus one, $\left|\mathcal{N}_{U, K, \mathrm{n}}^{\prime}\right|=$ $2 \times\left|\mathcal{N}_{U, K, \mathrm{n}}\right|+1$. In the case of non-empty tuple, $K \neq \emptyset$, the cardinality of the non-overlapping substrate partition-sets set, $\mathcal{N}_{U, K, \mathrm{n}}$, is

$$
\left|\mathcal{N}_{U, K, \mathrm{n}}\right|=\sum_{Y \in \mathrm{~B}(K)} \prod_{J \in Y}\left|\mathrm{~B}\left(J^{\mathrm{CS}}\right)\right|
$$

If the underlying variables are regular, having dimension $k=|K|$ and common valency $d$, $\{d\}=\left\{\left|U_{x}\right|: x \in K\right\}$, then the cardinality of the nonoverlapping substrate partition-sets set is

$$
\left|\mathcal{N}_{U, K, \mathrm{n}}\right|=\sum_{(L, c) \in \operatorname{bcd}(k)}\left(c \prod_{(j, p) \in L} \operatorname{bell}\left(d^{j}\right)^{p}\right)
$$

where bcd = bellcd and the partition function cardinality function is bellcd $\epsilon$ $\mathbf{N}_{>0} \rightarrow(\mathcal{L}(\mathbf{N}) \rightarrow \mathbf{N})$.

For the first layer, $F=\emptyset$, the cardinality of the set of next layer fuds is

$$
\begin{aligned}
&\left|\mathrm{P}\left(\left\{N^{\mathrm{T}}: K \subseteq V, N \in \mathcal{N}_{U, K, \mathrm{n}}^{\prime}, N \neq \emptyset\right\}\right)\right|-1= \\
& 2^{c}-1: c=\sum_{K \subseteq V} 2 \sum_{Y \in \mathrm{~B}(K)} \prod_{J \in Y} \operatorname{bell}\left(\left|J^{\mathrm{C}}\right|\right)
\end{aligned}
$$

In the case of regular substrate variables, having dimension $k=|K|$ and valency $d$, the cardinality is

$$
\begin{aligned}
& \left|\mathrm{P}\left(\left\{N^{\mathrm{T}}: K \subseteq V, N \in \mathcal{N}_{U, K, \mathrm{n}}^{\prime}, N \neq \emptyset\right\}\right)\right|-1= \\
& 2^{c}-1: c=\sum_{k \in\{0 \ldots n\}} 2\binom{n}{k} \sum_{(L, a) \in \operatorname{bcd}(k)} a \prod_{(j, p) \in L} \operatorname{bell}\left(d^{j}\right)^{p}
\end{aligned}
$$

For higher layers, $F \neq \emptyset$, the cardinality of the set of next layer fuds is

$$
\begin{aligned}
& \left|\mathrm{P}\left(\left\{N^{\mathrm{T}}: K \in \operatorname{tuples}(V, F), N \in \mathcal{N}^{\prime}{ }_{U, K, \mathrm{n}}, \quad N \neq \emptyset\right\}\right)\right|-1= \\
& 2^{c}-1: c=\sum_{K \subseteq W, K \cap X \neq \emptyset} 2 \sum_{Y \in \mathrm{~B}(K)} \prod_{J \in Y} \operatorname{bell}\left(\left|J^{\mathrm{C}}\right|\right)
\end{aligned}
$$

where $W=\operatorname{vars}(F) \cup V$ and $X=\operatorname{der}(F)$.
In the case of regular substrate variables $V$ and regular fud variables $\operatorname{vars}(F) \backslash$ $V$, having valency $d$, dimension $q=|W|$ and intersecting dimension $x=|X|$, the cardinality is

$$
\begin{aligned}
& \left|\mathrm{P}\left(\left\{N^{\mathrm{T}}: K \in \operatorname{tuples}(V, F), N \in \mathcal{N}^{\prime}, K, K, \mathrm{n}, N \neq \emptyset\right\}\right)\right|-1= \\
& \quad 2^{c}-1: c=\sum_{k \in\{1 \ldots q\}} 2\left(\binom{q}{k}-\binom{q-x}{k}\right) \sum_{(L, a) \in \operatorname{bdd}(k)} a \prod_{(j, p) \in L} \operatorname{bell}\left(d^{j}\right)^{p}
\end{aligned}
$$

where the binomial coefficient is defined such that $\forall a, b \in \mathbf{N}(b>a \Longrightarrow$ $\left.\binom{a}{b}=0\right)$.

The construction of the finite limited-models non-overlapping infinite-layer substrate fuds, $\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$, may also be made with contracted nonoverlapping substrate transforms rather than partition transforms. Define the finite limited-layer limited-underlying-volume limited-breadth contracted nonoverlapping substrate transform infinite-layer fud tree $\operatorname{tfitnubh}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times$

```
\(\mathcal{F}_{U, \mathrm{P}^{*}} \times \mathbf{N} \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)\) as
tfitnubh \((U)(V, F, h):=\)
    \(\{(F \cup G\), tfitnubh \((U)(V, F \cup G, h+1)):\)
    \(G \subseteq\left\{N^{\mathrm{T}}: K \in \operatorname{tuples}(V, F),\left|K^{\mathrm{C}}\right| \leq \operatorname{xmax}, N \in \mathcal{N}_{U, K, \mathrm{n}} \backslash\{\emptyset\}\right\}\),
    \(1 \leq|\operatorname{explode}(G)| \leq\) bmax,
    \(h \leq \operatorname{lmax}\}\)
```

Again, let tfitnubh $(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$ be defined $\operatorname{tfitnubh}(U)(V)=$
tfitnubh $(U)(V, \emptyset, 1)$.

The finite set of limited-models non-overlapping infinite-layer substrate fuds is

$$
\begin{aligned}
& \mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathbf{n}} \cap \mathcal{F}_{\mathrm{q}}= \\
& \quad\left\{F^{\prime}: M \in \operatorname{subpaths}(\operatorname{tfitnubh}(U)(V)), F^{\prime}=\operatorname{explode}\left(M_{|M|}\right), \operatorname{nd}\left(F^{\prime}\right)\right\}
\end{aligned}
$$

Similarly to the case of the limited-layer limited-underlying-volume limitedbreadth partition infinite-layer fud tree, tfiubh $(U)(V)$, above, a finite computer $I_{\text {tfitnq }} \in$ computers can be defined such that its application to the substrate variables, $V$, constructs the limited-models non-overlapping infinitelayer substrate fuds, $I_{\text {tfitnq }}^{*}(V)=\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$, by traversing the limitedlayer limited-underlying-volume limited-breadth contracted non-overlapping substrate transform infinite-layer fud tree, tfitnubh $(U)(V)$, such that all of the paths are searched in sequence. The cardinality of the contracted nonoverlapping substrate transform searched list is greater than or equal to the cardinality of the partition transform searched list,

$$
\mid \text { subpaths(tfitnubh }(U)(V))|\geq|\operatorname{subpaths}(\operatorname{tfiubh}(U)(V))|
$$

so the computation time must be greater than or equal to that of the previous case, $I_{\mathrm{tfitnq}}^{\mathrm{t}}(V) \geq I_{\text {tfinq }}^{\mathrm{t}}(V)$.

Given cardinality $b \in \mathbf{N}_{>0}$, the fixed-breadth non-overlapping substrate partitionsets set, $\mathcal{N}_{U, K, \mathrm{n}, b}$, applied to the tuple, $K$, is defined

$$
\mathcal{N}_{U, K, \mathrm{n}, b}=\left\{N: Y \in \mathrm{~B}(K), N \in \prod_{J \in Y} \mathrm{~B}\left(J^{\mathrm{CS}}\right),|N|=b\right\}
$$

If the underlying variables are regular, having dimension $k=|K|$ and common valency $d,\{d\}=\left\{\left|U_{x}\right|: x \in K\right\}$, then the cardinality of the fixed-breadth non-overlapping substrate partition-sets set is

$$
\left|\mathcal{N}_{U, K, \mathrm{n}, b}\right|=\sum_{(L, c) \in \operatorname{sscd}(k, b)}\left(c \prod_{(j, p) \in L} \operatorname{bell}\left(d^{j}\right)^{p}\right)
$$

where sscd $=$ stircd and the fixed cardinality partition function cardinality function is stircd $\in \mathbf{N}_{>0} \times \mathbf{N}_{>0} \rightarrow(\mathcal{L}(\mathbf{N}) \rightarrow \mathbf{N})$.

The cardinality of the set of next layer fuds is

$$
\begin{aligned}
& \mid\left\{G: G \subseteq\left\{N^{\mathrm{T}}: K \in \operatorname{tuples}(V, F),\left|K^{\mathrm{C}}\right| \leq \operatorname{xmax}, \quad N \in \mathcal{N}_{U, K, \mathrm{n}}^{\prime}, N \neq \emptyset\right\},\right. \\
& =\sum\left(\prod 2\left|\mathcal{N}_{U, K, \mathrm{n}, j}\right|:(K, j) \in Y, j>0\right): \\
& \quad \begin{array}{l}
\quad 1 \leq|\operatorname{explode}(G)| \leq \operatorname{bmax}\} \mid \\
\\
\\
\quad Y \in X, \forall(K, j) \in Y(j \leq|K|))
\end{array}
\end{aligned}
$$

where the weak composition function is $\mathrm{C}^{\prime} \in \mathrm{P}(\mathcal{X}) \times \mathbf{N} \rightarrow \mathrm{P}(\mathcal{X} \rightarrow \mathbf{N})$. Note that the constraint $\forall(K, j) \in Y(j \leq|K|)$ is required because for some tuples the cardinality of fixed-breadth non-overlapping substrate partition-sets set is too small to admit all weak compositions, $\left|\mathcal{N}_{U, K, \mathrm{n}, b}\right|<b$.

Consider the case where the fuds of the construction trees are constrained to consist of recursively non-overlapping multi-partition transforms. The construction of the finite limited-models non-overlapping infinite-layer substrate fuds, $\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$, may also be made with contracted non-overlapping substrate transforms to form a tree of recursively non-overlapping multipartition transform fuds. Define the finite limited-layer limited-underlyingvolume limited-breadth contracted recursively non-overlapping substrate transform infinite-layer fud tree $\operatorname{tfitrnubh}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{F}_{U, \mathrm{P}^{*}} \times \mathbf{N} \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$ as

```
tfitrnubh \((U)(V, F, h):=\)
    \(\{(F \cup G\), tfitrnubh \((U)(V, F \cup G, h+1)):\)
    \(G \subseteq\left\{N^{\mathrm{T}}: K \in \operatorname{tuples}(V, F),\left|K^{\mathrm{C}}\right| \leq \operatorname{xmax}, N \in \mathcal{N}_{U, K, \mathrm{n}}^{\prime} \backslash\{\emptyset\}\right.\),
    \(\neg\) overlap(depends(explode \(\left.\left.\left.\left(F \cup\left\{N^{\mathrm{T}}\right\}\right), N\right)\right)\right\}\),
    \(1 \leq|\operatorname{explode}(G)| \leq\) bmax,
    \(h \leq \operatorname{lmax}\}\)
```

Let titrnubh $(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$ be defined $\operatorname{tfitrnubh}(U)(V)=$ tfitnubh $(U)(V, \emptyset, 1)$.

Now each transform in the fud is constrained to be recursively non-overlapping,

```
\forallF\in elements(tfitrnubh(U)(V))}\forall(\cdot,W)\in
    (\negoverlap(depends(explode(F),W)))
```

but the recursively non-overlapping multi-partition fuds are a superset of the partition fuds, elements $(\operatorname{tfiubh}(U)(V)) \subset$ elements $($ tfitrnubh $(U)(V))$, because the non-overlapping substrate transforms are a superset of the partition transforms, $\left\{P^{\mathrm{T}}: P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\} \subseteq \mathcal{T}_{U, K, \mathrm{n}}$, so the set of all of the limitedmodels non-overlapping infinite-layer substrate fuds is constructed,

$$
\begin{aligned}
& \mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathbf{n}} \cap \mathcal{F}_{\mathrm{q}}= \\
& \quad\left\{F^{\prime}: F \in \operatorname{elements}(\operatorname{tfitrnubh}(U)(V)), F^{\prime}=\operatorname{explode}(F), \operatorname{nd}\left(F^{\prime}\right)\right\}
\end{aligned}
$$

The cardinality of the non-overlapping multi-partition fuds is greater than or equal to the cardinality of the recursively non-overlapping multi-partition fuds,

$$
\mid \operatorname{elements}(\operatorname{tfitnubh}(U)(V)))|\geq| \operatorname{elements}(\operatorname{tfitrnubh}(U)(V))) \mid
$$

If the recursively non-overlapping multi-partition fuds are restricted to those that are topped, then only a subset of the limited-models non-overlapping infinite-layer substrate fuds is constructed,

$$
\begin{array}{r}
\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}} \supseteq\{\operatorname{explode}(F): F \in \operatorname{elements}(\operatorname{tfitrnubh}(U)(V, \emptyset)), \\
\left.(\exists T \in F(\operatorname{der}(T)=\operatorname{der}(F))), W=\operatorname{der}(F),\left|W^{\mathrm{C}}\right| \leq \operatorname{wax}\right\}
\end{array}
$$

The topped recursively non-overlapping multi-partition fuds are necessarily non-overlapping so there is no need to test $\neg$ overlap(explode $(F)$ ).

The construction of a subset of the finite limited-models non-overlapping infinite-layer substrate fuds, $\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$, may also be made with contracted non-overlapping substrate transforms to form a tree of recursively non-overlapping pluri-derived-variate multi-partition transform fuds. Define the finite limited-layer limited-underlying-volume limited-breadth contracted recursively non-overlapping pluri-derived-variate substrate transform infinitelayer fud tree tfiptrnubh $(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{F}_{U, \mathrm{P}^{*}} \times \mathbf{N} \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$ as

```
tfiptrnubh \((U)(V, F, h):=\)
    \(\{(F \cup G\), tfiptrnubh \((U)(V, F \cup G, h+1)):\)
                                    \(G \subseteq\left\{N^{\mathrm{T}}: K \in \operatorname{tuples}(V, F),\left|K^{\mathrm{C}}\right| \leq \operatorname{xmax}, N \in \mathcal{N}^{\prime}{ }_{U, K, \mathrm{n}}\right.\),
                    \(|N|>1\),
                        \(\neg\) overlap \(\left(\right.\) depends \(\left.\left.\left(\operatorname{explode}\left(F \cup\left\{N^{\mathrm{T}}\right\}\right), N\right)\right)\right\}\),
\(1 \leq|\operatorname{explode}(G)| \leq \operatorname{bmax}\),
\(h \leq \operatorname{lmax}\}\)
```

Let tfiptrnubh $(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$ be defined tfiptrnubh $(U)(V)=$ tfitnubh $(U)(V, \emptyset, 1)$.

The pluri-derived-variate constraint means that only a subset of the limitedmodels non-overlapping infinite-layer substrate fuds is constructed,

$$
\begin{aligned}
& \mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathbf{n}} \cap \mathcal{F}_{\mathrm{q}} \supseteq \\
& \quad\left\{F^{\prime}: F \in \operatorname{elements}(\operatorname{tfiptrnubh}(U)(V)), F^{\prime}=\operatorname{explode}(F), \operatorname{nd}\left(F^{\prime}\right)\right\}
\end{aligned}
$$

The limited-layer limited-underlying-volume limited-breadth contracted nonoverlapping substrate transform infinite-layer fud tree, tfitnubh $(U)(V)$, does not readily yield a polynomial-complexity computation of the regular cardinality set of next layer fuds. Consider a restricted variation that limits the tuple derived dimension to a parameter mmax $\in \mathbf{N}_{>0}$. The tuple derived dimension limit is also constrained such that the breadth limit is a multiple, bmax/mmax $\in \mathbf{N}_{>0}$. Define the finite limited-layer limited-tuple-derived-dimension limited-underlying-volume limited-breadth contracted non-overlapping substrate transform infinite-layer fud tree titnmubh $(U) \in$ $\mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{F}_{U, \mathrm{P}^{*}} \times \mathbf{N} \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$ as

```
tfitnmubh \((U)(V, F, h):=\)
    \(\{(F \cup G, \operatorname{tfitnmubh}(U)(V, F \cup G, h+1)):\)
    \(G \subseteq\left\{N^{\mathrm{T}}: K \in \operatorname{tuples}(V, F),\left|K^{\mathrm{C}}\right| \leq \operatorname{xmax}, N \in \mathcal{N}_{U, K, \mathrm{n}, \max }\right\}\),
    \(1 \leq|G| \leq \operatorname{bmax} /\) mmax,
    \(h \leq \operatorname{lmax}\}\)
```

Again, let tfitnmubh $(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$ be defined $\operatorname{tfitnmubh}(U)(V)=$ tfitnmubh $(U)(V, \emptyset, 1)$.

Here the limited-tuple-derived-dimension non-overlapping substrate partitionsets set, $\mathcal{N}_{U, K, \mathrm{n}, \mathrm{mmax}}$, is defined as the limited-breadth non-overlapping substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{n}, \mathrm{bmax}}$, applied to the tuple,

$$
\mathcal{N}_{U, K, \mathrm{n}, \operatorname{mmax}}=\left\{N: Y \in \mathrm{~B}(K),|Y| \leq \operatorname{mmax}, N \in \prod_{J \in Y} \mathrm{~B}\left(J^{\mathrm{CS}}\right)\right\}
$$

In the case where mmax $\leq|K|$,
$\mathcal{N}_{U, K, \mathrm{n}, \operatorname{mmax}}=\left\{N: m \in\{1 \ldots \operatorname{mmax}\}, Y \in \mathrm{~S}(K, m), N \in \prod_{J \in Y} \mathrm{~B}\left(J^{\mathrm{CS}}\right)\right\}$

In the case of regular variables $K$, having valency $d$ and dimension $k$, the cardinality of the limited-tuple-derived-dimension non-overlapping substrate partition-sets set is

$$
\begin{aligned}
\left|\mathcal{N}_{U, K, \mathrm{n}, \operatorname{mmax}}\right| & =\sum\left(\prod_{J \in Y} \operatorname{bell}\left(d^{|J|}\right)\right): m \in\{1 \ldots \operatorname{mmax}\}, Y \in \mathrm{~S}(K, m) \\
& =\sum\left(a \prod_{(j, p) \in L} \operatorname{bell}\left(d^{j}\right)^{p}\right): m \in\{1 \ldots \operatorname{mmax}\},(L, a) \in \operatorname{sscd}(k, m)
\end{aligned}
$$

where $\operatorname{sscd}=$ stircd and the fixed cardinality partition function cardinality function is stircd $\in \mathbf{N}_{>0} \times \mathbf{N}_{>0} \rightarrow(\mathcal{L}(\mathbf{N}) \rightarrow \mathbf{N})$.

The limited-layer limited-tuple-derived-dimension limited-underlying-volume limited-breadth contracted non-overlapping substrate transform infinite-layer fud tree is defined with the limited-tuple-derived-dimension non-overlapping substrate partition-sets set, $\mathcal{N}_{U, K, \mathrm{n}, \mathrm{mmax}}$. This is a strong partition-sets set so it excludes the empty transform, ( $\emptyset, \emptyset)$, and the unary partition transform, $\left\{\emptyset^{\mathrm{CS}}\right\}^{\mathrm{T}}$. The finite set of strong limited-models non-overlapping infinite-layer substrate fuds is

$$
\begin{aligned}
& \left\{F: F \in \mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}},\left\{\emptyset^{\mathrm{CS}}\right\}^{\mathrm{T}} \notin F\right\}= \\
& \quad\left\{F^{\prime}: M \in \operatorname{subpaths}(\operatorname{tfitnmubh}(U)(V)), F^{\prime}=\operatorname{explode}\left(M_{|M|}\right), \operatorname{nd}\left(F^{\prime}\right)\right\}
\end{aligned}
$$

The cardinality of the limited-layer limited-tuple-derived-dimension limited-underlying-volume limited-breadth contracted non-overlapping substrate transform infinite-layer fud tree searched list is less than or equal to the cardinality of the limited-layer limited-underlying-volume limited-breadth contracted nonoverlapping substrate transform infinite-layer fud tree searched list, because of the additional constraint,

$$
|\operatorname{subpaths}(\operatorname{tfitnmubh}(U)(V))| \leq|\operatorname{subpaths}(\operatorname{tfitnubh}(U)(V))|
$$

For the first layer, $F=\emptyset$, the cardinality of the set of next layer fuds is

$$
\begin{aligned}
& \mid\left\{G: G \subseteq\left\{N^{\mathrm{T}}: K \subseteq V,\left|K^{\mathrm{C}}\right| \leq \mathrm{xmax}, \quad N \in \mathcal{N}_{U, K, \mathrm{n}, \operatorname{mmax}\}}\right\},\right. \\
& \quad 1 \leq|G| \leq \mathrm{bmax} / \mathrm{mmax}\} \mid \\
& =\left(\sum_{b \in\left\{0 \ldots \frac{\operatorname{bmax}}{\operatorname{mmax}}\right\}}\binom{c}{b}\right): \\
& c=\sum\left(\prod_{J \in Y} \operatorname{bell}\left(\left|J^{\mathrm{C}}\right|\right)\right): K \subseteq V,\left|K^{\mathrm{CS}}\right| \leq \mathrm{xmax}, \\
& \\
& m \in\{1 \ldots \operatorname{mmax}\}, Y \in \mathrm{~S}(K, m)
\end{aligned}
$$

In the case of pluri-valent regular substrate variables, having dimension $k=$ $|K|$ and valency $d>1$, if the implied underlying-dimension limit, $\mathrm{kmax}=$ $\ln \mathrm{xmax} / \ln d$, is integral, $\ln \mathrm{xmax} / \ln d \in \mathbf{N}$, the cardinality is

$$
\begin{aligned}
& \mid\left\{G: G \subseteq\left\{N^{\mathrm{T}}: K \subseteq V,\left|K^{\mathrm{C}}\right| \leq \mathrm{xmax}, N \in \mathcal{N}_{U, K, \mathrm{n}, \operatorname{mmax}}\right\},\right. \\
& =\left(\sum_{b \in\left\{0 \ldots \frac{\operatorname{bmax}}{\operatorname{mmax}}\right\}}\binom{c}{b}\right): \\
& c=\sum_{k \in\{0 \ldots \mathrm{kmax}\}}\binom{n}{k}\left(\sum\left(a \prod_{(j, p) \in L} \operatorname{bell}\left(d^{j}\right)^{p}\right):\right. \\
& \quad m \in\{1 \ldots \operatorname{mmax}\},(L, a) \in \operatorname{sscd}(k, m))
\end{aligned}
$$

For higher layers, $F \neq \emptyset$, the cardinality of the set of next layer fuds is

$$
\begin{aligned}
& \mid\left\{G: G \subseteq\left\{N^{\mathrm{T}}: K \in \operatorname{tuples}(V, F),\left|K^{\mathrm{C}}\right| \leq \operatorname{xmax}, \quad N \in \mathcal{N}_{U, K, \mathrm{n}, \operatorname{mmax}}\right\},\right. \\
& 1 \leq|G| \leq \operatorname{bmax} / \operatorname{mmax}\} \mid \\
& =\left(\sum_{b \in\left\{0 \ldots \frac{\operatorname{bmax}}{\operatorname{mmax}\}}\right\}}\binom{c}{b}\right): \\
& c=\sum^{c}\left(\prod_{J \in Y} \operatorname{bell}\left(\left|J^{\mathrm{C}}\right|\right)\right): K \subseteq W, K \cap X \neq \emptyset,\left|K^{\mathrm{CS}}\right| \leq \mathrm{xmax}, \\
& m \in\{1 \ldots \operatorname{mmax}\}, Y \in \mathrm{~S}(K, m)
\end{aligned}
$$

where $W=\operatorname{vars}(F) \cup V$ and $X=\operatorname{der}(F)$.
In the case of regular substrate variables $V$ and regular fud variables $\operatorname{vars}(F) \backslash$ $V$, having valency $d$, dimension $q=|W|$ and intersecting dimension $x=|X|$, the cardinality is

$$
\begin{aligned}
& \mid\left\{G: G \subseteq\left\{N^{\mathrm{T}}: K \in \operatorname{tuples}(V, F),\left|K^{\mathrm{C}}\right| \leq \mathrm{xmax}, \quad N \in \mathcal{N}_{U, K, \mathrm{n}, \operatorname{mmax}}\right\},\right. \\
& \\
& 1 \leq|G| \leq \operatorname{bmax} / \operatorname{mmax}\} \mid \\
& =\left(\sum_{b \in\left\{0 \ldots \frac{\mathrm{bmax}}{\operatorname{mmax}}\right\}}\binom{c}{b}\right): \\
& c=\sum_{k \in\{1 \ldots \mathrm{kmax}\}}\left(\binom{q}{k}-\binom{q-x}{k}\right)\left(\sum\left(a \prod_{(j, p) \in L} \operatorname{bell}\left(d^{j}\right)^{p}\right):\right. \\
& m \in\{1 \ldots \operatorname{mmax}\},(L, a) \in \operatorname{sscd}(k, m))
\end{aligned}
$$

In section 'Substrate structures' above it is shown that the strong nonoverlapping substrate transforms set, $\left\{N^{\mathrm{TV}}: N \in \mathcal{N}_{U, V, \mathrm{n}}\right\} \subseteq \mathcal{T}_{U, V, \mathrm{n}}$, can be constructed explicitly in terms of linear fuds of a strong non-overlapping substrate self-cartesian transform, $\left\{N^{\mathrm{T}}: N \in \mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}}\right\}$, followed by a sequence of strong self non-overlapping substrate decremented transforms, $\left\{N^{\mathrm{T}}: N \in \mathcal{N}_{U, W,-} \cap \mathcal{N}_{U, W, \mathrm{n}, \mathrm{s}}\right\}$. Let the finite set of contracted decrementing linear non-overlapping fuds $\mathcal{F}_{U, \mathrm{n},-, V} \subset \mathcal{F}_{U, \mathrm{P} *}$ be defined as

$$
\begin{aligned}
& \mathcal{F}_{U, \mathrm{n},-, V} \\
& =\quad\left\{\left\{N^{\mathrm{T}}:(\cdot, N) \in L\right\}: M \in \mathcal{N}_{U, V, \mathrm{c}} \cap \mathcal{N}_{U, V, \mathrm{n}},\right. \\
& =\quad L \in \operatorname{subpaths}(\{(M, \operatorname{tdec}(U)(M))\})\} \\
& =\left\{\left\{N^{\mathrm{T}}:(\cdot, N) \in L\right\}: Y \in \mathrm{~B}(V), M=\left\{K^{\mathrm{CS}\{ \}}: K \in Y\right\},\right. \\
& L \in \operatorname{subpaths}(\{(M, \operatorname{tdec}(U)(M))\})\}
\end{aligned}
$$

where the tree of self non-overlapping substrate decremented partition-sets is defined $\operatorname{tdec}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathrm{P}\left(\mathcal{R}_{U}\right)\right)$ as

$$
\operatorname{tdec}(U)(M):=\left\{(N, \operatorname{tdec}(U)(N)): N \in \mathcal{N}_{U, M,-} \cap \mathcal{N}_{U, M, \mathrm{n}, \mathrm{~s}}\right\}
$$

and $\operatorname{tdec}(U)(\emptyset):=\emptyset$. Explicitly this is

$$
\begin{aligned}
& \operatorname{tdec}(U)(M):=\{(N, \operatorname{tdec}(U)(N)): \\
& \left.\quad w \in M, Q \in \operatorname{decs}\left(\{w\}^{\operatorname{CS}\{ \}}\right), N=\{Q\} \cup\left\{\{u\}^{\operatorname{CS}\{ \}}: u \in M, u \neq w\right\}\right\}
\end{aligned}
$$

where decs $=$ decrements $\in \mathcal{R}_{U} \rightarrow \mathrm{P}\left(\mathcal{R}_{U}\right)$.
Then $\left\{N^{\mathrm{T} V}: N \in \mathcal{N}_{U, V, \mathrm{n}}\right\}=\left\{F^{\mathrm{T} V}: F \in \mathcal{F}_{U, \mathrm{n},-, V}\right\}$. Note that the contracted decrementing linear non-overlapping fuds, $\mathcal{F}_{U, \mathrm{n},-, V}$, are multi-partition fuds, $\mathcal{F}_{U, \mathrm{n},-, V} \subset \mathcal{F}_{U, \mathrm{P}^{*}}$, so are not necessarily substrate fuds, $\mathcal{F}_{U, V}$, because they do not necessarily consist of partition transforms, $\mathcal{F}_{U, V} \subset \mathcal{F}_{U, \mathrm{P}} \subset \mathcal{F}_{U, \mathrm{P} *}$. The transforms are already contracted so the corresponding substrate fuds can be constructed $\left\{\operatorname{explode}(F): F \in \mathcal{F}_{U, \mathrm{n},-, V}\right\} \subset \mathcal{F}_{U, V}$. Also, the computation of the contracted decrementing linear non-overlapping fuds would not need to check for flattened partition transforms, even if they were substrate fuds, because partitions in the linear fuds are necessarily distinct from all previous partitions in the sequence.

The cardinality of the self non-overlapping substrate decremented partitionsets tree may be computed by defining $\operatorname{tdeccd}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}(\mathbf{N} \times$ $\mathcal{L}(\mathbf{N}))$ as
$\operatorname{tdeccd}(U)(V):=\left\{((1, L), \operatorname{tdeccd}(1, L)): L=\left\{\left(i,\left|U_{v}\right|\right):(v, i) \in \operatorname{order}\left(D_{\mathrm{V}}, V\right)\right\}\right\}$
where order $D_{\mathrm{V}}$ is such that $\operatorname{order}\left(D_{\mathrm{V}}, V\right) \in \operatorname{enums}(V)$, and $\operatorname{tdeccd} \in \mathbf{N} \times$ $\mathcal{L}(\mathbf{N}) \rightarrow \operatorname{trees}(\mathbf{N} \times \mathcal{L}(\mathbf{N}))$ as
$\operatorname{tdeccd}(k, L):=\{((m, M), \operatorname{tdeccd}(m, M)):$

$$
\left.i \in\{1 \ldots|L|\}, L_{i}>1, m=k L_{i}\left(L_{i}-1\right), M=L \backslash\left\{\left(i, L_{i}\right)\right\} \cup\left\{\left(i, L_{i}-1\right)\right\}\right\}
$$

The cardinalities of the nodes of the tree of self non-overlapping substrate decremented partition-sets is
$|\operatorname{nodes}(\operatorname{tdec}(U)(V))|=\sum\left(p: L \in \operatorname{subpaths}(\operatorname{tdeccd}(U)(V)),(p, \cdot)=L_{|L|}\right)-1$ The cardinality of the contracted decrementing linear non-overlapping fuds is

$$
\begin{aligned}
& \left|\mathcal{F}_{U, \mathrm{n},-, V}\right| \\
& =\sum_{Y \in \mathrm{~B}(V)}\left(\left|\operatorname{nodes}\left(\operatorname{tdec}(U)\left(\left\{K^{\mathrm{CS}\{ \}}: K \in Y\right\}\right)\right)\right|+1\right) \\
& =\sum p: Y \in \mathrm{~B}(V), \\
& \quad L \in \operatorname{subpaths}\left(\operatorname{tdeccd}(U)\left(\left\{K^{\mathrm{CS}\{ \}}: K \in Y\right\}\right)\right),(p, \cdot)=L_{|L|}
\end{aligned}
$$

In the case of regular substrate variables of valency $d$ and dimension $n$, the cardinality of the contracted decrementing linear non-overlapping fuds is

$$
\begin{aligned}
& \left|\mathcal{F}_{U, \mathbf{n},-, V}\right| \\
& =\sum^{=} a p:(M, a) \in \operatorname{bcd}(n), R=\operatorname{reg}(d, M) \\
& L \in \operatorname{subpaths}(\{((1, R), \operatorname{tdeccd}(1, R))\}),(p, \cdot)=L_{|L|}
\end{aligned}
$$

where reg $\in \mathbf{N} \times \mathcal{L}(\mathbf{N}) \rightarrow \mathcal{L}(\mathbf{N})$ converts a histogram of regular cardinalities to a list of regular volumes, $\operatorname{reg}(d, M):=\operatorname{concat}\left(\operatorname{flip}\left(\operatorname{order}\left(D_{\mathcal{L}(\mathbf{N})},\{\{1 \ldots q\} \times\right.\right.\right.$ $\left.\left.\left.\left\{d^{j}\right\}:(j, q) \in M\right\}\right)\right)$ ), where $D_{\mathcal{L}(\mathbf{N})} \in \operatorname{enums}(\mathcal{L}(\mathbf{N}))$ is some order on integer lists.

Instead of constructing non-overlapping infinite-layer substrate fuds, $\mathcal{F}_{\infty, U, V} \cap$ $\mathcal{F}_{\mathrm{n}}$, from either (i) partition transforms, $\mathcal{T}_{U, \mathrm{P}}$, or (ii) non-overlapping substrate transforms, $\mathcal{T}_{U, V, \mathrm{n}}$, consider a construction with contracted decrementing linear non-overlapping fuds, $\mathcal{F}_{U, \mathrm{n},-, V}$. Define the infinite contracted decrementing linear non-overlapping fuds infinite-layer fud tree $\operatorname{tfifdn}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times$ $\mathcal{F}_{U, \mathrm{P}^{*}} \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$ as

$$
\begin{aligned}
& \operatorname{tfifdn}(U)(V, F):= \\
& \quad\{(F \cup \bigcup Q, \operatorname{tfifdn}(U)(V, F \cup \bigcup Q)):
\end{aligned}
$$

$$
Q \subseteq\left\{H: K \in \operatorname{tuples}(V, F), H \in \mathcal{F}_{U, \mathrm{n},-, K}\right\},
$$

$$
Q \neq \emptyset\}
$$

Note that, because the contracted decrementing linear non-overlapping fuds sometimes have more than one layer, the layer cardinality of the fuds no longer corresponds to the length of the construction path,

$$
\forall L \in \operatorname{subpaths}(\operatorname{tfifdn}(U)(V)) \forall i \in\{1 \ldots|L|\}\left(\operatorname{layer}\left(L_{i}, \operatorname{der}\left(L_{i}\right)\right) \geq i\right)
$$

The contracted decrementing linear non-overlapping fuds infinite-layer fud tree, $\operatorname{tfifdn}(U)(V)$, is constrained to contain only strong fud elements, so corresponding only to the strong subset of the non-overlapping substrate fuds

$$
\begin{aligned}
& \left\{F: F \in \mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}},\left\{\emptyset^{\mathrm{CS}}\right\}^{\mathrm{T}} \notin F\right\}= \\
& \quad\left\{F^{\prime}: F \in \operatorname{elements}(\operatorname{tfifdn}(U)(V)), F^{\prime}=\operatorname{explode}(F), \neg \operatorname{overlap}\left(F^{\prime}\right)\right\}
\end{aligned}
$$

Again note that, although contracted decrementing linear non-overlapping fuds are being added, it is still necessary to explicitly test that the tree fuds are non-overlapping, $\neg$ overlap(explode $(F))$. The addition of contracted decrementing linear non-overlapping fuds does not imply that ancestor fuds are non-overlapping.

Even though only a strong subset of the non-overlapping infinite-layer substrate fuds is computed, the computation time is greatest when constructed with contracted decrementing linear non-overlapping fuds, rather than partition transforms or contracted non-overlapping substrate transforms, because $\left|\mathcal{F}_{U, \mathrm{n},-, K}\right| \geq\left|\mathcal{T}_{U, K, \mathrm{n}}\right| \geq\left|\mathrm{B}\left(K^{\mathrm{CS}}\right)\right|$. There are sometimes multiple contracted decrementing linear non-overlapping fuds corresponding to a nonoverlapping substrate transform, $\operatorname{maxr}\left(\left\{(T,|Q|):(T, Q) \in\left\{\left(F, F^{\mathrm{TV}}\right): F \in\right.\right.\right.$ $\left.\left.\left.\mathcal{F}_{U, \mathrm{n},-, K}\right\}^{-1}\right\}\right) \geq 1$, because of multiple linear fud paths to the same nonoverlapping substrate transform. The cardinality of possible construction paths may be greater than when constructed with partition transforms,

$$
\begin{aligned}
& \left|\left\{M: M \in \operatorname{subpaths}(\operatorname{tfifdn}(U)(V)), M_{|M|}=F\right\}\right| \\
\geq & \left|\left\{M: M \in \operatorname{subpaths}(\operatorname{tfi}(U)(V)), M_{|M|}=\operatorname{explode}(F)\right\}\right|
\end{aligned}
$$

where $F \in$ elements $(\operatorname{tfifdn}(U)(V))$.

The construction of a strong subset of the limited-models non-overlapping infinite-layer substrate fuds, $\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$, may also be made with contracted decrementing linear non-overlapping fuds. Define the finite limitedlayer limited-tuple-derived-dimension limited-underlying-volume limited-breadth contracted decrementing linear non-overlapping fuds infinite-layer fud tree
$\operatorname{tfifdnmubh}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{F}_{U, \mathrm{P}^{*}} \times \mathbf{N} \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$ as
tfifdnmubh $(U)(V, F, h):=$

$$
\begin{aligned}
& \{(F \cup \bigcup Q, \text { tfifdnmubh }(U)(V, F \cup \bigcup Q, h+1)): \\
& \quad Q \subseteq\left\{H: K \in \operatorname{tuples}(V, F),\left|K^{\mathrm{C}}\right| \leq \operatorname{xmax}, H \in \mathcal{F}_{U, \mathrm{n},-, K, \operatorname{mmax}}\right\} \\
& \\
& \quad 1 \leq|Q| \leq \operatorname{bmax} / \operatorname{mmax}, \\
& \\
& h \leq \operatorname{lmax}\}
\end{aligned}
$$

Again, let tfifdnmubh $(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$ be defined $\operatorname{tfifdnmubh}(U)(V)=$ tfifdnmubh $(U)(V, \emptyset, 1)$.

Here the finite set of limited-tuple-derived-dimension contracted decrementing linear non-overlapping fuds $\mathcal{F}_{U, \mathrm{n},-, K, \operatorname{mmax}}$ is defined as

$$
\begin{aligned}
& \mathcal{F}_{U, \mathrm{n},-, K, \operatorname{mmax}} \\
& =\left\{\left\{N^{\mathrm{T}}:(\cdot, N) \in L\right\}: M \in \mathcal{N}_{U, K, \mathrm{c}} \cap \mathcal{N}_{U, K, \mathrm{n}, \operatorname{mmax}},\right. \\
& \quad L \in \operatorname{subpaths}(\{(M, \operatorname{tdec}(U)(M))\})\} \\
& =\left\{\left\{N^{\mathrm{T}}:(\cdot, N) \in L\right\}: Y \in \mathrm{~B}(K),|Y| \leq \operatorname{mmax}, M=\left\{J^{\mathrm{CS}\{ \}}: J \in Y\right\},\right. \\
& L \in \operatorname{subpaths}(\{(M, \operatorname{tdec}(U)(M))\})\}
\end{aligned}
$$

The set of limited-tuple-derived-dimension contracted decrementing linear non-overlapping fuds is defined with the limited-tuple-derived-dimension nonoverlapping substrate partition-sets set, $\mathcal{N}_{U, K, \mathrm{n}, \mathrm{mmax}}$, which is defined as the limited-breadth non-overlapping substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{n}, \mathrm{bmax}}$, applied to the tuple. In the case where $\operatorname{mmax} \leq k$, where $k=|K|$, the cardinality of the intersection of the substrate self-cartesian partition-sets set and the limited-tuple-derived-dimension non-overlapping substrate partition-sets set is

$$
\left|\mathcal{N}_{U, K, \mathrm{c}} \cap \mathcal{N}_{U, K, \mathrm{n}, \mathrm{~m} \max }\right|=\sum_{m \in\{1 \ldots \mathrm{~m} \max \}} \operatorname{stir}(k, m)
$$

where stir $\in \mathbf{N}_{>0} \times \mathbf{N} \rightarrow \mathbf{N}_{>0}$ is the Stirling number of the second kind.
The cardinality of the limited-tuple-derived-dimension contracted decrement-
ing linear non-overlapping fuds is

$$
\begin{aligned}
& \mid \mathcal{F}_{U, \mathrm{n},-, K, \operatorname{mmax} \mid} \\
& =\sum\left(\left|\operatorname{nodes}\left(\operatorname{tdec}(U)\left(\left\{J^{\mathrm{CS}\{ \}}: J \in Y\right\}\right)\right)\right|:\right. \\
& \quad m \in\{1 \ldots \operatorname{mmax}\}, Y \in \mathrm{~S}(K, m))+1 \\
& =\sum p: m \in\{1 \ldots \operatorname{mmax}\}, Y \in \mathrm{~S}(K, m), \\
& \quad L \in \operatorname{subpaths}\left(\operatorname{tdeccd}(U)\left(\left\{J^{\mathrm{CS}\{ \}}: J \in Y\right\}\right)\right),(p, \cdot)=L_{|L|}
\end{aligned}
$$

In the case of regular substrate variables of valency $d$ and dimension $n$, the cardinality of the limited-tuple-derived-dimension contracted decrementing linear non-overlapping fuds is

$$
\begin{aligned}
&\left|\mathcal{F}_{U, \mathrm{n},-, K, \mathrm{~m} \max }\right| \\
&=\sum a p: m \in\{1 \ldots \operatorname{mmax}\},(M, a) \in \operatorname{sscd}(k, m), R=\operatorname{reg}(d, M), \\
& L\left(\operatorname{subpaths}(\{((1, R), \operatorname{tdeccd}(1, R))\}),(p, \cdot)=L_{|L|}\right.
\end{aligned}
$$

where $k=|K|$.
The limited-layer limited-tuple-derived-dimension limited-underlying-volume limited-breadth contracted decrementing linear non-overlapping fuds infinitelayer fud tree tfifdnmubh $(U)(V)$, is defined with the set of strong limited-tuple-derived-dimension contracted decrementing linear non-overlapping fuds, $\mathcal{F}_{U, \mathbf{n},-, K, \text { mmax }}$. These exclude the empty transform, $(\emptyset, \emptyset)$, and the unary partition transform, $\left\{\emptyset^{\mathrm{CS}}\right\}^{\mathrm{T}}$. The finite set of strong limited-models nonoverlapping infinite-layer substrate fuds is

$$
\begin{aligned}
& \left\{F: F \in \mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}},\left\{\emptyset^{\mathrm{CS}}\right\}^{\mathrm{T}} \notin F\right\}= \\
& \quad\left\{F^{\prime}: M \in \operatorname{subpaths}(\text { tifdnmubh }(U)(V)), F^{\prime}=\operatorname{explode}\left(M_{|M|}\right), \operatorname{nd}\left(F^{\prime}\right)\right\}
\end{aligned}
$$

The application of the maximum layer limit is applied to the position in the tree path, $h \leq \operatorname{lmax}$, rather than constraining the layer cardinality of the fuds, because the contracted decrementing linear non-overlapping fuds are purely a means of construction and so could be flattened to a single layer, $\operatorname{layer}\left(\left\{H^{\mathrm{T}}\right\}, \operatorname{der}\left(\left\{H^{\mathrm{T}}\right\}\right)\right)=1$ where $H \in \mathcal{F}_{U, \mathrm{n},-, K}$. That is, the decrementing notionally takes place within each layer.

Similarly to the case (i) of the limited-layer limited-underlying-volume limitedbreadth partition infinite-layer fud tree, $\operatorname{tfiubh}(U)(V)$, and the case (ii) of the limited-layer limited-underlying-volume limited-breadth contracted nonoverlapping substrate transform infinite-layer fud tree, tfitnubh $(U)(V)$, above,
a finite computer $I_{\mathrm{tfifdnq}} \in$ computers can be defined such that its application to the substrate variables, $V$, constructs the strong subset of the limitedmodels non-overlapping infinite-layer substrate fuds, $I_{\text {tfifdnq }}^{*}(V) \subseteq \mathcal{F}_{\infty, U, V} \cap$ $\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$, by traversing the finite limited-layer limited-tuple-derived-dimension limited-underlying-volume limited-breadth contracted decrementing linear nonoverlapping fuds infinite-layer fud tree, tfifdnmubh $(U)(V)$, such that all paths are searched in sequence. The cardinality of the contracted decrementing linear non-overlapping fuds searched list is greater than or equal to the cardinality of the contracted non-overlapping substrate transform searched list which in turn is greater than or equal to the cardinality of the partition transform searched list,

$$
\begin{aligned}
|\operatorname{subpaths}(\operatorname{tfifdnmubh}(U)(V))| & \geq|\operatorname{subpaths}(\operatorname{tfitnub}(U)(V))| \\
& \geq|\operatorname{subpaths}(\operatorname{tfiubh}(U)(V))|
\end{aligned}
$$

so the computation time must be greater than or equal to that of the previous cases, $I_{\text {tfifdnq }}^{\mathrm{t}}(V) \geq I_{\text {tfitnq }}^{\mathrm{t}}(V) \geq I_{\text {tfinq }}^{\mathrm{t}}(V)$.

For the first layer, $F=\emptyset$, the cardinality of the set of next layer fuds is

$$
\begin{aligned}
& \mid\left\{Q: Q \subseteq\left\{H: K \subseteq V,\left|K^{\mathrm{C}}\right| \leq \operatorname{xmax}, H \in \mathcal{F}_{U, \mathrm{n},-, K, \operatorname{mmax}}\right\},\right. \\
& =\left(\sum_{b \in\{0 \ldots \mathrm{bmax}}\binom{c}{b}\right): \\
& \left.c=\sum p \mid \leq \operatorname{bmax} / \operatorname{mmax}\right\} \mid \\
& \quad p: K \subseteq V,\left|K^{\mathrm{CS}}\right| \leq \operatorname{xmax}, \\
& m \in\{1 \ldots \operatorname{mmax}\}, Y \in \mathrm{~S}(K, m), \\
& \quad L \in \operatorname{subpaths}\left(\operatorname{tdeccd}(U)\left(\left\{J^{\mathrm{CS}\{ \}}: J \in Y\right\}\right)\right),(p, \cdot)=L_{|L|}
\end{aligned}
$$

In the case of pluri-valent regular substrate variables, having dimension $k=$ $|K|$ and valency $d>1$, if the implied underlying-dimension limit, $\mathrm{kmax}=$
$\ln x \max / \ln d$, is integral, $\ln \mathrm{xmax} / \ln d \in \mathbf{N}$, the cardinality is

$$
\begin{aligned}
& \mid\left\{Q: Q \subseteq\left\{H: K \subseteq V,\left|K^{\mathrm{C}}\right| \leq \mathrm{xmax}, H \in \mathcal{F}_{U, \mathrm{n},-, K, \operatorname{mmax}}\right\},\right. \\
& =\left(\sum_{b \in\left\{0 \ldots \frac{\mathrm{bmax}}{\operatorname{mmax}}\right\}}\binom{c}{b}\right): \\
& c=\sum_{k \in\{0 \ldots \operatorname{kmax}\}}\binom{n}{k}\left(\sum a p:\right. \\
& \quad m \in\{1 \ldots \operatorname{mmax} / \operatorname{mmax}\} \mid \\
& \left.\quad L \in \operatorname{subpaths}(\{((1, R), \operatorname{tdeccd}(1, R))\}),(p, \cdot)=L_{|L|}\right)
\end{aligned}
$$

For higher layers, $F \neq \emptyset$, the cardinality of the set of next layer fuds is

$$
\begin{aligned}
& \mid\left\{Q: Q \subseteq\left\{H: K \in \operatorname{tuples}(V, F),\left|K^{\mathrm{C}}\right| \leq \mathrm{xmax}, \quad H \in \mathcal{F}_{U, \mathrm{n},-, K, \operatorname{mmax}}\right\},\right. \\
& \quad 1 \leq|Q| \leq \mathrm{bmax} / \operatorname{mmax}\} \mid \\
& =\left(\sum_{b \in\left\{0 \ldots \frac{\text { max }}{m \max }\right\}}\binom{c}{b}\right): \\
& c=\sum p: K \subseteq W, K \cap X \neq \emptyset,\left|K^{\mathrm{CS}}\right| \leq \mathrm{xmax}, \\
& \quad m \in\{1 \ldots \operatorname{mmax}\}, Y \in \mathrm{~S}(K, m), \\
& \quad L \in \operatorname{subpaths}\left(\operatorname{tdeccd}(U)\left(\left\{J^{\mathrm{CS}\{ \}}: J \in Y\right\}\right)\right),(p, \cdot)=L_{|L|}
\end{aligned}
$$

where $W=\operatorname{vars}(F) \cup V$ and $X=\operatorname{der}(F)$.
In the case of regular substrate variables $V$ and regular fud variables $\operatorname{vars}(F) \backslash$ $V$, having valency $d$, dimension $q=|W|$ and intersecting dimension $x=|X|$, the cardinality is

$$
\begin{aligned}
& \mid\left\{Q: Q \subseteq\left\{H: K \in \operatorname{tuples}(V, F),\left|K^{\mathrm{C}}\right| \leq \mathrm{xmax}, \quad H \in \mathcal{F}_{U, \mathrm{n},-, K, \operatorname{mmax}}\right\},\right. \\
& 1 \leq|Q| \leq \mathrm{bmax} / \operatorname{mmax}\} \mid \\
& =\left(\sum_{b \in\left\{0 \ldots \frac{\operatorname{bmax}}{\operatorname{mmax}}\right\}}\binom{c}{b}\right): \\
& c=\sum_{k \in\{1 \ldots \mathrm{kmax}\}}\left(\binom{q}{k}-\binom{q-x}{k}\right)\left(\sum a p:\right. \\
& m \in\{1 \ldots \operatorname{mmax}\},(M, a) \in \operatorname{sscd}(k, m), R=\operatorname{reg}(d, M), \\
& \left.\quad L \in \operatorname{subpaths}(\{((1, R), \operatorname{tdeccd}(1, R))\}),(p, \cdot)=L_{|L|}\right)
\end{aligned}
$$

### 4.22.2 Practicable shuffles

The application, $I_{z, \mathrm{p}}^{*}(A)$, of a substrate histogram $A \in \mathcal{A}_{z}$ in a practicable inducer $I_{z, \mathrm{p}} \in \operatorname{inducers}(z)$ requires that the histogram be practicably representable. For example, substrate histogram, A, may have a binary map histogram representation such that $I_{z, \mathrm{p}}^{\mathrm{s}}(A) \leq$ smax where the maximum space limit is smax $\in \mathbf{N}_{>0}$. In this case the representation space depends on the effective volume, $\left|A^{\mathrm{F}}\right|$.

In some cases the computation of the independent histogram, $A^{\mathrm{X}}$, may be impracticable because the effective volume, $\left|A^{\mathrm{XF}}\right|=v=\left|V_{A}^{\mathrm{C}}\right|$, is too large for available resources, for example, if $v>$ smax. If this is the case, the computation of the alignment of the histogram, $\operatorname{algn}(A)$, is also impracticable, for example $I_{\mathrm{a}}^{\mathrm{s}}(A)>\operatorname{smax}$. Consider the case where any subset of the cartesian, $A^{\mathrm{C}}$, of cardinality equal to the size, $\left\{B: B \subseteq A^{\mathrm{C}}\right.$, $\left.\operatorname{size}(B)=z\right\}$, is practicably representable. In this case of practicable size, a practicable inducer may use a shuffled histogram as a proxy for the independent histogram. For example, given some substrate transform $T \in \mathcal{T}_{U_{A}, V_{A}}$, the computation of the content alignment, $\operatorname{algn}(A * T)-\operatorname{algn}\left(A^{\mathrm{X}} * T\right)$, may be approximated by the computation of $\operatorname{algn}(A * T)-\operatorname{algn}(B * T)$, where the shuffled histogram, $B$, approximates to the independent, $B \approx A^{\mathrm{X}}$, and the effective volume is practicable, $\left|B^{\mathrm{F}}\right| \leq z$.

Section 'Shuffled history', above, defines the function shuffles $\in \mathcal{H} \rightarrow \mathrm{P}(\mathcal{H})$. Let the set of shuffled histories of the substrate histogram $A \in \mathcal{A}_{z}$ be $Q=$ $\operatorname{shuffles}($ history $(A)) \subset \mathcal{H}$. The independent of each of the shuffled histories is equal to that of the independent histogram, $\forall G \in Q \diamond B=\operatorname{his}(G)\left(B^{\mathrm{X}} \equiv A^{\mathrm{X}}\right)$, where his $=$ histogram. If the independent is integral, $A \in \mathcal{A}_{z, \mathrm{xi}}$, there must exist independent shuffles, $\exists G \in Q \diamond B=\operatorname{his}(G)\left(B=A^{\mathrm{X}}\right)$. In this case, there exist shuffles having zero alignment, $\exists G \in Q \diamond B=\operatorname{his}(G)(\operatorname{algn}(B)=$ $0)$.

As shown above in section 'Minimum alignment', the logarithm expected exponential alignment given distribution histogram of $A^{\mathrm{X}}$ is

$$
\begin{aligned}
& \ln \operatorname{expected}\left(\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)\right)\left(\left\{(B, \exp (\operatorname{algn}(B))): B \in \mathcal{A}_{U_{A}, \mathrm{i}, V_{A}, z}\right\}\right)= \\
& \ln \sum_{B \in \mathcal{A}_{U_{A}, i, V_{A}, z}} \operatorname{mpdf}\left(U_{A}\right)\left(A^{\mathrm{x}}, z\right)\left(B^{\mathrm{x}}\right)
\end{aligned}
$$

and that the expected alignment in the case where the independent is cartesian, $A^{\mathrm{X}}=\operatorname{scalar}(z / v) * V_{A}^{\mathrm{C}}$, is such that

$$
\begin{aligned}
& \operatorname{expected}\left(\hat{Q}_{\mathrm{m}, U_{A}}\left(V^{\mathrm{C}}, z\right)\right)\left(\left\{(B, \operatorname{algn}(B)): B \in \mathcal{A}_{U_{A}, \mathrm{i}, V_{A}, z}\right\}\right) \\
& \quad \leq \ln (z+v-1)!-\ln (v-1)!-v \ln (z / v)!-z \ln v
\end{aligned}
$$

where $v=\left|V_{A}^{\mathrm{CS}}\right|$. So conjecture that the expected alignment of the shuffled histories is also approximately subject to the same inequality,

$$
\begin{aligned}
& \text { average }(\{(G, \operatorname{algn}(B)): G \in Q, B=\operatorname{his}(G)\}) \\
& \quad \leq \ln (z+v-1)!-\ln (v-1)!-v \ln (z / v)!-z \ln v
\end{aligned}
$$

If $z \ll v$ then the expression above approximates to $z \ln (v / z)$. In the case of a regular volume of dimension $n$ and valency $d$, the expected alignment approximates to $z n \ln \left(d / z^{1 / n}\right)$. This may be compared to the maximum alignment which approximates to $z(n-1) \ln (d)$. So in this case, the inequality imposes little or no constraint. That is, if the volume, $v$, is impracticable, but the size, $z$, is practicable, the inequality above is not a practicable test of a randomly chosen shuffle histogram that ensures that its alignment does not exceed the expected alignment. In any case the computation of the alignment of the shuffle histogram is impracticable.

Even so, a practicable inducer may be implemented without guarantee that a randomly chosen shuffle histogram has an alignment that is small. Choose a shuffle histogram at random, $L_{r}$, where $X \in$ enums(shuffles(history $\left.(A)\right)$ ), $L=\operatorname{map}(\operatorname{his}, \operatorname{flip}(X)), r \in\left\{1 \ldots z!^{n}\right\}$ and $n=\left|V_{A}\right|$. The randomly chosen shuffle histogram, $L_{r}$, is expected to have alignment that is near zero with respect to maximum alignment, $\operatorname{algn}\left(L_{r}\right) \approx \operatorname{expected}\left(\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)\right)(\{(B, \operatorname{algn}(B))$ : $\left.\left.B \in \mathcal{A}_{U_{A}, \mathrm{i}, V_{A}, z}\right\}\right) \approx 0=\operatorname{algn}\left(A^{\mathrm{X}}\right)$. As the size, $z$, increases, the alignment, $\operatorname{algn}\left(L_{r}\right)$, decreases. Note that the computation of the alignment of the shuffle histogram, algn $\left(L_{r}\right)$, is impracticable.

The confidence in the shuffle histogram may be increased in a practicable inducer, $I_{z, \mathrm{p}}$, by scaling the sum of shuffle histograms, $B=\operatorname{scalar}(1 /|R|) *$ $\sum_{r \in R} L_{r}$, where $R \subset\left\{1 \ldots z!^{n}\right\}$ and $R \neq \emptyset$. Note that the scaled shuffle histogram, $B$, is not necessarily integral. The effective volume of the scaled shuffle histogram is greater than or equal to the effective volume of the contributing shuffle histograms, $\forall r \in R\left(\left|B^{\mathrm{F}}\right| \geq\left|L_{r}^{\mathrm{F}}\right|\right)$. If all possible shuffle histograms are used the resultant scaled shuffle histogram is the independent, $\operatorname{scalar}\left(1 / z!^{n}\right) * \sum_{r \in\left\{1 \ldots z!^{n}\right\}} L_{r}=A^{\mathrm{X}}$.

In addition, the alignment of the scaled shuffle histogram, $B$, may be tested for practicable subsets of the substrate. Choose the largest substrate subset cardinality $k \leq n$ such that the computation of the combinations, $\sum_{i \in\{1 \ldots k\}} n^{i} / i!=$ $|\{K: K \subseteq V,|K| \leq k\}|$, of reduced alignments is practicable. Then the highest reduced alignment is $\operatorname{maxr}(\{(K, \operatorname{algn}(B \% K)): K \subseteq V,|K| \leq k\})$.

### 4.22.3 Optimisation

In order to find lower bounds on the computation time and space of implementations of the derived alignment valency-density non-overlapping fud inducer, $I_{z, \mathrm{~d}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, given substrate histogram $A \in \mathcal{A}_{z}$, section 'Substrate models computation', above, considers the computation of the substrate models, $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$, by explicitly defining the (i) limited-models constraints, and (ii) layer-ordered limited-underlying limited-breadth infinitelayer substrate fuds trees. Together these constrain the computation to be a two stage process of (i) computation of finite search lists of the limitedlayer limited-underlying limited-breadth infinite-layer substrate fuds $N_{A} \in$ $\mathcal{L}\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}\right)$, where flip $\left(N_{A}\right) \in \operatorname{enums}\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}\right)$, and (ii) filtering subsequently applied to the search lists, set(filter(nd, $\left.N_{A}\right)$ ) $=$ $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$ where $\operatorname{nd}(F)=\neg \operatorname{overlap}(F) \wedge\left(\left|W^{\mathrm{C}}\right| \leq \operatorname{wmax}: W=\right.$ $\operatorname{der}(F))$.

In particular, the section 'Substrate models computation' defines these searches of the limited-models non-overlapping infinite-layer substrate fuds, $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap$ $\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$ : (i) the limited-layer limited-underlying-volume limited-breadth partition infinite-layer fud tree, $\operatorname{tfiubh}(U)(V) \in \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}}\right)$, which constructs the layer-ordered fuds from sets of partition transforms of the tuple, $\left\{P^{\mathrm{T}}\right.$ : $\left.P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}$, and (ii) the limited-layer limited-underlying-volume limitedbreadth contracted non-overlapping substrate transform infinite-layer fud tree, tfitnubh $(U)(V) \in \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$, which constructs the fuds with non-overlapping substrate transforms of the tuples, $\mathcal{T}_{U, K, \mathrm{n}}$.

Also defined are these strong limited-models non-overlapping infinite-layer substrate fuds searches: (iii) the limited-layer limited-tuple-derived-dimension limited-underlying-volume limited-breadth contracted non-overlapping substrate transform infinite-layer fud tree, $\operatorname{tfitnmubh}(U)(V) \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$, for which there is a non-trivial computation of the regular substrate cardinalities, and (iv) the limited-layer limited-tuple-derived-dimension limited-underlying-volume limited-breadth contracted decrementing linear non-overlapping fuds infinitelayer fud tree tfifdnmubh $(U)(V) \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$, which constructs the fuds with strong limited-tuple-derived-dimension contracted decrementing linear
non-overlapping fuds, $\mathcal{F}_{U, \mathrm{n},-, K, \operatorname{mmax}}$, on the tuples.
The section also defines searches which are restricted to subsets of the strong limited-models non-overlapping infinite-layer substrate fuds: (v) the limitedlayer limited-derived-volume limited-underlying-volume limited-breadth partition infinite-layer fud tree, $\operatorname{tfiubhd}(U)(V) \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}}\right)$, which constructs the layer-ordered fuds from tuple partition transforms but constrains the derived volume of the fuds, and (vi) the limited-layer limited-underlying-volume limited-breadth contracted recursively non-overlapping pluri-derived-variate substrate transform infinite-layer fud tree, $\operatorname{tfiptrnubh}(U)(V) \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$, in which the fuds are constructed with non-overlapping substrate transforms of the tuples that are recursively non-overlapping in the dependent fud.

In the case where the computation time and space requirements exceed available resources, a practicable inducer implementation of the derived alignment valency-density non-overlapping fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, must choose a subset of the substrate models. That is, (i) computation time limits imply that only a searched selection select $\left(T_{A}, N_{A}\right) \in \mathcal{L}\left(\operatorname{set}\left(N_{A}\right)\right)$, where $T_{A} \subset$ $\left\{1 \ldots\left|N_{A}\right|\right\}$, of the traversable list $N_{A}$ may be computed, and (ii) computation space limits imply that only a further subset $\operatorname{select}\left(S_{A}(t), N_{A}\right)$, where $S_{A}(t) \subset T_{A}$, of these may be simultaneously represented at any step $t$ of the computation.

Given that a selection of the traversable search list, $N_{A}$, is necessary in some circumstances, the choice of selection can be made according to various criteria. Let $P \in \mathcal{L}(\mathcal{X})$ be a tuple of parameters. Consider a practicable derived alignment valency-density non-overlapping fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, P}^{\prime}$, which, given substrate histogram $A \in \mathcal{A}_{z}$, is defined such that the substrate models of its application is a subset of that of the derived alignment valency-density non-overlapping fud inducer, $\operatorname{dom}\left(I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, P}^{\prime *}(A)\right) \subseteq \operatorname{dom}\left(I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)\right)$. That is,

$$
\begin{aligned}
& I_{z, \mathrm{ad}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}, P}^{\prime *}(A) \subseteq \\
& \quad\left\{\left(F, I_{\mathrm{a}}^{*}\left(A * F^{\mathrm{T}}\right) / I_{\mathrm{cvl}}^{*}(F)\right): F \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right\}
\end{aligned}
$$

where $I_{\text {cvl }}^{*}(F):=\left(I_{\approx \text { pow }}^{*}((w, 1 / m)): W=\operatorname{der}(F), w=\left|W^{\mathrm{C}}\right|, m=|W|\right)$, and the power approxer $I_{\approx \text { pow }} \in$ computers, is such that (i) domain $\left(I_{\approx \text { pow }}\right)=$ $\mathbf{Q} \times \mathbf{Q}$, (ii) range $\left(I_{\approx \text { pow }}\right)=\mathbf{Q}$, and (iii) $I_{\approx \text { pow }}^{*}((x, y)) \approx x^{y}$. The practicable fud inducer is defined in terms of the alignmenter, $I_{\mathrm{a}}$, and the power approxer, $I_{\approx \text { pow }}$, and so the application approximates to the application of the tractable fud inducer, $I_{\mathrm{a}}^{*}\left(A * F^{\mathrm{T}}\right) / I_{\mathrm{cvl}}^{*}(F) \approx I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}\left(A * F^{\mathrm{T}}\right) / \operatorname{cvl}(F)\right)$.

Let the practicable inducer have (i) computation time limit $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, P}^{\prime \mathrm{P}}(A) \leq$ tmax, where the maximum time limit is $\operatorname{tmax} \in \mathbf{N}_{>0}$, and (ii) computation space limit $I_{z, \text { ad, } \mathrm{F}, \propto, \mathrm{n}, \mathrm{q}, P}^{\prime}(A) \leq$ smax, where the maximum space limit is smax $\in \mathbf{N}_{>0}$. These limits are parameters of the practicable inducer, tmax, $\operatorname{smax} \in \operatorname{set}(P)$.

In some cases the computation time and space limits will be such that the application of the practicable inducer will be a proper subset of the application of its corresponding tractable inducer, $\left|I_{z, \text { ad, }, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, P}^{\prime *}(A)\right|<\left|I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)\right|$. This would be the case, for example, if $\left|I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}(A)\right|>\operatorname{tmax}$. If it is also the case that the maximum substrate models are excluded from the practicable inducer, $\operatorname{dom}\left(I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, P}^{\prime *}(A)\right) \cap \operatorname{maxd}\left(I_{z, \mathrm{~d}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)\right)=\emptyset$, then the correlation between the maximum functions must be less than one, $\operatorname{corr}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, P}^{\prime *}\right)<1$. The following sections consider various definitions of practicable inducers having different selection criteria and the effect on the correlation of the maximum functions between the practicable inducer and the corresponding tractable inducer.

Consider an implementation of a practicable fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, P}^{\prime}$, which, given substrate histogram $A \in \mathcal{A}_{z}$, optimises its subset of the limitedmodels non-overlapping infinite-layer substrate fuds, $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$, by first optimising the limited-layer limited-underlying limited-breadth infinitelayer substrate fuds, $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}$, and then filtering for the limited-derived non-overlapping, $\mathcal{F}_{\mathrm{d}} \cap \mathcal{F}_{\mathrm{n}}$. The optimisation is implemented by means of a list maximiser. See appendix 'Search and optimisation' for a definition of list maximisers. The maximisation is of a rational-valued lefttotal optimise function $X_{P, A, \text { ad }}$ of the limited-layer limited-underlying limitedbreadth infinite-layer substrate fuds, $X_{P, A, \text { ad }} \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathbf{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}: \rightarrow$ Q. Given (i) maximum optimise step cardinality omax $\in \mathbf{N}_{>0}$, such that omax $<$ tmax, (ii) initial subset $R_{P, A, \text { ad }} \subset X_{P, A, \text { ad }}$, and (iii) neighbourhood function $P_{P, A, \text { ad }} \in \mathrm{P}\left(X_{P, A, \text { ad }}\right) \rightarrow \mathrm{P}\left(X_{P, A, \text { ad }}\right)$, the list maximiser $Z_{P, A, \text { ad }} \in$ maximisers ( $X_{P, A, \text { ad }}$ ) is constructed

$$
Z_{P, A, \text { ad }}=\operatorname{maximiseLister}\left(X_{P, A, \mathrm{ad}}, P_{P, A, \mathrm{ad}}, \operatorname{top}(\max ), R_{P, A, \mathrm{ad}}\right)
$$

The cardinality of the elements of the list maximiser is constrained by the maximum optimise step cardinality,

$$
\left|\operatorname{elements}\left(Z_{P, A, \text { ad }}\right)\right| \leq \operatorname{omax} \times\left|\operatorname{list}\left(Z_{P, A, \text { ad }}\right)\right|
$$

where elements $(Z):=\bigcup \operatorname{set}(\operatorname{list}(Z))$. Note that strictly speaking this is true only in the case where cardinality of the top(omax) function in each step is
less than or equal to omax, $\forall Y \in \operatorname{set}\left(\operatorname{list}\left(Z_{P, A, \mathrm{ad}}\right)\right)\left(Y \in \operatorname{dom}\left(X_{P, A, \mathrm{ad}}\right) \leftrightarrow\right.$ $\mathbf{Q} \Longrightarrow|Y| \leq$ omax).

Given (iv) that the neighbourhood function, $P_{P, A, \text { ad }}$, is further constrained such that it terminates before the maximum time limit, the cardinality of the searched set is such that

$$
\left|\operatorname{elements}\left(Z_{P, A, \mathrm{ad}}\right)\right| \leq\left|\operatorname{searched}\left(Z_{P, A, \mathrm{ad}}\right)\right|<\operatorname{tmax}
$$

where $\operatorname{searched}(Z):=\bigcup\{P(Y): Y \in \operatorname{set}(\operatorname{list}(Z))\} \cup R$.
The domain of the elements of the list maximiser is a subset of the limitedlayer limited-underlying limited-breadth infinite-layer substrate fuds,

$$
\operatorname{dom}\left(\operatorname{elements}\left(Z_{P, A, \mathrm{ad}}\right)\right) \subset \operatorname{dom}\left(X_{P, A, \mathrm{ad}}\right)=\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}
$$

The subset of the substrate fuds is the further subset

$$
\text { filter }\left(\operatorname{nd}, \operatorname{dom}\left(\operatorname{elements}\left(Z_{P, A, \text { ad }}\right)\right)\right) \subset \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}
$$

So the domain of the searched set is the subset of the limited-layer limitedunderlying limited-breadth infinite-layer substrate fuds search list,

$$
\operatorname{dom}\left(\operatorname{searched}\left(Z_{P, A, \mathrm{ad}}\right)\right)=\operatorname{set}\left(\operatorname{select}\left(T_{A}, N_{A}\right)\right)
$$

where $\operatorname{flip}\left(N_{A}\right) \in \operatorname{enums}\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathbf{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}\right)$ and $T \subset\left\{1 \ldots\left|N_{A}\right|\right\}$.
The practicable inducer is implemented

$$
\begin{aligned}
& I_{z, \mathrm{ad}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}, P}^{\prime *}(A)= \\
& \quad\left\{\left(F, I_{\mathrm{a}}^{*}\left(A * F^{\mathrm{T}}\right) / I_{\mathrm{cvl}}^{*}(F)\right): F \in \operatorname{filter}\left(\mathrm{nd}, \operatorname{dom}\left(\operatorname{elements}\left(Z_{P, A, \mathrm{ad}}\right)\right)\right)\right\}
\end{aligned}
$$

The fuds optimise function, $X_{P, A, \text { ad }}$, cannot be simply a derived alignment valency-density function, $X_{P, A, \mathrm{ad}} \neq\left\{\left(F, I_{\mathrm{a}}^{*}\left(A * F^{\mathrm{T}}\right) / I_{\mathrm{cv1}}^{*}(F)\right): F \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap\right.$ $\left.\mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}\right\}$, because the fuds are not necessarily non-overlapping nor limited-derived, $\operatorname{nd}(F)$, where $F \in \operatorname{dom}\left(X_{P, A, \mathrm{ad}}\right)$. That is, if the fud is overlapping then the derived alignment may, for example, be purely formal, $\operatorname{algn}\left(A * F^{\mathrm{T}}\right)=\operatorname{algn}\left(A^{\mathrm{X}} * F^{\mathrm{T}}\right)$. This would be the case if the fud was tautological, tautology $\left(F^{\mathrm{T}}\right)$, which is allowed in the infinite-layer fuds, $\mathcal{F}_{\infty, U_{A}, V_{A}}$. Also, if the derived volume of the fud exceeds the maximum derived volume limit, $\left|W^{\mathrm{C}}\right|>$ wmax, the computation of the independent derived, $\left(A * F^{\mathrm{T}}\right)^{\mathrm{X}}$,
necessary to compute the derived alignment, $\operatorname{algn}\left(A * F^{\mathrm{T}}\right)$, may be impracticable. However it is defined, the fuds optimise function, $X_{P, A, \text { ad }}$, is constrained such that the practicable fud inducer is positively correlated with the tractable fud inducer,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{ad}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{ad}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}, P}^{\prime *}\right) \geq 0\right)
$$

even if the fuds neighbourhood function, $P_{P, A, \text { ad }}$, is purely arbitrary. In this way, the practicable fud inducer transitively satisfies the requirement that the maximum functions of inducers are positively correlated with the finite alignment-bounded iso-transform space ideal transform maximum function, $\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ I_{z, \mathrm{ad}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}, P}^{\prime *}\right) \geq 0\right)
$$

The fuds neighbourhood function, $P_{P, A, \text { ad }}$, is considered to be arbitrary if the maximiser gain is zero, $\operatorname{optimum}\left(Z_{P, A, \text { ad }}\right)=\operatorname{arbitrary}\left(Z_{P, A, \text { ad }}\right)$, where $\operatorname{optimum}(Z):=\operatorname{maxr}(\operatorname{elements}(Z))$ and $\operatorname{arbitrary}(Z):=\operatorname{average}(\{(Y, \operatorname{maxr}(Y)):$ $Y \subseteq X,|Y|=|\operatorname{searched}(Z)|\})$. If the gain of the neighbourhood function is greater than zero, $\operatorname{optimum}\left(Z_{P, A, \text { ad }}\right)>\operatorname{arbitrary}\left(Z_{P, A, \text { ad }}\right)$, then the correlation of the maximum functions, $\operatorname{cov}(z)\left(\operatorname{maxro}_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}, \operatorname{maxro} I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, P}^{\prime *}\right)$, may be higher than would otherwise be the case. The discussion below considers various limited-layer limited-underlying limited-breadth infinite-layer substrate fud optimise functions and neighbourhood functions.

An optimisation of the two stage computation of the substrate models, $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$, must (i) first compute a possibly overlapping fuds subset of the limited-layer limited-underlying limited-breadth infinite-layer substrate fuds, $\operatorname{select}\left(T_{A}, N_{A}\right) \subset \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}$, and (ii) then compute a nonoverlapping fuds subset of these by filtering, $\left\{F: F \in \operatorname{select}\left(T_{A}, N_{A}\right), \operatorname{nd}(F)\right\} \subset$ $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$. In some definitions of the optimisation, computation time and space limits may constrain the cardinality of the possibly overlapping fuds, $\left|\operatorname{select}\left(T_{A}, N_{A}\right)\right|$, such that none are non-overlapping. That is, computational resources may be such that the filtered subset is empty, $\{F: F \in$ $\left.\operatorname{select}\left(T_{A}, N_{A}\right), \operatorname{nd}(F)\right\} \subset\left\{F: F \in \operatorname{select}\left(T_{A}, N_{A}\right), \neg \operatorname{overlap}(F)\right\}=\emptyset$. In this case, the maximum function of a practicable inducer would be undefined, $\max \left(I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, P}^{\prime *}(A)\right)=\emptyset$.

A fud, $F$, must be pluri-derived-variate, $|\operatorname{der}(F)|>1$, if the derived alignment is non-zero, $\operatorname{algn}\left(A * F^{\mathrm{T}}\right)>0$. Let $F \in \mathcal{F}_{U_{A}, \mathrm{P} *}$ be a topped recursively nonoverlapping contracted pluri-derived-variate multi-partition fud such that its explode is a non-overlapping substrate fud, explode $(F) \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}}$. That
is, the fud, $F$, is subject to (i) contracted transforms, $\forall T \in F\left(T=T^{\%}\right)$, (ii) pluri-partition transforms, $\forall T \in F(|\operatorname{der}(T)|>1)$, (iii) recursively nonoverlapping, $\forall T \in F(\neg$ overlap(depends(explode $(F)$, $\operatorname{der}(T)))$ ), (iv) topped, $\exists T \in F(\operatorname{der}(T)=\operatorname{der}(F))$, and (v) underlying variables are in the substrate, $\operatorname{und}(F) \subseteq V_{A}$. Then the cardinality of the substrate $n=\left|V_{A}\right|$ implies a maximum layer, layer $(F, \operatorname{der}(F)) \leq\left\lfloor\log _{2}(n)\right\rfloor$, and a minimum substrate cardinality, $n \geq 2$. Thus the maximum layer limit is itself limited, $\operatorname{lmax} \leq\left\lfloor\log _{2}(n)\right\rfloor$, where maximum function is non-zero and the topped recursively non-overlapping fud does not contain mono-partition transforms.

Let fud, $F$, be further subject to (vi) bi-underlying-variate transforms, $\forall T \in$ $F(|\operatorname{und}(T)|=2)$, (vii) bi-partition transforms, $\forall T \in F(|\operatorname{der}(T)|=2)$, (viii) the fud layer is $l=\operatorname{layer}(F, \operatorname{der}(F))=\log _{2}(n) \in \mathbf{N}_{>0}$, and (ix) the cardinality of the set of bi-partition transforms in each layer is $n / 2^{i}$ where $i \in\{1 \ldots l\}$. The cardinality of all such topped recursively non-overlapping bi-underlyingvariate bi-partition linear fuds is less than $n!^{l / 2}$. The cardinality of possibly overlapping linear fuds similarly constrained is less than $n^{n l / 2}$. The fraction that are non-overlapping may be compared to $\left(n!/ n^{n}\right)^{l / 2}$. This fraction is less than $10^{-6}$ where $n=16$. In fact, the limited-layer limited-underlying limited-breadth infinite-layer multi-partition fuds are only constrained such that there no more than maximum breadth limit, bmax, transforms in each layer, rather than $n / 2^{i}$, so the constraint on the cardinality is greater than $n^{\mathrm{bmax} \times l / 2}$. That is, if $\operatorname{bmax}>n$, the fraction of the possibly overlapping optimised fuds that are non-overlapping may be compared to the smaller fraction, $\left(n!/ n^{\text {bmax }}\right)^{l / 2}$.

A possible solution is to constrain the optimisation to construct only recursively non-overlapping pluri-partition fuds corresponding to limited-layer limited-underlying limited-breadth infinite-layer substrate fuds, $\operatorname{select}\left(T_{A}, N_{A}\right) \subset$ $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}$. For example, section 'Substrate models computation' defines the limited-layer limited-underlying-volume limited-breadth contracted recursively non-overlapping pluri-derived-variate substrate transform infinite-layer fud tree, $\operatorname{tfiptrnubh}(U)(V) \in \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$, which is a tree of recursively non-overlapping pluri-partition fuds constructed from contracted non-overlapping substrate transforms. This tree is such that
$\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathbf{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}} \supseteq\left\{\operatorname{explode}(F): F \in \operatorname{elements}\left(\operatorname{tfiptrnubh}\left(U_{A}\right)\left(V_{A}\right)\right)\right\}$
Each of the recursively non-overlapping pluri-partition fuds

$$
F \in \operatorname{elements}\left(\operatorname{tfiptrnubh}\left(U_{A}\right)\left(V_{A}\right)\right)
$$

can be topped by choosing a transform $T$ in the top layer, $\operatorname{der}(T) \subseteq \operatorname{der}(F)$, so that $\operatorname{top}(\operatorname{depends}(F, \operatorname{der}(T)))=T$. Any such fud is necessarily nonoverlapping and is itself in the fud tree

$$
\operatorname{depends}(F, \operatorname{der}(T)) \in \operatorname{elements}\left(\operatorname{tfiptrnubh}\left(U_{A}\right)\left(V_{A}\right)\right)
$$

Thus the non-overlapping subset of the selection is not empty, $\{F: F \in$ $\left.\operatorname{select}\left(T_{A}, N_{A}\right), \neg \operatorname{overlap}(F)\right\} \neq \emptyset$, if the selection contains topped fuds. In the case where the maximum derived volume limit is greater than or equal to the maximum underlying volume limit, wmax $\geq \mathrm{xmax}$, the filtered subset is not empty, $\left\{F: F \in \operatorname{select}\left(T_{A}, N_{A}\right), \operatorname{nd}(F)\right\} \neq \emptyset$, because the top transform satisfies the limited-derived constraint.

However, in some cases only a proper subset of the substrate models, $\mathcal{F}_{\infty, U_{A}, V_{A} \cap} \cap$ $\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$, can be constructed when constrained to a top transform,

$$
\left.\left.\left.\begin{array}{rl}
\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}} \supseteq & \left\{\operatorname{explode}(F): F \in \operatorname{elements}\left(\operatorname{tfiptrnubh}\left(U_{A}\right)\left(V_{A}\right)\right),\right. \\
& (\exists T
\end{array}\right) F(\operatorname{der}(T)=\operatorname{der}(F))\right), W=\operatorname{der}(F),\left|W^{\mathrm{C}}\right| \leq \mathrm{wmax}\right\}
$$

In section 'Transform alignment', above, a definition of degree of overlap is $\operatorname{alignmentOverlap}(U)(T, z):=\operatorname{algn}\left(\operatorname{resize}\left(z, V^{\mathrm{C}}\right) * T\right)$, where $T \in \mathcal{T}_{U, \mathrm{f}, 1}$ and $V=\operatorname{und}(T)$. An optimisation method that contains only topped recursively non-overlapping multi-partition fuds may exclude a fud $F \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}$ with a small degree of overlap, algn $\left(\operatorname{resize}\left(z, V_{A}^{\mathrm{C}}\right) * F^{\mathrm{T}}\right)$, but high derived alignment, $\operatorname{algn}\left(A * F^{\mathrm{T}}\right)$. Also, some or all of the derived variables of an excluded fud, $F \notin$ elements $\left(\right.$ tfiptrnubh $\left.\left(U_{A}\right)\left(V_{A}\right)\right)$, may form the lower layers of a descendant non-overlapping fud $G \supset F$, where $\neg$ overlap $(\operatorname{explode}(G))$, subsequent in the search path.

In section 'Intractable literal substrate model inclusion', above, it is shown that the formal-abstract equality inclusion test, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{x}}$, is intractable in the literal derived alignment integral-independent substrate ideal formal-abstract transform inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, which computes the derived alignment, $\operatorname{algn}(A * T)$, for each of the formal-abstract-equal ideal substrate transforms, $\left\{T: T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}$. The discussion considers (i) first weakening it to the independent-formal constraint, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, in the derived alignment substrate ideal independentformal transform inducer, $I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}$, which computes the derived alignment, $\operatorname{algn}(A * T)$, for each of the independent-formal ideal substrate transforms, $\left\{T: T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}$, and (ii) then dropping it altogether in the content alignment substrate ideal transform inducer, $I_{z, \mathrm{c}, \mathrm{j}}^{\prime}$, which computes the content alignment, $\operatorname{algn}(A * T)-\operatorname{algn}\left(A^{\mathrm{X}} * T\right)$, for
each of the ideal substrate transforms, $\left\{T: T \in \mathcal{T}_{U_{A}, V_{A}}, A=A * T * T^{\dagger A}\right\}$. However, both (i) the independent-formal inclusion test, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, in the independent-formal inducer, $I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}$, and (ii) the formal alignment, $\operatorname{algn}\left(A^{\mathrm{X}} * T\right)$, in the content alignment inducer, $I_{z, \mathrm{c}, \mathrm{j}}^{\prime}$, remain intractable because of intractable substrate volume, $\left|A^{\mathrm{XF}}\right|=\left|V_{A}^{\mathrm{C}}\right|$. The discussion then considers the derived alignment substrate ideal non-overlapping transform inducer, $I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime}$, in which the substrate models consist only of non-overlapping transforms, $\rightarrow \operatorname{overlap}(T) \Longrightarrow A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$. That is, the derived alignment substrate ideal non-overlapping transform inducer, $I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime}$, computes the derived alignment, $\operatorname{algn}(A * T)$, for each of the ideal non-overlapping substrate transforms, $\left\{T: T \in \mathcal{T}_{U_{A}, V_{A}, \mathrm{n}}, A=A * T * T^{\dagger A}\right\}$. The discussion then proceeds to drop the ideality inclusion test, $A=A * T * T^{\dagger A}$, and consider the midisation pseudo-alignment substrate independent-formal transform inducer, $I_{z, \mathrm{~m}, \mathrm{fx}}$, and the derived alignment valency-density substrate non-overlapping transform inducer, $I_{z, \mathrm{ad}, \mathrm{n}}^{\prime}$, in order to partly recover the formal-abstract equality. The discussion eventually defines the tractable derived alignment valency-density non-overlapping fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$.

However, section 'Practicable shuffles', above, considers the use of a shuffle histogram as practicable approximation to the independent, $A^{\mathrm{X}}$. The computation of an approximation to the formal alignment, $\operatorname{algn}\left(A^{\mathrm{X}} * F^{\mathrm{T}}\right)$, is then practicable. Although there is no guarantee that a randomly chosen shuffle histogram has an alignment that is small, consider a practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, which, given substrate histogram $A \in \mathcal{A}_{z}$, is defined

$$
\begin{aligned}
& I_{z, \mathrm{csd}, \mathrm{~F}, \infty, \mathrm{q}, P}^{\prime *}(A) \subseteq \\
& \quad\left\{\left(F,\left(I_{\mathrm{a}}^{*}\left(A * F^{\mathrm{T}}\right)-I_{\mathrm{a}}^{*}\left(A_{R} * F^{\mathrm{T}}\right)\right) / I_{\mathrm{cvl}}^{*}(F)\right): F \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}\right\}
\end{aligned}
$$

The scaled shuffle histogram, $A_{R}$, is defined $A_{R}=\operatorname{scalar}(1 /|R|) * \sum_{r \in R} L_{r}$ where $X \in \operatorname{enums(shuffles(history}(A))), L=\operatorname{map}($ his, flip $(X)), R \subseteq\left\{1 \ldots z!^{n}\right\}$ and $n=\left|V_{A}\right|$. The shuffle indices, $R$, are in the practicable parameters, $R \in \operatorname{set}(P)$. The cardinality of the shuffle indices, $|R|$, is chosen such that the effective volume of the scaled shuffle histogram, $\left|A_{R}^{\mathrm{F}}\right| \leq\left|A^{\mathrm{XF}}\right|$, is practicable. In the case where the entire volume of the independent, $\left|A^{\mathrm{XF}}\right|=\left|V_{A}^{\mathrm{C}}\right|$, is practicable then $R=\left\{1 \ldots z!^{n}\right\}$ and $A_{R}=A^{\mathrm{X}}$. In this case the shuffle content alignment equals the content alignment.

The computation of the substrate models, $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}$, in the practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, still takes place in two stages but the filtering need only test for limited-derived.

That is (i) first compute the limited-layer limited-underlying limited-breadth infinite-layer substrate fuds, select $\left(T_{A}, N_{A}\right) \subset \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}$, and (ii) then compute a limited-derived subset of these by filtering, $\{F: F \in$ $\left.\operatorname{select}\left(T_{A}, N_{A}\right), W=\operatorname{der}(F),\left|W^{\mathrm{C}}\right| \leq \operatorname{wmax}\right\} \subset \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}$. In terms of an implementation with a list maximiser define

$$
Z_{P, A, A_{R}, \mathrm{csd}}=\operatorname{maximiseLister}\left(X_{P, A, A_{R}, \mathrm{csd}}, P_{P, A, A_{R}, \mathrm{csd}}, \operatorname{top}(\operatorname{omax}), R_{P, A, A_{R}, \mathrm{csd}}\right)
$$

The limited-derived is $\left\{F: F \in \operatorname{dom}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, \operatorname{csd}}\right)\right), W=\operatorname{der}(F),\left|W^{\mathrm{C}}\right| \leq\right.$ wmax $\} \subset \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}$. The fuds optimise function, $X_{P, A, A_{R}, \text { csd }}$, is related to content alignment valency-density, $\left(\operatorname{algn}\left(A * F^{\mathrm{T}}\right)-\operatorname{algn}\left(A^{\mathrm{X}} * F^{\mathrm{T}}\right)\right) / \operatorname{cvl}(F)$. However it is defined, the fuds optimise function, $X_{P, A, A_{R}, \mathrm{csd}}$, is constrained such that the practicable fud inducer is positively correlated with the tractable fud inducer,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{da}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}, \operatorname{maxr} \circ I_{z, \mathrm{csd}, \mathrm{~F}, \infty, \mathrm{q}, P}^{\prime *}\right) \geq 0\right)
$$

However, the correlation of the maximum functions between the tractable derived alignment valency-density non-overlapping fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, and an intractable content alignment valency-density fud inducer, $I_{z, \mathrm{~cd}, \mathrm{~F}, \infty, \mathrm{q}}^{\prime *}$, is imperfect,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{corr}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{ad}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{~cd}, \mathrm{~F}, \infty, \mathrm{q}}^{\prime *}\right)<1\right)
$$

where the content alignment valency-density fud inducer, $I_{z, \mathrm{~cd}, \mathrm{~F}, \infty, \mathrm{q}}^{\prime *}$, is defined

$$
\begin{aligned}
& I_{z, \mathrm{~cd}, \mathrm{~F}, \infty, \mathrm{q}}^{\prime *}(A)= \\
& \quad\left\{\left(F, I_{\approx \mathbf{R}}^{*}\left(\left(\operatorname{algn}\left(A * F^{\mathrm{T}}\right)-\operatorname{algn}\left(A^{\mathrm{X}} * F^{\mathrm{T}}\right)\right) / \operatorname{cvl}(F)\right)\right): F \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}\right\}
\end{aligned}
$$

So, depending on available computational resources, the practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, may have lower correlation than the practicable derived alignment valency-density nonoverlapping fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, P}^{\prime}$.

In some cases the computation time of the overlap test, $\neg \operatorname{overlap}(F)$, consisting of set intersection and union operations on the substrate variables, $V_{A}$, may exceed the computation time of the shuffle formal alignment, $\operatorname{algn}\left(A_{R} *\right.$ $F^{\mathrm{T}}$ ). So a practicable derived alignment valency-density non-overlapping fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}, P}^{\prime}$, which is additionally constrained to construct only non-overlapped fuds, may have a smaller searched set than the practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$.

The discussion below considers the optimisation in a practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$. The implementation of the optimisation is not restricted to a single optimiser such as the notional list maximiser $Z_{P, A, A_{R}, \mathrm{csd}}$.

Consider the limited-path-models tuple partition practicable shuffle content alignment valency-density fud inducer $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{p}}^{\prime}$ which is implemented by means of a list maximiser $Z_{P, A, A_{R}, \text { csd, } \mathrm{p}}$ that has a neighbourhood function that constructs the fuds in the layer sequence of the paths of the limitedlayer limited-derived-volume limited-underlying-volume limited-breadth partition infinite-layer fud tree, $\operatorname{tfiubhd}(U)(V) \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}}\right)$, described in section 'Substrate models computation' above. The fud tree constructs the fuds from tuple partition transforms but constrains the derived volume of the fuds by applying the limited-derived-volume constraint, $\left|W^{\mathrm{C}}\right| \leq$ wmax, at every layer, so only a subset of the limited-models infinite-layer substrate fuds is searched

$$
\mathcal{F}_{\infty, U, V} \cap \mathcal{F}_{\mathrm{q}} \supseteq \text { elements }(\operatorname{tfiubhd}(U)(V))
$$

The limited-path-models tuple partition list maximiser, $Z_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}$, is constructed

$$
\begin{aligned}
& Z_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}= \\
& \quad \text { maximiseLister }\left(X_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}, P_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}, \operatorname{top}(\mathrm{omax}), R_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}\right)
\end{aligned}
$$

The optimise function $X_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}} \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}: \rightarrow \mathbf{Q}$, is the rational approximation to the shuffle content alignment valency-density valued total function of the limited-models infinite-layer substrate fuds, defined

$$
X_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}=\left\{\left(F, I_{\mathrm{csd}}^{*}\left(\left(A, A_{R}, F\right)\right)\right): F \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}\right\}
$$

where the shuffle content alignment valency-density computer $I_{\mathrm{csd}} \in$ computers is defined as

$$
I_{\mathrm{csd}}^{*}\left(\left(A, A_{R}, F\right)\right)=\left(I_{\mathrm{a}}^{*}\left(A * F^{\mathrm{T}}\right)-I_{\mathrm{a}}^{*}\left(A_{R} * F^{\mathrm{T}}\right)\right) / I_{\mathrm{cvl}}^{*}(F)
$$

The neighbourhood function $P_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}} \in \mathrm{P}\left(X_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}\right) \rightarrow \mathrm{P}\left(X_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}\right)$, derived from the limited-layer limited-derived-volume limited-underlying-volume
limited-breadth partition infinite-layer fud tree, $\operatorname{tfiubhd}(U)(V)$, is defined

$$
\begin{aligned}
& P_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}(Q)= \\
& \quad\left\{\left(F \cup G, I_{\mathrm{csd}}^{*}\left(\left(A, A_{R}, F \cup G\right)\right)\right):\right. \\
& \quad(F, \cdot) \in Q, \operatorname{layer}(F, \operatorname{der}(F))<\operatorname{lmax}, \\
& \quad G \subseteq\left\{P^{\mathrm{T}}: K \in \operatorname{tuples}\left(V_{A}, F\right),\left|K^{\mathrm{C}}\right| \leq \operatorname{xmax}, P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right),|P| \geq 2\right\}, \\
& \quad 1 \leq|G| \leq \operatorname{bmax}, \\
& \\
& \left.W=\operatorname{der}(F \cup G),\left|W^{\mathrm{C}}\right| \leq \operatorname{wmax}\right\}
\end{aligned}
$$

The definition of the neighbourhood function is stricter than the definition of the fud tree because only pluri-valent partitions are allowed, $|P| \geq 2$. This avoids the increase in capacity caused by the addition of mono-valent variables which increase the dimension but do not affect the alignment. The pluri-valent constraint also excludes empty tuples, $K=\emptyset$, because the unary partition variable is mono-valent, $\left|\left\{\emptyset^{\mathrm{CS}}\right\}\right|=1$.

The initial function, $R_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}} \subset X_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}$, is a singleton of the empty fud, $R_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}=\{(\emptyset, 0)\}$.

Then the limited-path-models tuple partition practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{p}}^{\prime}$, is defined,

$$
I_{z, \mathrm{csd}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{p}}^{\prime *}(A)=\operatorname{elements}\left(Z_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}\right) \subseteq X_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}
$$

The fud inducer is defined without the need for filtering the elements of the list maximiser because (i) the maximisation of the shuffle content alignment tends to minimise the degree of overlap, and (ii) the list maximiser limits the fud derived volume.

The limited-derived-volume constraint means that in some cases the optimise function is not completely traversable, dom(traversable $\left.\left(Z_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}\right)\right) \subseteq$ $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}$ where traversable $(Z):=$ elements(searchLister $(X, P, R)$ ), and so the searched set is sometimes a proper subset, depending on the substrate and limits,

$$
\begin{aligned}
\operatorname{dom}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, \operatorname{csd}, \mathrm{p}}\right)\right) & \subseteq \operatorname{dom}\left(\operatorname{searched}\left(Z_{P, A, A_{R}, \operatorname{csd}, \mathrm{p}}\right)\right) \\
& \subseteq \operatorname{dom}\left(\operatorname{traversable}\left(Z_{P, A, A_{R}, \operatorname{csd}, \mathrm{p}}\right)\right) \\
& \subseteq \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}
\end{aligned}
$$

The post-application of the limited-derived-volume test implies that the computation of the cardinality of the first layer fuds and subsequent layer fuds
of a regular substrate of valency $d$ has non-deterministic time. That is, the computation requires that the set itself be explicitly constructed. For the first layer, $F=\emptyset$, the set of next layer fuds corresponds to the nonempty pluri-valent partition-sets of the intersection of (i) the lower-limitedvalency substrate partition-sets set $\mathcal{N}_{U, V, \text { umin }}$, where umin $=2$, (ii) the limited-underlying-volume substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{xmax}}$, (iii) the limitedbreadth substrate partition-sets set, $\mathcal{N}_{U, V, b m a x}$, (iv) and the limited-derivedvolume substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{wmax}}$,

$$
\begin{aligned}
& \left|P_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}(\{(\emptyset, \cdot)\})\right|= \\
& \quad\left|\mathcal{N}_{U_{A}, V_{A}, \overline{2}} \cap \mathcal{N}_{U_{A}, V_{A}, \mathrm{xmax}} \cap \mathcal{N}_{U_{A}, V_{A}, \mathrm{bmax}} \cap \mathcal{N}_{U_{A}, V_{A}, \mathrm{wmax}}\right|-1
\end{aligned}
$$

The cardinality has upper bounds equal to the cardinality of the non-empty pluri-valent partition-sets subset of the partition-sets corresponding to the first layer fuds of the limited-layer limited-underlying-volume limited-breadth partition infinite-layer fud tree, tfiubh $(U)(V)$. That is, the non-empty plurivalent partition-sets subset of the intersection of the limited-underlying-volume substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{xmax}}$, and the limited-breadth substrate partitionsets set, $\mathcal{N}_{U, V, b \max }$,

$$
\left|P_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}(\{(\emptyset, \cdot)\})\right| \leq\left|\mathcal{N}_{U_{A}, V_{A}, \overline{2}} \cap \mathcal{N}_{U_{A}, V_{A}, \mathrm{xmax}} \cap \mathcal{N}_{U_{A}, V_{A}, \operatorname{bmax}}\right|-1
$$

In the case of pluri-valent regular variables $V$, having valency $d>1$ and dimension $n$, if the implied underlying-dimension limit, $\mathrm{kmax}=\ln \mathrm{xmax} / \ln d$, is integral, $\ln x \max / \ln d \in \mathbf{N}$, then the cardinality of the intersection is

$$
\begin{aligned}
& \left|\mathcal{N}_{U, V, \overline{2}} \cap \mathcal{N}_{U, V, \operatorname{xmax}} \cap \mathcal{N}_{U, V, \mathrm{~b} \max }\right|= \\
& \left(\sum_{b \in\{0 \ldots \mathrm{bmax}\}}\binom{c}{b}\right): c=\sum_{k \in\{0 \ldots \mathrm{kmax}\}}\binom{n}{k}\left(\operatorname{bell}\left(d^{k}\right)-1\right)
\end{aligned}
$$

For higher layers, computation of the cardinality requires that the set itself be explicitly constructed for the additional reason that the constraint, $\left|W^{\mathrm{C}}\right| \leq$ wmax where $W=\operatorname{der}(F \cup G)$, depends on both the given $f u d, F$, and the next layer fud, $G$, for its determination. For higher layers where the list element of the list maximiser is a singleton of a non-empty fud $F \neq \emptyset$, for example if omax $=1$, the set of next layer fuds corresponds to a subset of (i) the lower-limited-valency substrate partition-sets set $\mathcal{N}_{U, V, \mathrm{umin}}$, where umin $=2$, (ii) the intersection of the intersecting substrate partition-sets set, $\mathcal{N}_{U, W, X}$, (iii) the limited-underlying-volume substrate partition-sets set, $\mathcal{N}_{U, W, \mathrm{xmax}}$, and (iv) the limited-breadth substrate partition-sets set $\mathcal{N}_{U, W, b m a x}$

$$
\left|P_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}(\{(F, \cdot)\})\right| \leq\left|\mathcal{N}_{U_{A}, V_{A}, \overline{2}} \cap \mathcal{N}_{U_{A}, W, X} \cap \mathcal{N}_{U_{A}, W, \mathrm{xmax}} \cap \mathcal{N}_{U_{A}, W, \mathrm{bmax}}\right|
$$

where $W=\operatorname{vars}(F) \cup V_{A}$ and $X=\operatorname{der}(F)$. In the case of regular substrate variables $V$ and regular fud variables $\operatorname{vars}(F) \backslash V$, having valency $d$, dimension $q=|W|$ and intersecting dimension $x=|X|$, such that the implied underlying-dimension limit is integral, $\mathrm{kmax}=\ln \mathrm{xmax} / \ln d \in \mathbf{N}$, the cardinality of the intersection is

$$
\begin{aligned}
& \left|\mathcal{N}_{U, V, \overline{2}} \cap \mathcal{N}_{U, W, X} \cap \mathcal{N}_{U, W, \mathrm{xmax}} \cap \mathcal{N}_{U, W, \mathrm{bmax}}\right|= \\
& \quad\left(\sum_{b \in\{0 \ldots \mathrm{bmax}\}}\binom{c}{b}\right): c=\sum_{k \in\{1 \ldots \mathrm{kmax}\}}\left(\binom{q}{k}-\binom{q-x}{k}\right)\left(\operatorname{bell}\left(d^{k}\right)-1\right)
\end{aligned}
$$

The degree of constraint imposed by the limited-underlying-volume of the tuple, $\left|K^{\mathrm{C}}\right| \leq$ xmax, depends on the maximum derived volume limit of the fud, wmax. For example, the tuple self-partition may be excluded, wmax $\leq\left|K^{\mathrm{CS}\{ \}}\right|=\left|K^{\mathrm{CS}}\right| \leq$ xmax. Similarly the degree of constraint imposed by the limited-breadth, $|G| \leq$ bmax, also depends on the maximum derived volume, wmax. For example, for implied valency of at least two, $\operatorname{bmax} \leq\lfloor\ln w \max / \ln 2\rfloor$. The limited-derived-volume constraint is weakest when the maximum derived volume is much greater than the maximum underlying volume, $\mathrm{xmax} \ll$ wmax, and the maximum breadth, $2^{\text {bmax }} \ll$ wmax. The weaker the limited-derived-volume constraint, the smaller the difference between the next layer cardinalities and the computed upper bounds. However, the maximum derived volume is sometimes restricted to be less than or equal to the sample size, wmax $<z$ where $z=\operatorname{size}(A)$, in order to avoid arguments to the unit-translated gamma function, $\Gamma_{!}$, that are less than one.

In the cases where the substrate and fud variables are not regular, the cardinalities may estimated with a regular valency equal to the geometric product of the valencies of the variables. That is, for the first layer

$$
d=\left(\prod_{v \in V_{A}}\left|U_{A}(v)\right|\right)^{1 / n}
$$

where $n=\left|V_{A}\right|$. For subsequent layers

$$
d=\left(\prod_{w \in W}\left|U_{A}(w)\right|\right)^{1 / q}
$$

where $W=\operatorname{vars}(F) \cup V_{A}$ and $q=|W|$. The implied maximum underlying dimension is $\mathrm{kmax}=\lceil\ln \mathrm{xmax} / \ln d\rceil$. If omax $>1$, the total cardinality may be estimated by summing the estimates of the cardinalities of the fuds
in the list element, $Q$, which is the argument to the neighbourhood function. Only the cardinalities of the next layer fuds may be estimated. The geometric average valency of successive layers is not necessarily constant, although alignment valency-density maximisation tends to shorter diagonals. However, in some cases the inducer time may be constrained to be less than the maximum time limit, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{p}}^{\prime \mathrm{t}}(A) \leq \mathrm{tmax}$, at least for the next layer fuds, by reducing the other parameters to reduce the estimated cardinality. For example the maximum optimise step cardinality may be restricted, $\operatorname{omax}=1$.

The limited-path-models tuple partition practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{p}}^{\prime}$, is implemented with a list maximiser, $Z_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}$, but a tree maximiser could also be used if time and space is available for the elements of the tree. Note that an implementation of a list maximiser can lazily evaluate the list, but an implementation of a tree maximiser must evaluate its tree strictly because the set operations require instantiation of the elements of the set. That is, a list maximiser need only evaluate the elements of the layer-ordered list in sequence as they are required. A lazy solution for tree maximiser would be to implement it a with a list tree (see appendix 'Trees'), but then it may contain multiple instances of the same fud.

The limited-path-models tuple partition practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{p}}^{\prime}$, has some limitations. First, in some cases only a subset of the limited-models infinite-layer substrate fuds is traversable

$$
\operatorname{dom}\left(I_{z, \mathrm{csd}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{p}}^{\prime *}(A)\right) \subset \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}
$$

This is because the derived volumes of the intermediate layers of the fud are limited, as well as the derived volume of the top layer.

Secondly, this limitation of the intermediate layers may restrict the derived dimensions of these layers to be considerably less than the dimension of the substrate. For example, in the case where the maximum derived volume equals the sample size, $\operatorname{wmax}=z$, then a size of 10000 implies a maximum breadth of at most bmax $=\lfloor\ln \mathrm{wmax} / \ln 2\rfloor=13$, where the derived valency is at least two. Maximum alignment is approximately $z(n-1) \ln d$ and so the ratio of the maximum alignment of an intermediate layer to the maximum alignment of the substrate is roughly equal to the ratio of their dimensions. For example, if the substrate dimension is $n=26$, then the ratio of the maximum alignments is roughly half. This is also true for maximum alignment
valency-density. Of course, this is also the case for the top layer, not just intermediate layers, but the summation alignment of the decomposition partially compensates for this.

Thirdly, as described in section 'Substrate models computation' above, consider the special case of a fud $F \in \operatorname{dom}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}\right)\right)$ which is such that (i) the underlying variables equals the substrate, $\operatorname{und}(F)=V$, (ii) it has lmax layers, $\operatorname{layer}(F, \operatorname{der}(F))=\operatorname{lmax}$, (iii) the first layer has breadth bmax $-n$, (iv) subsequent layers have breadth bmax, and (v) the variables are regular, $\forall w \in \operatorname{vars}(F)\left(\left|U_{w}\right|=d\right)$. In this case the cardinality of the variables is $|\operatorname{vars}(F) \cup V|=\operatorname{lmax} \times$ bmax. The cardinality of the set of next layer fuds is bounded

$$
\begin{aligned}
& \left|\mathcal{N}_{U, W, X} \cap \mathcal{N}_{U, W, \mathrm{xmax}} \cap \mathcal{N}_{U, W, \mathrm{bmax}}\right|= \\
& \quad\left(\sum_{b \in\{0 \ldots \mathrm{bmax}\}}\binom{c}{b}\right): \\
& \quad c=\sum_{k \in\{1 \ldots \mathrm{kmax}\}}\left(\binom{\operatorname{lmax} \times \operatorname{bmax}}{k}-\binom{(\operatorname{lmax}-1) \times \operatorname{bmax}}{k}\right) \operatorname{bell}\left(d^{k}\right)
\end{aligned}
$$

The cardinality of the selectable set, $c$, is therefore bounded

$$
c<(\operatorname{lmax} \times \operatorname{bmax})^{\frac{\mathrm{kmax}}{\max } \times \operatorname{bell}(\operatorname{xmax})}
$$

This expression is dominated by the right-most term, bell(xmax), if $\operatorname{lmax} \times$ bmax $\leq$ xmax, because kmax $<$ xmax. The cardinality of the set of next layer fuds is bounded,
$\left|\mathcal{N}_{U, W, X} \cap \mathcal{N}_{U, W, \mathrm{xmax}} \cap \mathcal{N}_{U, W, \mathrm{bmax}}\right|<\left((\operatorname{lmax} \times \operatorname{bmax})^{\underline{\mathrm{kmax}}} \times \operatorname{bell}(\mathrm{xmax})\right)^{\mathrm{bmax}}$
and so the upper bound on the cardinality of the neighbourhood function is also bounded
$\left|P_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}\left(\left\{\left(F, X_{P, A, A_{R}, \operatorname{csd}, \mathrm{p}}(F)\right)\right\}\right)\right|<\left((\operatorname{lmax} \times \operatorname{bmax})^{\underline{\mathrm{kmax}} \times \operatorname{bell}(\mathrm{xmax}))^{\mathrm{bmax}}, ~}\right.$
In the case where $\operatorname{xmax}=\operatorname{wmax}=z$ the second term, $\operatorname{bell}(x m a x)$, equals $\operatorname{bell}(z)$, which is impracticable in the example above where $z=10000$. The first term, $(\operatorname{lmax} \times \operatorname{bmax})^{\underline{\mathrm{kmax}}}$, has complexity $(\ln z)$ !, but the second term, bell(xmax), has complexity $z$ !. So while the limited-path-models tuple partition practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{p}}^{\prime}$, strongly constrains the intermediate layer derived volume, the tuple partition cardinality is only weakly constrained.

Given the limitations of the limited-path-models tuple partition practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{p}}^{\prime}$, and given that optimisation in a practicable inducer is necessary because of limited time or space, consider an alternative method of optimisation that maximises maximum function correlation by optimising within the tuple.

The cardinality of the second term of the upper bound on the cardinality of the neighbourhood function of the limited-path-models tuple partition inducer, $\left|\mathrm{B}\left(K^{\mathrm{CS}}\right)\right| \leq \operatorname{bell}(\operatorname{xmax})$ where $K \in \operatorname{tuples}(V, F)$ and $\left|K^{\mathrm{C}}\right| \leq \operatorname{xmax}$, can be addressed by choosing only a subset $Q$ of the partitions of a tuple, $Q \subset \mathrm{~B}\left(K^{\mathrm{CS}}\right)$. The cardinality of the subset must be less than or equal to the maximum optimise step cardinality $|Q| \leq$ omax. If the subset, $Q$, is chosen arbitrarily then the practicable inducer correlation can be expected to be reduced. However, considered by itself a single partition of the subset $P \in Q$ cannot have an optimise function that depends on alignment because a fud $G$ constructed from it must be independent, $A * G^{\mathrm{T}}=\left(A * G^{\mathrm{T}}\right)^{\mathrm{X}} \Longrightarrow \operatorname{algn}\left(A * G^{\mathrm{T}}\right)=0$, where $G=$ depends $\left(F \cup\left\{P^{\mathrm{T}}\right\},\{P\}\right)=\operatorname{depends}(F, K) \cup\left\{P^{\mathrm{T}}\right\}$. This is because the constructed fud, $G$, is mono-derived-variate, $|\operatorname{der}(G)|=1$.

Section 'Substrate models computation' defines the limited-layer limited-underlying-volume limited-breadth partition infinite-layer fud tree, $\operatorname{tfiubh}(U)(V) \in$ $\operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}}\right)$, which constructs the layer-ordered fuds from sets of partition transforms of the tuple, $\left\{P^{\mathrm{T}}: P \in \mathrm{~B}\left(K^{\mathrm{CS}}\right)\right\}$. The discussion then goes on to define the limited-layer limited-tuple-derived-dimension limited-underlyingvolume limited-breadth contracted non-overlapping substrate transform infinitelayer fud tree, tfitnmubh $(U)(V) \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$, which constructs the fuds with non-overlapping substrate transforms of the tuples, $\mathcal{T}_{U, K, \mathrm{n}}$, such that the regular substrate cardinalities may be computed. The latter fud tree constructs transforms of the limited-tuple-derived-dimension non-overlapping substrate partition-sets set, $\mathcal{N}_{U, K, \mathrm{n}, \mathrm{mmax}}$, which is defined as the limited-breadth non-overlapping substrate partition-sets set, $\mathcal{N}_{U, V, \mathrm{n}, \mathrm{bmax}}$, applied to the tuple,

$$
\mathcal{N}_{U, K, \mathrm{n}, \operatorname{mmax}}=\left\{N: Y \in \mathrm{~B}(K),|Y| \leq \operatorname{mmax}, N \in \prod_{J \in Y} \mathrm{~B}\left(J^{\mathrm{CS}}\right)\right\}
$$

Consider a stricter set of transforms of the partition-sets on the tuple such that the derived variables are pluri-variate and pluri-valent, which avoid necessarily independent derived histograms that have zero alignment. The pluri-valent pluri-limited-tuple-derived-dimension non-overlapping substrate partition-sets set, $\mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{b}}, \mathrm{mmax}, \overline{2}}$, is the intersection of the lower-limitedvalency substrate partition-sets set, $\mathcal{N}_{U, K, \text { umin }}$, where umin $=2$, and the
range-limited-tuple-derived-dimension non-overlapping substrate partition-sets set, $\mathcal{N}_{U, K, \mathrm{n}, \text { mran }}$, where $\operatorname{mran}=(2, \max )$ and $\max \geq 2$, is defined

$$
\begin{aligned}
& \mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{~b}, \mathrm{mmax}, \overline{2}}}= \\
& \quad\left\{N: Y \in \mathrm{~B}(K), 2 \leq|Y| \leq \operatorname{mmax}, N \in \prod_{J \in Y}\left(\mathrm{~B}\left(J^{\mathrm{CS}}\right) \backslash\left\{\left\{J^{\mathrm{CS}}\right\}\right\}\right)\right\}
\end{aligned}
$$

In the case where max $\leq|K|$, the cardinality is

$$
\begin{aligned}
& \left|\mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{~b}, \mathrm{mmax}, \overline{2}} \mid}\right|= \\
& \quad \sum\left(\prod_{J \in Y}\left(\operatorname{bell}\left(\left|J^{\mathrm{CS}}\right|\right)-1\right)\right): m \in\{2 \ldots \operatorname{mmax}\}, Y \in \mathrm{~S}(K, m)
\end{aligned}
$$

In the case of regular variables $K$, having valency $d$ and dimension $k$, the cardinality of the pluri-valent pluri-limited-tuple-derived-dimension non overlapping substrate partition-sets set is

$$
\begin{aligned}
& \left|\mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{~b}}, \mathrm{mmax}, \overline{2}}\right|= \\
& \sum\left(a \prod_{(j, p) \in L}\left(\operatorname{bell}\left(d^{j}\right)-1\right)^{p}\right): m \in\{2 \ldots \operatorname{mmax}\},(L, a) \in \operatorname{stircd}(k, m)
\end{aligned}
$$

where the fixed cardinality partition function cardinality function is stircd $\in$ $\mathbf{N}_{>0} \times \mathbf{N}_{>0} \rightarrow(\mathcal{L}(\mathbf{N}) \rightarrow \mathbf{N})$.

Therefore, given pluri-variate tuple, $|K|>1$, consider instead a subset of the transforms of the pluri-valent pluri-limited-tuple-derived-dimension non-overlapping substrate partition-sets set of the tuple $Q \subset\left\{N^{\mathrm{T}}: N \in\right.$ $\left.\mathcal{N}_{U, K, \mathbf{n}, \overline{\mathrm{~b}}, \mathrm{mmax}, \overline{2}}\right\}$ such that $|Q| \leq$ pmax, where the maximum tuple optimise limit is pmax $=\lfloor$ omax $/$ bmax $\rfloor \in \mathbf{N}_{>0}$ and omax $\geq$ bmax. The derived variables are pluri-variate and pluri-valent, $\forall T \in Q(|\operatorname{der}(T)|>1)$, and $\forall T \in Q \forall w \in \operatorname{der}(T)\left(\left|U_{w}\right|>1\right)$. Each of these transforms has a corresponding partition, $\forall T \in Q\left(T^{\mathrm{PK}} \in \mathrm{B}\left(K^{\mathrm{CS}}\right)\right)$, but now are not restricted to zero derived alignment. That is, in some cases, $A * G^{\mathrm{T}} \neq\left(A * G^{\mathrm{T}}\right)^{\mathrm{X}}$, where $T \in Q$ and $G=\operatorname{depends}(F \cup\{T\}, \operatorname{der}(T))$.

The tuple transform, $T \in Q$, is non-overlapping, $\forall P_{1}, P_{2} \in \operatorname{der}(T)\left(P_{1} \neq\right.$ $\left.P_{2} \Longrightarrow \operatorname{vars}\left(P_{1}\right) \cap \operatorname{vars}\left(P_{2}\right)=\emptyset\right)$. That is, there exists a partition $Y$ of the tuple, $Y \in \mathrm{~B}(K)$, which is such that $\exists M \in \operatorname{der}(T): \leftrightarrow Y \forall(P, J) \in$ $M(\operatorname{vars}(P)=J)$. However, the constructed exploded fud $G^{\prime}=\operatorname{explode}(G)$ is not necessarily non-overlapping if overlap(depends $(F, K)$ ), so the tuple transforms, $Q$, are chosen by maximising the shuffle content alignment valencydensity rather than derived alignment valency-density.

Together the optimised subset is defined

$$
\begin{aligned}
& Q=\operatorname{topd}(\operatorname{pmax})\left(\left\{\left(N^{\mathrm{T}},\left(\operatorname{algn}\left(A * G^{\mathrm{T}}\right)-\operatorname{algn}\left(A_{R} * G^{\mathrm{T}}\right)\right) / \operatorname{cvl}(G)\right):\right.\right. \\
& \\
& \left.\left.N \in \mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{~b}}, \mathrm{mmax}, \overline{2}}, G=\operatorname{depends}\left(F \cup\left\{N^{\mathrm{T}}\right\}, N\right)\right\}\right)
\end{aligned}
$$

Maximising the shuffle content alignment, $\operatorname{algn}\left(A * G^{\mathrm{T}}\right)-\operatorname{algn}\left(A_{R} * G^{\mathrm{T}}\right)$, tends to minimise the formal alignment, $\operatorname{algn}\left(A^{\mathrm{X}} * G^{\mathrm{T}}\right)$. The formal alignment is zero when non-overlapping, $\neg \operatorname{overlap}\left(G^{\prime}\right) \Longrightarrow \operatorname{algn}\left(A^{\mathrm{X}} * G^{\mathrm{T}}\right)=0$.

As mentioned above, an alternative method to shuffle content alignment would be to simply exclude overlapping constructed exploded fuds, overlap $\left(G^{\prime}\right)$, from the optimisation, but note that each fud, $G^{\prime}$, must be tested because it is insufficient to exclude it on the basis that the tuple, $K$, is overlapping, $\operatorname{overlap}(\operatorname{depends}(F, K)) \Longleftarrow \operatorname{overlap}\left(G^{\prime}\right)$.

As shown in section 'Substrate structures', above, the cardinality of the strong non-overlapping substrate transforms set is bounded

$$
\operatorname{bell}\left(\left|K^{\mathrm{C}}\right|\right) \leq\left|\left\{N^{\mathrm{T} K}: N \in \mathcal{N}_{U, K, \mathrm{n}}\right\}\right| \leq \operatorname{bell}(|K|) \times \operatorname{bell}\left(\left|K^{\mathrm{C}}\right|\right)
$$

That is, to search for the optimised subset from the strong non-overlapping substrate transforms set, $Q \subset\left\{N^{\mathrm{T}}: N \in \mathcal{N}_{U, K, \mathrm{n}}\right\}$, would require computation time in some cases of bell(kmax) $\times$ bell(xmax), if the tuple volume equals the maximum underlying volume limit, $\left|K^{\mathrm{C}}\right|=$ xmax. The lower bound is the cardinality of the partitions of the tuple, bell(xmax). So the search for non-overlapping substrate transforms of the tuple requires more computation time than the search for partition transforms of the tuple. As shown in section 'Substrate models computation', above, the cardinality of the searched list of the limited-layer limited-underlying-volume limitedbreadth contracted non-overlapping substrate transform infinite-layer fud tree tfitnubh $(U)(V)$, is greater than or equal to the cardinality of the searched list of the limited-layer limited-underlying-volume limited-breadth partition infinite-layer fud tree $\operatorname{tfiubh}(U)(V)$,

$$
|\operatorname{subpaths}(\operatorname{tfitnubh}(U)(V))| \geq|\operatorname{subpaths}(\operatorname{tfiubh}(U)(V))|
$$

However, only a subset of the derived histograms of the strong non-overlapping substrate transforms are non-independent, and hence aligned, so only this subset is searched. Even in the case where the maximum derived dimension equals the tuple dimension, $\max =k$, the exclusion of the partitions of the unary partition of the tuple, $\mathrm{B}\left(K^{\mathrm{CS}}\right)$, because of the maximum derived
dimension, $\mathrm{mmin}=2$, means that the cardinality of the pluri-valent pluri-limited-tuple-derived-dimension non-overlapping substrate partition-sets set, $\mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{b}}, \mathrm{mmax}, \overline{2}}$, is less than or equal to the cardinality of the partitions of the tuple, $\left|\mathcal{N}_{U, K, \mathbf{n}, \overline{\mathrm{~b}}, \text { mmax }, \overline{2}}\right| \leq\left|\mathrm{B}\left(K^{\mathrm{CS}}\right)\right|$. This is because the Bell number is log-convex.

In the case where computational resources are still exceeded by this cardinality, $\left|\mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{b}}, \mathrm{mmax}, \overline{2}}\right|$, consider searches restricted to subsets of the transforms of the pluri-valent pluri-limited-tuple-derived-dimension non-overlapping substrate partition-sets set, $\mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{b}}, \mathrm{mmax}, \overline{2}}$.

Consider the subset of the pluri-valent pluri-limited-tuple-derived-dimension non-overlapping substrate partition-sets set, $\mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{b}, m m a x}, \overline{2}}$, where the partition of the tuple is given, in the case where the tuple is at least bi-variate, $|K|>1$. Let the given partition be $Y \in \mathrm{~B}(K) \backslash\{\{K\}\}$. Then

$$
\prod_{J \in Y}\left(\mathrm{~B}\left(J^{\mathrm{CS}}\right) \backslash\left\{\left\{J^{\mathrm{CS}}\right\}\right\}\right) \subset \mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{~b}}, \mathrm{mmax}, \overline{2}}
$$

The cardinality of this set is $\prod_{J \in Y}\left(\operatorname{bell}\left(\left|J^{\mathrm{CS}}\right|\right)-1\right)<\operatorname{bell}(\mathrm{xmax})$. The com-

Consider an optimisation where the search is broken into two separate searches. The first search determines the partition of the tuple, $Y$, by searching the transforms of the intersection of the substrate self-cartesian partition-sets set, $\mathcal{N}_{U, K, \mathrm{c}}$, and the pluri-limited-tuple-derived-dimension non-overlapping substrate partition-sets set, $\mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{b}}, \operatorname{mmax}}$, where $2 \leq \operatorname{mmax} \leq|K|$, which is
$\mathcal{N}_{U, K, \mathrm{c}} \cap \mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{b}}, \mathrm{m} \text { max }}=\left\{\left\{J^{\mathrm{CS}\{ \}}: J \in Y\right\}: m \in\{2 \ldots \mathrm{mmax}\}, Y \in \mathrm{~S}(K, m)\right\}$
The cardinality of the intersection is

$$
\left|\mathcal{N}_{U, K, \mathrm{c}} \cap \mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{~b}}, \mathrm{mmax}}\right|=\sum_{m \in\{2 \ldots \operatorname{mmax}\}} \operatorname{stir}(|K|, m)
$$

If the tuple is bi-variate the cardinality is $\operatorname{stir}(2,2)=1$, so in this case the tuple partition search need not be performed. The tuple partition search is optimised by maximising the shuffle content alignment valency-density,

$$
\begin{aligned}
& Y \in \operatorname{maxd}\left(\left\{\left(Z,\left(\operatorname{algn}\left(A * G^{\mathrm{T}}\right)-\operatorname{algn}\left(A_{R} * G^{\mathrm{T}}\right)\right) / \operatorname{cvl}(G)\right):\right.\right. \\
& \quad m \in\{2 \ldots \operatorname{mmax}\}, Z \in \mathrm{~S}(K, m), \\
& \\
& \left.\left.N=\left\{J^{\mathrm{CS}\{ \}}: J \in Z\right\}, G=\operatorname{depends}\left(F \cup\left\{N^{\mathrm{T}}\right\}, N\right)\right\}\right)
\end{aligned}
$$

Note that if the tuple partition search, $Y$, had been optimised by maximising the derived alignment valency-density, $\operatorname{algn}\left(A * G^{\mathrm{T}}\right) / \operatorname{cvl}(G)$, instead of the shuffle content alignment valency-density, $\left(\operatorname{algn}\left(A * G^{\mathrm{T}}\right)-\operatorname{algn}\left(A_{R} *\right.\right.$ $\left.\left.G^{\mathrm{T}}\right)\right) / \operatorname{cvl}(G)$, then (i) the valency capacity, $\operatorname{cvl}(G)$, would not need to be computed because the derived alignment, $\operatorname{algn}\left(A * G^{\mathrm{T}}\right)$, and the derived alignment valency-density, $\operatorname{algn}\left(A * G^{\mathrm{T}}\right) / \operatorname{cvl}(G)$, are monotonic functions with respect to their common domain, $\mathcal{N}_{U, K, \mathrm{c}} \cap \mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{b}, m m a x}}$, (see section 'Transform alignment', above), and (ii) there would be no need to compute tuple partitions of cardinality less than the maximum tuple derived dimension, $m<\operatorname{mmax}$, because parent partitions necessarily have lower or equal alignment. That is, the derived alignment valued function of partition-sets and the parent partition relation are monotonic, $\forall Y_{1}, Y_{2} \in \mathrm{~B}(K)\left(\operatorname{parent}\left(Y_{1}, Y_{2}\right) \Longrightarrow \operatorname{algn}\left(A *\left\{J^{\mathrm{CS}\{ \}}\right.\right.\right.$ : $\left.\left.J \in Y_{1}\right\}^{\mathrm{T}}\right) \leq \operatorname{algn}\left(A *\left\{J^{\mathrm{CS}\{ \}}: J \in Y_{2}\right\}^{\mathrm{T}}\right)$. So it would only be necessary to compute $\mathrm{S}(K, \operatorname{mmax})$. However, the optimisation depends on the shuffle derived histogram, $A_{R} * G^{\mathrm{T}}$, which in turn depends on the given fud, $F$, so the monotonicity does not necessarily hold for either pair of relations.

Then, given the partition, $Y$, of the tuple, the second search, optimised by shuffle content alignment valency-density, is

$$
\begin{aligned}
& Q=\operatorname{topd}(\operatorname{pmax})\left(\left\{\left(N^{\mathrm{T}},\left(\operatorname{algn}\left(A * G^{\mathrm{T}}\right)-\operatorname{algn}\left(A_{R} * G^{\mathrm{T}}\right)\right) / \operatorname{cvl}(G)\right):\right.\right. \\
& \left.\left.N \in \prod_{J \in Y}\left(\mathrm{~B}\left(J^{\mathrm{CS}}\right) \backslash\left\{\left\{J^{\mathrm{CS}}\right\}\right\}\right), G=\operatorname{depends}\left(F \cup\left\{N^{\mathrm{T}}\right\}, N\right)\right\}\right)
\end{aligned}
$$

The maximum cardinality of the worst-case searched is

$$
\operatorname{maxr}\left(\left\{\left(Y, \prod_{J \in Y}\left(\operatorname{bell}\left(\left|J^{\mathrm{CS}}\right|\right)-1\right)\right): m \in\{2 \ldots \operatorname{mmax}\}, Y \in \mathrm{~S}(K, m)\right\}\right)
$$

In the case of a regular tuple of dimension $k=|K|$ and valency $d$, the maximum cardinality of the worst-case searched is

$$
\operatorname{maxr}\left(\left\{\left(L, a \prod_{(j, p) \in L}\left(\operatorname{bell}\left(d^{j}\right)-1\right)^{p}\right): m \in\{2 \ldots \operatorname{mmax}\},(L, a) \in \operatorname{sscd}(k, m)\right\}\right)
$$

where sscd $=$ stircd and the fixed cardinality partition function cardinality function is stircd $\in \mathbf{N}_{>0} \times \mathbf{N}_{>0} \rightarrow(\mathcal{L}(\mathbf{N}) \rightarrow \mathbf{N})$.

The overall computation time of the searches is at least

$$
\sum_{m \in\{2 \ldots \operatorname{mmax}\}}(\operatorname{stir}(|K|, m))+\prod_{J \in Y}\left(\operatorname{bell}\left(\left|J^{\mathrm{CS}}\right|\right)-1\right)
$$

The tuple partition search term is comparable to bell(kmax). The transforms search term is comparable to bell $\left(\mathrm{xmax}^{1 / m \max }\right)^{\operatorname{mmax}}$. The computation time of the transforms search, $Q$, dominates that of the tuple partition search $Y$.

Consider another subset of the pluri-valent pluri-limited-tuple-derived-dimension non-overlapping substrate partition-sets set, $\mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{b}, m \max , \overline{2}}}$. If the tuple is at least bi-variate, $|K|>1$, the binary non-overlapping substrate transforms set of the tuple, $\mathcal{T}_{U, K, \mathrm{n}, \mathrm{b}}$, is a proper subset of the non-overlapping substrate transforms set, $\mathcal{T}_{U, K, \mathrm{n}, \mathrm{b}} \subset \mathcal{T}_{U, K, \mathrm{n}}$. This corresponds to the special case of the pluri-valent pluri-limited-tuple-derived-dimension non-overlapping substrate partition-sets set, $\mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{b}}, \mathrm{mmax}, \overline{2}}$, where the maximum derived dimension is two, $\operatorname{mmax}=2$. The pluri-valent binary non-overlapping substrate partitionsets set $\mathcal{N}_{U, K, \mathrm{n}, \mathrm{b}, \overline{2}} \subseteq \mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{b}}, \mathrm{mmax}, \overline{2}}$ is defined

$$
\begin{aligned}
\mathcal{N}_{U, K, \mathrm{n}, \mathrm{~b}, \overline{2}}=\{\{ & P, Q\}: J \subset K, J \neq \emptyset, J \neq K, \\
& \left.P \in \mathrm{~B}\left(J^{\mathrm{CS}}\right) \backslash\left\{\left\{J^{\mathrm{CS}}\right\}\right\}, Q \in \mathrm{~B}\left((K \backslash J)^{\mathrm{CS}}\right) \backslash\left\{\left\{(K \backslash J)^{\mathrm{CS}}\right\}\right\}\right\}
\end{aligned}
$$

The cardinality is

$$
\left|\mathcal{N}_{U, K, \mathrm{n}, \mathrm{~b}, \overline{2}}\right|=1 / 2 \times \sum_{J \in \mathrm{P}(K) \backslash\{\emptyset, K\}}\left(\operatorname{bell}\left(\left|J^{\mathrm{CS}}\right|\right)-1\right) \times\left(\operatorname{bell}\left(\left|(K \backslash J)^{\mathrm{CS}}\right|\right)-1\right)
$$

In the case of regular variables of valency $d$ and dimension $k$, the cardinality is

$$
\left|\mathcal{N}_{U, K, \mathrm{n}, \mathrm{~b}, \overline{2}}\right|=1 / 2 \times \sum_{j \in\{1 \ldots k-1\}}\binom{k}{j}\left(\operatorname{bell}\left(d^{j}\right)-1\right) \times\left(\operatorname{bell}\left(d^{k-j}\right)-1\right)
$$

The subset of the transforms of the pluri-valent binary non-overlapping substrate partition-sets set of the tuple $Q \subset\left\{N^{\mathrm{T}}: N \in \mathcal{N}_{U, K, \mathrm{n}, \mathrm{b}, \overline{2}}\right\}$, is such that the derived variables of the transforms are bi-variate, $\forall T \in Q(|\operatorname{der}(T)|=2)$.

Again, the choice of tuple transforms, $Q$, can be made by maximising the shuffle content alignment valency-density,

$$
\begin{aligned}
& Q=\operatorname{topd}(\operatorname{pmax})\left(\left\{\left(N^{\mathrm{T}},\left(\operatorname{algn}\left(A * G^{\mathrm{T}}\right)-\operatorname{algn}\left(A_{R} * G^{\mathrm{T}}\right)\right) / \operatorname{cvl}(G)\right):\right.\right. \\
& \left.\left.N \in \mathcal{N}_{U, K, \mathrm{n}, \mathrm{~b}, \overline{2}}, G=\operatorname{depends}\left(F \cup\left\{N^{\mathrm{T}}\right\}, N\right)\right\}\right)
\end{aligned}
$$

A further subset of the pluri-valent binary non-overlapping substrate partitionsets set, $\mathcal{N}_{U, K, \mathrm{n}, \mathrm{b}, \overline{2}}$, is where the binary partition of the tuple is given. Let $J \subset K$ be such that $\{J, K \backslash J\} \in \mathrm{B}(K)$ where $|K|>1$. Then
$\left\{\{P, Q\}: P \in \mathrm{~B}\left(J^{\mathrm{CS}}\right) \backslash\left\{\left\{J^{\mathrm{CS}}\right\}\right\}, Q \in \mathrm{~B}\left((K \backslash J)^{\mathrm{CS}}\right) \backslash\left\{\left\{(K \backslash J)^{\mathrm{CS}}\right\}\right\}\right\} \subset \mathcal{N}_{U, K, \mathrm{n}, \mathrm{b}, \overline{2}}$

The cardinality of this set is $\left(\operatorname{bell}\left(\left|J^{\mathrm{C}}\right|\right)-1\right) \times\left(\operatorname{bell}\left(\left|(K \backslash J)^{\mathrm{C}}\right|\right)-1\right)<$ bell(xmax). The computation time is comparable at least to bell $\left(\mathrm{xmax}^{1 / 2}\right)^{2}<$ bell(xmax).

Again, the optimisation search can be broken into two separate searches. The first search determines the binary partition of the tuple, $\{J, K \backslash J\}$, by searching the intersection of the substrate self-cartesian partition-sets set and the binary non-overlapping substrate partition-sets set which is

$$
\mathcal{N}_{U, K, \mathrm{c}} \cap \mathcal{N}_{U, K, \mathrm{n}, \mathrm{~b}}=\left\{\left\{J^{\mathrm{CS}\{ \}},(K \backslash J)^{\mathrm{CS}\{ \}}\right\}: J \subset K, J \neq \emptyset, J \neq K\right\}
$$

The tuple binary partition search is optimised by maximising the shuffle content alignment,

$$
\begin{aligned}
& J \in \operatorname{maxd}\left(\left\{\left(M, \operatorname{algn}\left(A * G^{\mathrm{T}}\right)-\operatorname{algn}\left(A_{R} * G^{\mathrm{T}}\right)\right):\right.\right. \\
& M \subset K, M \neq \emptyset, M \neq K, N=\left\{M^{\mathrm{CS}\{ \}},(K \backslash M)^{\mathrm{CS}\{ \}}\right\} \\
& \\
& \left.\left.G=\operatorname{depends}\left(F \cup\left\{N^{\mathrm{T}}\right\}, N\right)\right\}\right)
\end{aligned}
$$

Note that in the case of binary tuple partition search, $\{J, K \backslash J\}$, it does not matter whether the optimisation maximises the shuffle content alignment, $\operatorname{algn}\left(A * G^{\mathrm{T}}\right)-\operatorname{algn}\left(A_{R} * G^{\mathrm{T}}\right)$, or the shuffle content alignment valency-density, $\left(\operatorname{algn}\left(A * G^{\mathrm{T}}\right)-\operatorname{algn}\left(A_{R} * G^{\mathrm{T}}\right)\right) / \operatorname{cvl}(G)$. This is because the valency capacity is constant for all binary partitions of the tuple, $\forall J \subset K\left(\left(\left|J^{\mathrm{C}}\right|\left|(K \backslash J)^{\mathrm{C}}\right|\right)^{1 / 2}=\right.$ $\left|K^{\mathrm{C}}\right|^{1 / 2}$ ).

The intersection has cardinality $\left|\mathcal{N}_{U, K, \mathrm{c}} \cap \mathcal{N}_{U, K, \mathrm{n}, \mathrm{b}}\right|=2^{|K|-1}-1$. Then, given the binary partition of the tuple, $\{J, K \backslash J\}$, the second search is the transforms search optimised by shuffle content alignment valency-density,

$$
\begin{aligned}
& Q=\operatorname{topd}(\operatorname{pmax})\left(\left\{\left(N^{\mathrm{T}},\left(\operatorname{algn}\left(A * G^{\mathrm{T}}\right)-\operatorname{algn}\left(A_{R} * G^{\mathrm{T}}\right)\right) / \operatorname{cvl}(G)\right):\right.\right. \\
& P \in \mathrm{~B}\left(J^{\mathrm{CS}}\right), R \in \mathrm{~B}\left((K \backslash J)^{\mathrm{CS}}\right), N=\{P, R\}, \\
&\left.\left.G=\operatorname{depends}\left(F \cup\left\{N^{\mathrm{T}}\right\}, N\right)\right\}\right)
\end{aligned}
$$

The maximum cardinality of the worst-case searched is

$$
\operatorname{maxr}\left(\left\{\left(J,\left(\operatorname{bell}\left(\left|J^{\mathrm{CS}}\right|\right)-1\right) \times\left(\operatorname{bell}\left(\left|(K \backslash J)^{\mathrm{CS}}\right|\right)-1\right)\right): J \in \mathrm{P}(K) \backslash\{\emptyset, K\}\right\}\right)
$$

In the case of a regular tuple of dimension $k=|K|$ and valency $d$, the maximum cardinality of the worst-case searched is

$$
\operatorname{maxr}\left(\left\{\left(j,\binom{k}{j}\left(\operatorname{bell}\left(d^{j}\right)-1\right) \times\left(\operatorname{bell}\left(d^{k-j}\right)-1\right)\right): j \in\{1 \ldots k-1\}\right\}\right)
$$

The overall computation time of the searches is at least

$$
2^{|K|-1}-1+\left(\operatorname{bell}\left(\left|J^{\mathrm{C}}\right|\right)-1\right) \times\left(\operatorname{bell}\left(\left|(K \backslash J)^{\mathrm{C}}\right|\right)-1\right)
$$

The tuple binary partition search term is comparable to $2^{\text {kmax }}$. The transforms search term is comparable to bell $\left(\mathrm{xmax}^{1 / 2}\right)^{2}$. The computation time of the transforms search, $Q$, dominates that of the tuple binary partition search, $\{J, K \backslash J\}$.

Having discussed the limited-layer limited-tuple-derived-dimension limited-underlying-volume limited-breadth contracted non-overlapping substrate transform infinite-layer fud tree, $\operatorname{tfitnmubh}(U)(V) \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$, which constructs the fuds with non-overlapping substrate transforms of the tuples, $\mathcal{T}_{U, K, \mathrm{n}}$, section 'Substrate models computation' goes on to consider the limitedlayer limited-tuple-derived-dimension limited-underlying-volume limited-breadth contracted decrementing linear non-overlapping fuds infinite-layer fud tree tfifdnmubh $(U)(V) \rightarrow \operatorname{trees}\left(\mathcal{F}_{U, \mathrm{P}^{*}}\right)$, which constructs the fuds with strong limited-tuple-derived-dimension contracted decrementing linear non-overlapping fuds, $\mathcal{F}_{U, \mathrm{n},-, K, \mathrm{mmax}}$, on the tuples, defined

$$
\begin{aligned}
& \mathcal{F}_{U, \mathrm{n},-, K, \operatorname{mmax}} \\
& =\left\{\left\{N^{\mathrm{T}}:(\cdot, N) \in L\right\}: M \in \mathcal{N}_{U, K, \mathrm{c}} \cap \mathcal{N}_{U, K, \mathrm{n}, \operatorname{mmax}},\right. \\
& =\quad L \in \operatorname{subpaths}(\{(M, \operatorname{tdec}(U)(M))\})\} \\
& =\left\{\left\{N^{\mathrm{T}}:(\cdot, N) \in L\right\}: Y \in \mathrm{~B}(K),|Y| \leq \operatorname{mmax}, M=\left\{J^{\mathrm{CS}\{ \}}: J \in Y\right\},\right. \\
& L \in \operatorname{subpaths}(\{(M, \operatorname{tdec}(U)(M))\})\}
\end{aligned}
$$

where the tree of self non-overlapping substrate decremented partition-sets is defined $\operatorname{tdec}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathrm{P}\left(\mathcal{R}_{U}\right)\right)$ as

$$
\operatorname{tdec}(U)(M):=\left\{(N, \operatorname{tdec}(U)(N)): N \in \mathcal{N}_{U, M,-} \cap \mathcal{N}_{U, M, \mathrm{n}, \mathrm{~s}}\right\}
$$

and $\operatorname{tdec}(U)(\emptyset):=\emptyset$. Explicitly this is

$$
\begin{aligned}
& \operatorname{tdec}(U)(M):=\{(N, \operatorname{tdec}(U)(N)): \\
& \left.\quad w \in M, Q \in \operatorname{decs}\left(\{w\}^{\operatorname{CS}\{ \}}\right), N=\{Q\} \cup\left\{\{u\}^{\operatorname{CS}\{ \}}: u \in M, u \neq w\right\}\right\}
\end{aligned}
$$

where decs $=$ decrements $\in \mathcal{R}_{U} \rightarrow \mathrm{P}\left(\mathcal{R}_{U}\right)$.
Instead of a subset of the transforms of the pluri-valent pluri-limited-tuple-derived-dimension non-overlapping substrate partition-sets of the tuple, $Q \subset$ $\left\{N^{\mathrm{T}}: N \in \mathcal{N}_{U, K, \mathrm{n}, \bar{b}, \mathrm{mmax}, \overline{2}}\right\}$, consider a subset of the pluri-valent pluri-limited-tuple-derived-dimension contracted decrementing linear non-overlapping fuds
of the tuple $Q \subset \mathcal{F}_{U, \mathrm{n},-, K, \overline{\mathrm{~b}, \text { mmax }, \overline{2}}}$ such that $|Q| \leq$ pmax. The pluri-valent pluri-limited-tuple-derived-dimension contracted decrementing linear non-overlapping fuds is defined

$$
\begin{aligned}
& \mathcal{F}_{U, \mathrm{n},-, K, \overline{\mathrm{~b}}, \operatorname{mmax}, \overline{2}} \\
& =\left\{\left\{N^{\mathrm{T}}:(\cdot, N) \in L\right\}: M \in \mathcal{N}_{U, K, \mathrm{c}} \cap \mathcal{N}_{U, K, \mathrm{n}, \bar{b}, \operatorname{mmax}},\right. \\
& \quad L \in \operatorname{subpaths}(\{(M, \operatorname{tdecp}(U)(M))\})\} \\
& =\left\{\left\{N^{\mathrm{T}}:(\cdot, N) \in L\right\}: Y \in \mathrm{~B}(K), 2 \leq|Y| \leq \operatorname{mmax}, M=\left\{J^{\mathrm{CS}\{ \}}: J \in Y\right\},\right. \\
& \quad L \in \operatorname{subpaths}(\{(M, \operatorname{tdecp}(U)(M))\})\}
\end{aligned}
$$

where $\operatorname{mmax} \geq 2$ and the tree of pluri-valent self non-overlapping substrate decremented partition-sets is defined $\operatorname{tdecp}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \operatorname{trees}\left(\mathrm{P}\left(\mathcal{R}_{U}\right)\right)$ as

$$
\operatorname{tdecp}(U)(M):=\left\{(N, \operatorname{tdecp}(U)(N)): N \in \mathcal{N}_{U, M, \overline{2}} \cap \mathcal{N}_{U, M,-} \cap \mathcal{N}_{U, M, \mathrm{n}, \mathrm{~s}}\right\}
$$

and $\operatorname{tdecp}(U)(\emptyset):=\emptyset$. Explicitly this is

$$
\begin{aligned}
& \operatorname{tdecp}(U)(M):=\{(N, \operatorname{tdecp}(U)(N)): \\
& \qquad w \in M,\left|\{w\}^{\mathrm{C}}\right|>2, Q \in \operatorname{decs}\left(\{w\}^{\mathrm{CS}\{ \}}\right), \\
& \\
& \left.N=\{Q\} \cup\left\{\{u\}^{\mathrm{CS}\{ \}}: u \in M, u \neq w\right\}\right\}
\end{aligned}
$$

The cardinality of the pluri-valent pluri-limited-tuple-derived-dimension contracted decrementing linear non-overlapping fuds is

$$
\begin{aligned}
& \left|\mathcal{F}_{U, \mathrm{n},-, K, \overline{\mathrm{~b}}, \mathrm{mmax}, \overline{2} \mid}\right| \\
& =\sum\left(\left|\operatorname{nodes}\left(\operatorname{tdecp}(U)\left(\left\{J^{\mathrm{CS}\{ \}}: J \in Y\right\}\right)\right)\right|:\right. \\
& \quad m \in\{2 \ldots \operatorname{mmax}\}, Y \in \mathrm{~S}(K, m))+1 \\
& =\sum p: m \in\{2 \ldots \operatorname{mmax}\}, Y \in \mathrm{~S}(K, m), \\
& \quad L \in \operatorname{subpaths}\left(\operatorname{tdecpcd}(U)\left(\left\{J^{\mathrm{CS}\{ \}}: J \in Y\right\}\right)\right),(p, \cdot)=L_{|L|}
\end{aligned}
$$

In the case of regular substrate variables of valency $d$ and dimension $n$, the cardinality of the pluri-valent pluri-limited-tuple-derived-dimension contracted decrementing linear non-overlapping fuds is

$$
\begin{aligned}
& \left|\mathcal{F}_{U, \mathbf{n},-, K, \overline{\mathrm{~b}}, \operatorname{mmax}, \overline{2} \mid}\right| \\
& =\sum a p: m \in\{2 \ldots \operatorname{mmax}\},(M, a) \in \operatorname{sscd}(k, m), R=\operatorname{reg}(d, M), \\
& \quad L \in \operatorname{subpaths}(\{((1, R), \operatorname{tdeccpd}(1, R))\}),(p, \cdot)=L_{|L|}
\end{aligned}
$$

where $k=|K|$ and $\operatorname{reg} \in \mathbf{N} \times \mathcal{L}(\mathbf{N}) \rightarrow \mathcal{L}(\mathbf{N})$ is defined $\operatorname{reg}(d, M):=$ concat(flip $\left.\left(\operatorname{order}\left(D_{\mathcal{L}(\mathbf{N})},\left\{\{1 \ldots q\} \times\left\{d^{j}\right\}:(j, q) \in M\right\}\right)\right)\right)$.

The cardinality of the pluri-valent self non-overlapping substrate decremented partition-sets tree may be computed by defining $\operatorname{tdecpcd}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow$ trees $(\mathbf{N} \times \mathcal{L}(\mathbf{N}))$ as

$$
\begin{aligned}
& \operatorname{tdecpcd}(U)(V):= \\
& \quad\left\{((1, L), \operatorname{tdecpcd}(1, L)): L=\left\{\left(i,\left|U_{v}\right|\right):(v, i) \in \operatorname{order}\left(D_{\mathrm{V}}, V\right)\right\}\right\}
\end{aligned}
$$

where order $D_{\mathrm{V}}$ is such that $\operatorname{order}\left(D_{\mathrm{V}}, V\right) \in \operatorname{enums}(V)$, and tdecpcd $\in \mathbf{N} \times$ $\mathcal{L}(\mathbf{N}) \rightarrow \operatorname{trees}(\mathbf{N} \times \mathcal{L}(\mathbf{N}))$ as

$$
\begin{aligned}
& \operatorname{tdecpcd}(k, L):=\{((m, M), \operatorname{tdecpcd}(m, M)): \\
& \left.\quad i \in\{1 \ldots|L|\}, L_{i}>2, m=k L_{i}\left(L_{i}-1\right), M=L \backslash\left\{\left(i, L_{i}\right)\right\} \cup\left\{\left(i, L_{i}-1\right)\right\}\right\}
\end{aligned}
$$

In the case of regular substrate variables of valency $d$ and dimension $n$, the cardinality of the pluri-valent self non-overlapping substrate decremented partition-sets cardinality tree may be computed by defining tdecpcd $\in \mathbf{N} \times$ $\mathbf{N} \rightarrow \operatorname{trees}(\mathbf{N} \times \mathcal{L}(\mathbf{N}))$ as

$$
\operatorname{tdecpcd}(d, n):=\{((1, L), \operatorname{tdecpcd}(1, L)): L=\{1 \ldots n\} \times\{d\}\}
$$

If the tuple is pluri-variate and pluri-valent, $|K|>1$, and $\forall v \in K\left(\left|U_{v}\right|>1\right)$, then the derived variables are pluri-variate and pluri-valent, $\forall H \in Q(|\operatorname{der}(H)|>$ $1)$, and $\forall H \in Q \forall w \in \operatorname{der}(H)\left(\left|U_{w}\right|>1\right)$. Each of these fuds has a corresponding partition, $\forall H \in Q\left(H^{\mathrm{TPK}} \in \mathrm{B}\left(K^{\mathrm{CS}}\right)\right)$, but now are not restricted to zero derived alignment. That is, in some cases, $A * G^{\mathrm{T}} \neq\left(A * G^{\mathrm{T}}\right)^{\mathrm{X}}$, where $H \in Q$ and $G=\operatorname{depends}(F \cup H, \operatorname{der}(H))$. The tuple fud, $H$, is non-overlapping, $\neg \operatorname{overlap}(H)$. However, the constructed exploded fud $G^{\prime}=$ explode $(G)$ is not necessarily non-overlapping so the choice of tuple fuds, $Q \subset \mathcal{F}_{U_{A}, \mathrm{n},-, K, \bar{b}, \mathrm{mmax}, \overline{2}}$, is made by maximising the shuffle content alignment valency-density,

$$
\begin{aligned}
& Q=\operatorname{topd}(\operatorname{pmax})\left(\left\{\left(H,\left(\operatorname{algn}\left(A * G^{\mathrm{T}}\right)-\operatorname{algn}\left(A_{R} * G^{\mathrm{T}}\right)\right) / \operatorname{cvl}(G)\right):\right.\right. \\
&\left.\left.H \in \mathcal{F}_{U_{A}, \mathrm{n},-, K, \overline{\mathrm{~b}, \mathrm{mmax}, \overline{2}}}, G=\operatorname{depends}(F \cup H, \operatorname{der}(H))\right\}\right)
\end{aligned}
$$

The cardinality of the contracted decrementing linear non-overlapping fuds is greater than or equal to the cardinality of the non-overlapping substrate transforms, $\left|\mathcal{F}_{U, \mathrm{n},-, K, \overline{\mathrm{~b}}, \mathrm{mmax}, \overline{2}}\right| \geq\left|\mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{b}}, \mathrm{mmax}, \overline{2}}\right|$, so the computation time is increased. However, consider the optimisation of the tree of decrements. Define the contracted decrementing linear non-overlapping fuds list maximiser

$$
\begin{aligned}
& Z_{P, A, A_{R}, F \mathrm{n},-, K}= \\
& \quad \text { maximiseLister }\left(X_{P, A, A_{R}, F, \mathrm{n},-, K}, N_{P, A, A_{R}, F, \mathrm{n},-, K}, \operatorname{top}(\text { pmax }), R_{P, A, A_{R}, F, \mathrm{n},-, K}\right)
\end{aligned}
$$

where (i) the optimiser function is

$$
\begin{aligned}
& X_{P, A, A_{R}, F, \mathrm{n},-, K}=\left\{\left(H,\left(I_{\mathrm{a}}^{*}\left(A * G^{\mathrm{T}}\right)-I_{\mathrm{a}}^{*}\left(A_{R} * G^{\mathrm{T}}\right)\right) / I_{\mathrm{cv}}^{*}(G)\right):\right. \\
& \left.\quad H \in \mathcal{F}_{U_{A}, \mathrm{n},-, K, \overline{\mathrm{~b}}, \mathrm{mmax}, \overline{2}}, G=\operatorname{depends}(F \cup H, \operatorname{der}(H))\right\}
\end{aligned}
$$

(ii) the initial subset is

$$
\begin{aligned}
R_{P, A, A_{R}, F, \mathrm{n},-, K}=\left\{\left(\left\{M^{\mathrm{T}}\right\},\right.\right. & \left.X_{P, A, A_{R}, F, \mathrm{n},-, K}\left(\left\{M^{\mathrm{T}}\right\}\right)\right): \\
& \left.Y \in \mathrm{~B}(K), 2 \leq|Y| \leq \operatorname{mmax}, M=\left\{J^{\mathrm{CS}\{ \}}: J \in Y\right\}\right\}
\end{aligned}
$$

and (iii) the neighbourhood function is

$$
\begin{aligned}
& N_{P, A, A_{R}, F, \mathrm{n},-, K}(C)=\left\{\left(H \cup\left\{N^{\mathrm{T}}\right\}, X_{P, A, A_{R}, F, \mathrm{n},-, K}\left(H \cup\left\{N^{\mathrm{T}}\right\}\right)\right):\right. \\
&(H, \cdot) \in C, M=\operatorname{der}(H), \\
& w \in M,\left|\{w\}^{\mathrm{C}}\right|>2, Q \in \operatorname{decs}\left(\{w\}^{\mathrm{CS}\{ \}}\right), \\
&\left.N=\{Q\} \cup\left\{\{u\}^{\mathrm{CS}\{ \}}: u \in M, u \neq w\right\}\right\}
\end{aligned}
$$

Then the subset of the decrementing linear non-overlapping fuds is

$$
\operatorname{dom}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{n},-, K}\right)\right) \subset \mathcal{F}_{U_{A}, \mathrm{n},-, K, \overline{\mathrm{~b}}, \mathrm{mmax}, \overline{2}}
$$

So the choice of tuple fuds, $Q \subset \mathcal{F}_{U_{A}, \mathrm{n},-, K, \overline{\mathrm{~b}}, \mathrm{mmax}, \overline{2}}$, can be made by maximising the shuffle content alignment valency-density of the elements of the tree maximiser, $Z_{P, A, A_{R}, F, \mathrm{n},-, K}$,

$$
Q=\operatorname{topd}(\operatorname{pmax})\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{n},-, K}\right)\right)
$$

The cardinality of the initial set is

$$
\begin{aligned}
\left|R_{P, A, A_{R}, F, \mathrm{n},-, K}\right| & =\left|\mathcal{N}_{U, K, \mathrm{c}} \cap \mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{~b}}, \operatorname{mmax}}\right| \\
& =\sum_{m \in\{2 \ldots \mathrm{mmax}\}} \operatorname{stir}(|K|, m) \\
& \leq \operatorname{bell}(|K|)-1
\end{aligned}
$$

For a given tuple partition $Y \in \mathrm{~B}(K)$ the cardinality of the neighbourhood searched could be computed by constructing a tree of lists of valencies, $\operatorname{trees}\left(\mathcal{L}\left(\mathbf{N}_{>0}\right)\right)$, congruent to the pluri-valent self non-overlapping substrate decremented partition-sets cardinality tree, $\operatorname{tdecpcd}(Y) \in \operatorname{trees}(\mathbf{N} \times \mathcal{L}(\mathbf{N}))$, and such that (i) at the root the list consists of the volumes of the components, $\left\{\left(i,\left|J^{\mathrm{C}}\right|\right):(J, i) \in \operatorname{order}\left(D_{\mathrm{P}(\mathrm{P}(\mathcal{V}))}, Y\right)\right\}$, and (ii) at each step one of the valencies is decremented. The cardinality of the searched at each node $L$ is
then $\sum(c(c-1) / 2:(\cdot, c) \in L)$. However, the computation of the tree is exponential and so is impracticable as a measure of expected computation time.

Instead of finding the cardinalities of searched for all possible search paths, consider the cardinality of the searched in the worst case which is found by decrementing the head of a sorted list of component volumes. Rolling the shortest first is the worst case because the cardinality of the decrements, $c(c-1) / 2$, is convex. Let srch $\in \mathcal{L}(\mathbf{N}) \rightarrow \mathbf{N}$ be defined $\operatorname{srch}(L):=$ $\sum(c(c-1) / 2:(\cdot, c) \in L, c>2)$. Let dec $\in \mathcal{K}(\mathbf{N}) \rightarrow \mathcal{K}(\mathbf{N})$ be defined $\operatorname{dec}((x, K)):=\operatorname{if}(x>2,(x-1, K), \operatorname{dec}(K))$. Let srchmax $\in \mathbf{N} \times \mathcal{L}(\mathbf{N}) \rightarrow$ $\mathbf{N}$ be defined $\operatorname{srchmax}(m, \emptyset):=m$ and $\operatorname{srchmax}(m, L):=\operatorname{srchmax}(m+$ $\operatorname{srch}(L), \operatorname{dec}(L))$. Let $\operatorname{srchmax} \in \mathrm{P}\left(\mathrm{P}\left(\mathcal{V}_{U}\right)\right) \rightarrow \mathbf{N}$ be defined $\operatorname{srchmax}(Y):=$ $\operatorname{srchmax}\left(0, \operatorname{sort}\left(\left\{\left(i,\left|J^{\mathrm{C}}\right|\right):(J, i) \in \operatorname{order}\left(D_{\mathrm{P}(\mathrm{P}(\mathcal{V}))}, Y\right)\right\}\right)\right)$, where $\operatorname{sort}(L):=$ $\left\{(i, a):((a, \cdot), i) \in \operatorname{order}\left(D_{\mathrm{N}^{2}}, \operatorname{flip}(L)\right)\right\}$. Then $\operatorname{srchmax}(Y) \in \mathbf{N}$ is the greatest cardinality of the searched for the given partition, $Y$.

The maximum cardinality of the worst-case searched is

$$
\operatorname{maxr}(\{(Y, \operatorname{srchmax}(Y)): m \in\{2 \ldots \operatorname{mmax}\}, Y \in \mathrm{~S}(K, m)\})
$$

In the case of a regular tuple of dimension $k=|K|$ and valency $d$, the maximum cardinality of the worst-case searched is

$$
\operatorname{maxr}(\{(L, \operatorname{srchmax}(L)): m \in\{2 \ldots \operatorname{mmax}\},(L, a) \in \operatorname{sscd}(k, m)\})
$$

where $\operatorname{srchmax}(L):=\operatorname{srchmax}\left(0, \operatorname{sort}\left(\operatorname{concat}\left(\left\{\{1 \ldots p\} \times\left\{d^{j}\right\}:(j, p) \in\right.\right.\right.\right.$ $L\}))$ ).

If it is the case that the topd (pmax) optimisation is such that each step of the list has no more than pmax $f u d s, \forall(i, C) \in \operatorname{list}\left(Z_{P, A, A_{R}, F, \mathrm{n},-, K}\right)(|C| \leq \operatorname{pmax})$, then the cardinality of the elements must be less than (a) the maximum tuple optimise limit, pmax, times (b) the length of the longest path of decrements, $\left|K^{\mathrm{C}}\right| / 2$. Thus $\left|\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{n},-, K}\right)\right| \leq \operatorname{pmax} \times \mathrm{xmax} / 2$. The cardinality of the searched must be less than or equal to (i) the cardinality of the initial set, $\left|R_{P, A, A_{R}, F, \mathrm{n},-, K}\right|=\left|\mathcal{N}_{U, K, \mathrm{c}} \cap \mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{b}}, \max }\right| \leq \operatorname{bell}(|K|)-1$, plus (ii) (a) the cardinality of the elements, $\mid$ elements $\left(Z_{P, A, A_{R}, F, \mathbf{n},-, K}\right) \mid$, times (b) the cardinality of the decrements, which is less than $\left|\mathcal{N}_{U, M, \overline{2}} \cap \mathcal{N}_{U, M,-} \cap \mathcal{N}_{U, M, \mathrm{n}, \mathrm{s}}\right|$. If the tuple is partitioned into a singleton component and a remainder component the worst case cardinality of decrements is less than $\mathrm{xmax}^{2} / 2^{3}$. Thus cardinality of the searched set is constrained

$$
\left|\operatorname{searched}\left(Z_{P, A, A_{R}, F, \mathrm{n},-, K}\right)\right| \leq \operatorname{bell}(\operatorname{kmax})+\operatorname{pmax} \times \operatorname{xmax}^{3} / 2^{4}
$$

If the maximum tuple optimise limit is one, pmax $=1$, this cardinality is smaller than that of the contracted non-overlapping substrate transforms, $\left|\mathcal{T}_{U, K, \mathrm{n}}\right| \leq \operatorname{bell}(\operatorname{kmax}) \times \operatorname{bell}(\mathrm{xmax})$.

Again, the cardinality of the searched set, $\left|\operatorname{searched}\left(Z_{P, A, A_{R}, F, \mathrm{n},-, K}\right)\right|$, can be reduced further by restricting the initial set to binary non-overlapping substrate transforms set, $\mathcal{T}_{U, K, \mathrm{n}, \mathrm{b}} \subseteq \mathcal{T}_{U, K, \mathrm{n}}$, which is the special case where $\operatorname{mmax}=2$. Define the tuple-binary-partition contracted decrementing linear non-overlapping fuds list maximiser

$$
\begin{aligned}
& Z_{P, A, A_{R}, F, \mathrm{n}, \mathrm{~b},-, K}= \\
& \quad \text { maximiseLister }\left(X_{P, A, A_{R}, F, \mathbf{n},-, K}, N_{P, A, A_{R}, F, \mathrm{n},-, K}, \operatorname{top}(\operatorname{pmax}), R_{P, A, A_{R}, F, \mathrm{n}, \mathrm{~b},-, K}\right)
\end{aligned}
$$

where the initial set is

$$
\begin{aligned}
R_{P, A, A_{R}, F, \mathrm{n}, \mathrm{~b},-, K}=\left\{\left(\left\{M^{\mathrm{T}}\right\}\right.\right. & \left., X_{P, A, A_{R}, F, \mathrm{n},-, K}\left(\left\{M^{\mathrm{T}}\right\}\right)\right): \\
& \left.J \subset K, J \neq \emptyset, J \neq K, M=\left\{J^{\mathrm{CS}\{ \}},(K \backslash J)^{\mathrm{CS}\{ \}}\right\}\right\}
\end{aligned}
$$

In this case the choice of tuple fuds is

$$
Q=\operatorname{topd}(\operatorname{pmax})\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{n}, \mathrm{~b},-, K}\right)\right)
$$

The cardinality of the initial set is

$$
\left|R_{P, A, A_{R}, F, \mathrm{n}, \mathrm{~b},-, K}\right|=\left|\mathcal{N}_{U_{A}, K, \mathrm{c}} \cap \mathcal{N}_{U_{A}, K, \mathrm{n}, \mathrm{~b}}\right|=2^{|K|-1}-1
$$

The maximum cardinality of the worst-case searched is

$$
\operatorname{maxr}(\{(J, \operatorname{srchmax}(\{J, K \backslash J\})): J \in \mathrm{P}(K)\})
$$

In the case of a regular tuple of dimension $k=|K|$ and valency $d$, the maximum cardinality of the worst-case searched is

$$
\operatorname{maxr}\left(\left\{\left(j, \operatorname{srchmax}\left(0, \operatorname{sort}\left(\left\{\left(1, d^{j}\right),\left(2, d^{k-j}\right)\right\}\right)\right)\right): j \in\{1 \ldots k-1\}\right\}\right)
$$

The cardinality of the searched is constrained

$$
\left|\operatorname{searched}\left(Z_{P, A, A_{R}, F, \mathrm{n}, \mathrm{~b},-, K}\right)\right| \leq 2^{\mathrm{kmax}}+\operatorname{pmax} \times \operatorname{xmax}^{3} / 4
$$

In this case the latter term dominates because $2^{\mathrm{kmax}} \leq$ xmax.
A variation of the contracted decrementing linear non-overlapping fuds list maximiser is to restrict the neighbourhood optimisation to the maximum, $\operatorname{pmax}=1$, and apply pmax only to the initial set. To do this a tree tail
maximiser is used with an inclusion function of max and the initial set is explicitly optimised beforehand. Define the maximum-roll contracted decrementing linear non-overlapping fuds tree maximiser

$$
\begin{aligned}
& Z_{P, A, A_{R}, F, \mathrm{n},-, K, \mathrm{mr}}= \\
& \text { maximiseTailTreer }\left(X_{P, A, A_{R}, F, \mathrm{n},-, K}, N_{P, A, A_{R}, F, \mathrm{n},-, K}, \max ,\right. \\
& \left.\operatorname{top}(\operatorname{pmax})\left(R_{P, A, A_{R}, F, \mathrm{n},-, K}\right)\right)
\end{aligned}
$$

This restriction pushes the pmax path selection into the initial set rather than towards the end of the optimise path where sometimes different decrementing linear fuds roll to the same derived partition variables.

The decrementing maximiser initial set, top $(\operatorname{pmax})\left(R_{P, A, A_{R}, F, \mathrm{n},-, K}\right)$, is biased to larger tuple partition cardinalities, $|Y|$, where $Y \in \mathrm{~B}(K)$. This is because the valency-capacity varies against the partition cardinality, $\left(\prod_{J \in Y}\left|J^{\mathrm{C}}\right|\right)^{1 /|Y|}=$ $\left|K^{\mathrm{C}}\right|^{1 /|Y|}$. Therefore consider a variation of the maximum-roll maximiser that has an initial set of cardinality pmax for each of the possible tuple partition cardinalities, $m \in\{2 \ldots \max \}$. Define the maximum-roll-by-derived-dimension contracted decrementing linear non-overlapping fuds tree maximiser

$$
\begin{aligned}
& Z_{P, A, A_{R}, F, \mathrm{n},-, K, \mathrm{~mm}}= \\
& \quad \text { maximiseTailTreer }\left(X_{P, A, A_{R}, F, \mathrm{n},-, K}, N_{P, A, A_{R}, F, \mathrm{n},-, K}, \max , R_{P, A, A_{R}, F, \mathrm{n},-, K, \mathrm{~mm}}\right)
\end{aligned}
$$

where the initial subset is

$$
\begin{aligned}
& R_{P, A, A_{R}, F, \mathrm{n},-, K, \mathrm{~mm}}= \\
& \qquad \begin{array}{l}
\text { \{top }(\operatorname{pmax})\left(\left\{\left(\left\{M^{\mathrm{T}}\right\}, X_{P, A, A_{R}, F, \mathrm{n},-, K}\left(\left\{M^{\mathrm{T}}\right\}\right)\right):\right.\right. \\
\left.\left.\left.\quad Y \in \mathrm{~S}(K, m), M=\left\{J^{\mathrm{CS}\{ \}}: J \in Y\right\}\right\}\right): m \in\{2 \ldots \operatorname{mmax}\}\right\}
\end{array}
\end{aligned}
$$

Now the cardinality of the searched is constrained
$\left|\operatorname{searched}\left(Z_{P, A, A_{R}, F, \mathrm{n},-, K, \mathrm{~mm}}\right)\right| \leq \operatorname{bell}(\operatorname{kmax})+(\operatorname{mmax}-1) \times \operatorname{pmax} \times \operatorname{xmax}^{3} / 2^{4}$
Another constraint that may be applied to reduce the cardinality of the searched set, $\left|\operatorname{searched}\left(Z_{P, A, A_{R}, F, \mathrm{n},-, K}\right)\right|$, is to restrict the initial set such that the volume of each component of the tuple partition is limited. The maximum valency is umax $\in \mathbf{N}_{>0}$. The initial partition-set forming the bottom layer of the decrementing linear fud is in the intersection of the substrate selfcartesian partition-sets set, the pluri-limited-tuple-derived-dimension nonoverlapping substrate transforms set and the limited-valency substrate partitionsets set, $\mathcal{N}_{U, K, \mathrm{c}} \cap \mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{b}}, \operatorname{mmax}} \cap \mathcal{N}_{U, K, \mathrm{umax}}$. The pluri-limited-valency pluri-limited-tuple-derived-dimension contracted decrementing linear non-overlapping
fuds is defined

$$
\begin{aligned}
& \mathcal{F}_{U, \mathrm{n},-, K, \overline{\mathrm{~b}}, \text { mmax }, \overline{2}, \mathrm{umax}} \\
& =\left\{\left\{N^{\mathrm{T}}:(\cdot, N) \in L\right\}: M \in \mathcal{N}_{U, K, \mathrm{c}} \cap \mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{~b}, \max }} \cap \mathcal{N}_{U, K, \mathrm{umax}},\right. \\
& \quad L \in \operatorname{subpaths}(\{(M, \operatorname{tdecp}(U)(M))\})\} \\
& =\left\{\left\{N^{\mathrm{T}}:(\cdot, N) \in L\right\}: Y \in \mathrm{~B}(K), 2 \leq|Y| \leq \operatorname{mmax},\right. \\
& \quad\left(\forall J \in Y\left(\left|J^{\mathrm{C}}\right| \leq \operatorname{umax}\right)\right), M=\left\{J^{\mathrm{CS}\{ \}}: J \in Y\right\}, \\
& L \in \operatorname{subpaths}(\{(M, \operatorname{tdecp}(U)(M))\})\}
\end{aligned}
$$

Define the limited-valency contracted decrementing linear non-overlapping fuds list maximiser

$$
\begin{aligned}
& Z_{P, A, A_{R}, F, \mathrm{n}, \mathrm{w},-, K}= \\
& \quad \text { maximiseLister }\left(X_{P, A, A_{R}, F, \mathrm{n},-, K}, N_{P, A, A_{R}, F, \mathrm{n},-, K}, \operatorname{top}(\mathrm{pmax}), R_{P, A, A_{R}, F, \mathrm{n}, \mathrm{w},-, K}\right)
\end{aligned}
$$

where the initial set is

$$
\begin{aligned}
& R_{P, A, A_{R}, F, \mathrm{n}, \mathrm{w},-, K}=\left\{\left(\left\{M^{\mathrm{T}}\right\},\right.\right. \\
& \left.\quad X_{P, A, A_{R}, F, \mathrm{n},-, K}\left(\left\{M^{\mathrm{T}}\right\}\right)\right): \\
& \quad Y \in \mathrm{~B}(K), 2 \leq|Y| \leq \operatorname{mmax} \\
& \\
& \left.\left(\forall J \in Y\left(\left|J^{\mathrm{C}}\right| \leq \mathrm{umax}\right)\right), M=\left\{J^{\mathrm{CS}\{ \}}: J \in Y\right\}\right\}
\end{aligned}
$$

In this case the choice of tuple fuds is

$$
Q=\operatorname{topd}(\operatorname{pmax})\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{n}, \mathrm{w},-, K}\right)\right)
$$

The cardinality of the initial set now depends on the system,

$$
\begin{aligned}
\left|R_{P, A, A_{R}, F, \mathrm{n}, \mathrm{w},-, K}\right| & =\left|\mathcal{N}_{U, K, \mathrm{c}} \cap \mathcal{N}_{U, K, \mathrm{n}, \overline{\mathrm{~b}, \mathrm{~m} \max }} \cap \mathcal{N}_{U, K, \mathrm{umax}}\right| \\
& =\sum_{m \in\{2 \ldots \mathrm{mmax}\}}\left|\left\{Y: Y \in \mathrm{~S}(K, m), \quad\left(\forall J \in Y\left(\left|J^{\mathrm{C}}\right| \leq \mathrm{umax}\right)\right)\right\}\right| \\
& \leq \sum_{m \in\{2 \ldots \mathrm{mmax}\}} \operatorname{stir}(|K|, m)
\end{aligned}
$$

The maximum cardinality of the worst-case searched is

$$
\begin{aligned}
& \operatorname{maxr}(\{(Y, \operatorname{srchmax}(Y)): m \in\{2 \ldots \max \}, \quad Y \in \mathrm{~S}(K, m) \\
& \left.\left.\quad\left(\forall J \in Y\left(\left|J^{\mathrm{C}}\right| \leq \text { umax }\right)\right)\right\}\right)
\end{aligned}
$$

In the case of a regular tuple of dimension $k=|K|$ and valency $d$, the maximum cardinality of the worst-case searched is

$$
\begin{aligned}
\operatorname{maxr}(\{(L, \operatorname{srchmax}(L)): m \in\{2 \ldots \operatorname{mmax}\}, & (L, a) \in \operatorname{sscd}(k, m) \\
& \left.\left.\left(\forall(j, p) \in L\left(q>0 \Longrightarrow d^{j} \leq u \max \right)\right)\right\}\right)
\end{aligned}
$$

The effect of the valency limit is to make the partitions of the tuple larger and more regular. For example, a binary partition such that all but one of the tuple variables, having common valency $d$, is in one component has initial valencies of $d^{k-1}$ and $d$. The cardinality of the searched approximately varies as the cube of the longest valency, so a binary irregular search may require considerably more computation time than a poly-component regular search in the same tuple.

Having addressed the cardinality of the second term of the upper bound on the cardinality of the neighbourhood function of the limited-path-models tuple partition inducer, $\left|\mathrm{B}\left(K^{\mathrm{CS}}\right)\right| \leq \operatorname{bell}(\mathrm{xmax})$ where $K \in \operatorname{tuples}(V, F)$ and $\left|K^{\mathrm{C}}\right| \leq$ xmax, by optimising a subset $Q$ of the partitions of a tuple, $Q \subset$ $\mathrm{B}\left(K^{\mathrm{CS}}\right)$, above, now consider the first term. A subset of the neighbourhood function of the limited-path-models tuple partition inducer, $P_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}$, may be defined which allows only one partition transform for each tuple,

$$
\begin{aligned}
& P_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}, \mathrm{u}}(Q)= \\
& \left\{\left(F \cup G, I_{\mathrm{csd}}^{*}\left(\left(A, A_{R}, F \cup G\right)\right)\right):\right. \\
& \quad(F, \cdot) \in Q, \operatorname{layer}(F, \operatorname{der}(F))<\operatorname{lmax}, \\
& \quad B \subseteq\left\{K: K \in \operatorname{tuples}\left(V_{A}, F\right),\left|K^{\mathrm{C}}\right| \leq \mathrm{xmax}\right\}, \\
& \\
& 1 \leq|B| \leq \operatorname{bmax}, \\
& \\
& G \in\left\{\left\{P^{\mathrm{T}}: P \in N\right\}: N \in \prod_{K \in B}\left(\mathrm{~B}\left(K^{\mathrm{CS}}\right) \backslash\left\{\left\{K^{\mathrm{CS}}\right\}\right\}\right)\right\}, \\
& \\
& \left.W=\operatorname{der}(F \cup G),\left|W^{\mathrm{C}}\right| \leq \operatorname{wmax}\right\}
\end{aligned}
$$

In the case of the fud $F$, defined above, of variable cardinality $|\operatorname{vars}(F)|=$ $\operatorname{lmax} \times$ bmax, the upper bound on the cardinality of the neighbourhood function is

$$
\begin{aligned}
\left|P_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}, \mathrm{u}}\left(\left\{\left(F, X_{P, A, A_{R}, \mathrm{csd}, \mathrm{p}}(F)\right)\right\}\right)\right| \\
\quad<\left((\operatorname{lmax} \times \mathrm{bmax})^{\underline{\mathrm{kmax}}}\right)^{\underline{\mathrm{bmax}}} \times \operatorname{bell}(\mathrm{xmax})^{\mathrm{bmax}}
\end{aligned}
$$

The cardinality of the set of next limited-underlying-volume limited-breadth layers depends on (i) the cardinality of the set of next limited-underlyingvolume limited-breadth layer tuple sets,

$$
\begin{aligned}
& \mid\left\{B: B \subseteq\left\{K: K \in \operatorname{tuples}\left(V_{A}, F\right),\left|K^{\mathrm{C}}\right| \leq \mathrm{xmax}\right\}\right., 1 \leq|B| \leq \operatorname{bmax}\} \mid \\
&<\left((\operatorname{lmax} \times \operatorname{bmax})^{\mathrm{kmax}}\right)^{\mathrm{bmax}}
\end{aligned}
$$

and (ii) the product of the cardinalities of the sets of partitions of each tuple,

$$
\prod_{K \in B}\left|\mathrm{~B}\left(K^{\mathrm{CS}}\right)\right|<\operatorname{bell}(\mathrm{xmax})^{\mathrm{bmax}}
$$

within each layer tuple set, $B$.
The cardinality of the set of next limited-underlying limited-breadth tuple sets, $\left|\left\{B: B \subseteq\left\{K: K \in \operatorname{tuples}\left(V_{A}, F\right),\left|K^{\mathrm{C}}\right| \leq \operatorname{xmax}\right\}, 1 \leq|B| \leq \operatorname{bmax}\right\}\right|$, can be addressed by (i) constructing only a single content alignment optimised next limited-underlying limited-breadth layer tuple set $B_{\mathrm{B}} \subseteq\{K: K \in$ tuples $\left.\left(V_{A}, F\right),\left|K^{\mathrm{C}}\right| \leq \mathrm{xmax}\right\}$, and (ii) constructing the tuples of that tuple set, $B_{\mathrm{B}}$, one variable at a time. The tuple set, $B_{\mathrm{B}}$, consists of the maximum breadth, bmax, per maximum tuple derived dimension, mmax, top-most tuples, $\left|B_{\mathrm{B}}\right|=\lfloor\operatorname{bmax} / \mathrm{mmax}\rfloor$, if the tuples are uniquely aligned, so that the cardinality of derived variables in the layer optimised by applying the contracted decrementing linear non-overlapping fuds list maximiser, $Z_{P, A, A_{R}, F, \mathrm{n},-, K}$, to each tuple, $K \in B_{\mathrm{B}}$, is no greater than the maximum breadth, bmax. Define the limited-underlying tuple set list maximiser
$Z_{P, A, A_{R}, F, \mathrm{~B}}=\operatorname{maximiseLister}\left(X_{P, A, A_{R}, F, \mathrm{~B}}, P_{P, A, A_{R}, F, \mathrm{~B}}, \operatorname{top}(\mathrm{omax}), R_{P, A, A_{R}, F, \mathrm{~B}}\right)$
where (i) the optimiser function is

$$
\begin{aligned}
& X_{P, A, A_{R}, F, \mathrm{~B}}= \\
& \quad\left\{\left(K, I_{\mathrm{a}}^{*}\left(\operatorname{apply}\left(V_{A}, K, \operatorname{his}(F), A\right)\right)-I_{\mathrm{a}}^{*}\left(\operatorname{apply}\left(V_{A}, K, \operatorname{his}(F), A_{R}\right)\right)\right):\right. \\
& \left.K \in \operatorname{tuples}\left(V_{A}, F\right)\right\}
\end{aligned}
$$

where his $=$ histograms $\in \mathcal{F} \rightarrow \mathrm{P}(\mathcal{A})$, apply $\in \mathrm{P}(\mathcal{V}) \times \mathrm{P}(\mathcal{V}) \times \mathrm{P}(\mathcal{A}) \times \mathcal{A} \rightarrow \mathcal{A}$, and (ii) the neighbourhood function is

$$
\begin{aligned}
P_{P, A, A_{R}, F, \mathrm{~B}}(B) & =\left\{\left(J, X_{P, A, A_{R}, F, \mathrm{~B}}(J)\right):\right. \\
(K, \cdot) & \left.\in B, w \in \operatorname{vars}(F) \cup V_{A} \backslash K, J=K \cup\{w\},\left|J^{\mathrm{C}}\right| \leq \mathrm{xmax}\right\}
\end{aligned}
$$

and (iii) the initial subset is

$$
\begin{aligned}
R_{P, A, A_{R}, \emptyset, \mathrm{~B}}= & \left\{\left(\{w, u\}, X_{P, A, A_{R}, \emptyset, \mathrm{~B}}(\{w, u\})\right):\right. \\
& \left.w, u \in V_{A}, u \neq w,\left|\{w, u\}^{\mathrm{C}}\right| \leq \mathrm{xmax}\right\} \\
R_{P, A, A_{R}, F, \mathrm{~B}}= & \left\{\left(\{w, u\}, X_{P, A, A_{R}, F, \mathrm{~B}}(\{w, u\})\right):\right. \\
& \left.w \in \operatorname{der}(F), u \in \operatorname{vars}(F) \cup V_{A}, u \neq w,\left|\{w, u\}^{\mathrm{C}}\right| \leq \operatorname{xmax}\right\}
\end{aligned}
$$

Then the shuffle content alignment optimised next limited-underlying limitedbreadth layer tuple set, $B_{\mathrm{B}}$, is

$$
\begin{aligned}
& B_{\mathrm{B}}=\operatorname{topd}(\lfloor\operatorname{bmax} / \operatorname{mmax}\rfloor)\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{~B}}\right)\right) \in \\
& \quad\left\{B: B \subseteq\left\{K: K \in \operatorname{tuples}\left(V_{A}, F\right),\left|K^{\mathrm{C}}\right| \leq \operatorname{xmax}\right\}\right\}
\end{aligned}
$$

The fud application, apply $\in \mathrm{P}(\mathcal{V}) \times \mathrm{P}(\mathcal{V}) \times \mathrm{P}(\mathcal{A}) \times \mathcal{A} \rightarrow \mathcal{A}$, traverses from the substrate variables, $V_{A}$, to the tuple, $K$, via the histograms of the transforms of the fud, his $(F)$. The fud application is a tractable application equivalent to the application of the fud's transform's histogram followed by reduction, $\operatorname{apply}\left(V_{A}, K, \operatorname{his}(F), A\right)=A * \operatorname{histogram}\left(F^{\mathrm{T}}\right) \% K$. The shuffle content fud application alignment, algn $\left(\operatorname{apply}\left(V_{A}, K, \operatorname{his}(F), A\right)\right)-$ $\operatorname{algn}\left(\operatorname{apply}\left(V_{A}, K, \operatorname{his}(F), A_{R}\right)\right)$, resembles the shuffle content alignment, $\operatorname{algn}(A *$ $\left.G^{\mathrm{T}}\right)-\operatorname{algn}\left(A_{R} * G^{\mathrm{T}}\right)$, where $G=\operatorname{depends}(F, K)$, except that fud variables cannot be hidden by being nested in the higher layer depends fud of another fud variable. That is, in some cases $K \neq \operatorname{der}(\operatorname{depends}(F, K))$ and so $\operatorname{apply}\left(V_{A}, K, \operatorname{his}(F), A\right) \neq A * \operatorname{depends}(F, K)^{\mathrm{T}}$.

The tuple set search, $Z_{P, A, A_{R}, F, \mathrm{~B}}$, is optimised by maximising the shuffle content fud application alignment,

$$
\operatorname{algn}\left(\operatorname{apply}\left(V_{A}, K, \operatorname{his}(F), A\right)\right)-\operatorname{algn}\left(\operatorname{apply}\left(V_{A}, K, \operatorname{his}(F), A_{R}\right)\right)
$$

not the shuffle content fud application alignment valency-density,

$$
\left(\operatorname{algn}\left(\operatorname{apply}\left(V_{A}, K, \operatorname{his}(F), A\right)\right)-\operatorname{algn}\left(\operatorname{apply}\left(V_{A}, K, \operatorname{his}(F), A_{R}\right)\right)\right) / y^{1 / k}
$$

where $y=\left|K^{\mathrm{C}}\right|$ and $k=|K|$. The maximum alignment varies with dimension, for example a regular histogram of dimension $k$ and valency $d$ has approximate maximum alignment of $z(k-1) \ln d$. Therefore a maximiser function value of shuffle content alignment tends to select tuples of larger dimension. In contrast, the maximum alignment valency-density varies against geometric-average valency, approximately $z(k-1)(\ln d) / d$, and so tends to smaller tuple dimension, $k$, especially where the entropy of valencies, entropy $\left(\left\{\left(w,\left|U_{A}(w)\right|\right): w \in K\right\}\right)$, is low. The contracted decrementing linear non-overlapping fuds in subsequent applications of contracted decrementing linear non-overlapping fuds list maximisers to each tuple of the tuple set, $\bigcup\left\{\operatorname{dom}\left(X_{P, A, A_{R}, F, \mathrm{n},-, K}\right): K \in B_{\mathrm{B}}\right\} \subset \mathcal{F}_{U_{A}, \mathrm{P}^{*}}$, have derived volume less than or equal to the tuple volume, $\left|\operatorname{der}(H)^{\mathrm{C}}\right| \leq\left|K^{\mathrm{C}}\right|$ where $H \in \mathcal{F}_{U_{A}, \mathrm{n},-, K}$, so larger tuples can value roll down to smaller subsets of the tuple, but not the reverse. That is, a maximiser function value of shuffle content alignment increases the searched cardinality for each tuple making the neighbourhood function, $P_{P, A, A_{R}, \mathrm{csd}}$, of the notional list maximiser, $Z_{P, A, A_{R}, \mathrm{csd}}$, less arbitrary, so increasing the maximum function correlation of the practicable inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, to the tractable inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$.

An upper bound on the expected cardinality of the searched may be computed given the maximum underlying dimension, kmax. The upper bound
on the expected cardinality in the first layer, $F=\emptyset$, is

$$
\sum_{k \in\{2 \ldots \min (\operatorname{kmax}, n)\}}\binom{n}{k}
$$

where $n=\left|V_{A}\right|$ and min $=$ minimum. In subsequent layers, $F \neq \emptyset$, the upper bound on the expected cardinality is

$$
\sum_{k \in\{2 \ldots \min (\mathrm{kmax}, q)\}}\binom{q}{k}-\binom{q-x}{k}
$$

where $W=\operatorname{vars}(F) \cup V_{A}, q=|W|, X=\operatorname{der}(F)$ and $x=|X|$.
The maximum underlying dimension, kmax, may be approximated from the geometric average valency $d=\left|W^{\mathrm{C}}\right|^{1 / q}$, and the maximum underlying volume, xmax,

$$
\operatorname{kmax}=\left\lceil\frac{\ln \mathrm{xmax}}{\ln d}\right\rceil
$$

If it is the case that the topd (omax) optimisation is such that each step of the list has no more than omax tuples, then in the first layer, $F=\emptyset$, the cardinality of the searched set is constrained

$$
\left|\operatorname{searched}\left(Z_{P, A, A_{R}, \emptyset, \mathrm{~B}}\right)\right|<n^{2}+(\operatorname{kmax}-2) \times \operatorname{omax} \times n
$$

In subsequent layers, $F \neq \emptyset$, the cardinality of the searched set is constrained

$$
\left|\operatorname{searched}\left(Z_{P, A, A_{R}, F, \mathrm{~B}}\right)\right|<x q+(\operatorname{kmax}-2) \times \operatorname{omax} \times q
$$

The limited-underlying tuple set list maximiser, $Z_{P, A, A_{R}, F, \mathrm{~B}}$, has an inclusion function defined top $($ omax $) \in \mathrm{P}\left(X_{P, A, A_{R}, F, \mathrm{~B}}\right) \rightarrow \mathrm{P}\left(X_{P, A, A_{R}, F, \mathrm{~B}}\right)$. The application of the $\operatorname{top}(n) \in \mathrm{P}(\mathcal{X} \times \mathcal{Y}) \rightarrow \mathrm{P}(\mathcal{X} \times \mathcal{Y})$ aggregation function with parameter $n$ to a relation $R$ may result in a subset of the relation having a cardinality greater than the given parameter, $|\operatorname{top}(n)(R)|>n$, if there are duplicate range values at the $n$-th position of the ordered relation. This might be the case, for example, in a tuple set list maximiser searched set, $\operatorname{searched}\left(Z_{P, A, A_{R}, F, \mathrm{~B}}\right)$, that contains tuples which contain variables having a partition equal to the self-partition of a singleton underlying variable.

An implementation of the tuple set list maximiser, $Z_{P, A, A_{R}, F, \mathrm{~B}}$, that guarantees no more than omax tuples at each step of the optimiser list, $\forall B \in$
$\operatorname{set}\left(\operatorname{list}\left(Z_{P, A, A_{R}, F, \mathrm{~B}}\right)\right)(|B| \leq \operatorname{omax})$, must have additional inclusion order criteria. An example is where the tuples are ordered first by ascending alignment, $X_{P, A, A_{R}, F, \mathrm{~B}}(K)$, and then by descending sum derived variables layer, - sumlayer $(F, K)$, where sumlayer $\in \mathcal{F} \times \mathrm{P}(\mathcal{V}) \rightarrow \mathbf{N}$ is defined as

$$
\operatorname{sumlayer}(F, K):=\sum_{w \in K} \operatorname{layer}(F,\{w\})
$$

For example, the tuples $J, K \subset \operatorname{vars}(F)$, such that variable $u \in K$, self partition variable $\{u\}^{\mathrm{CS}\{ \}} \in J$ and $J=K \backslash\{u\} \cup\left\{\{u\}^{\mathrm{CS}\{ \}}\right\}$, have the same alignments, $X_{P, A, A_{R}, F, \mathrm{~B}}(J)=X_{P, A, A_{R}, F, \mathrm{~B}}(K)$, but different sum derived variables layers, $\operatorname{sumlayer}(F, J)=\operatorname{sumlayer}(F, K)+1$. Ordering by descending sum derived variables layer avoids the addition of extra variables to the model which are merely redundant reframe variables, where these reframe variables are at the inclusion boundary.

There are other order criteria including (i) descending shuffle alignment, $-\operatorname{algn}\left(\operatorname{apply}\left(V_{A}, K, \operatorname{his}(F), A_{R}\right)\right)$, and (ii) descending tuple volume, $\left|K^{\mathrm{C}}\right|$. Ordering by descending tuple volume tends to prevent tuples from adding monoeffective variables, $\left|(A \%\{u\})^{\mathrm{F}}\right|=1<\left|\{u\}^{\mathrm{C}}\right|$.

Given the single content alignment optimised next limited-underlying limitedbreadth layer tuple set, $B_{\mathrm{B}}=\operatorname{topd}(\lfloor\operatorname{bmax} / \operatorname{mmax}\rfloor)\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{~B}}\right)\right)$, from the limited-underlying tuple set list maximiser, $Z_{P, A, A_{R}, F, \mathrm{~B}}$, each tuple $K$ of the tuple set, $B_{\mathrm{B}}$, can be optimised in a contracted decrementing linear non-overlapping fuds list maximiser, $Z_{P, A, A_{R}, F, \mathbf{n},-, K}$, to construct the single content alignment optimised next limited-underlying limited-breadth layer. The limited-layer limited-underlying limited-breadth fud tree searcher creates a path of layer-cumulative fuds of length lmax. Define the limited-layer limited-underlying limited-breadth fud tree searcher

$$
Z_{P, A, A_{R}, \mathrm{~L}}=\operatorname{searchTreer}\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}, P_{P, A, A_{R}, \mathrm{~L}},\{\emptyset\}\right)
$$

where the neighbourhood function returns a singleton

$$
\begin{aligned}
& P_{P, A, A_{R}, \mathrm{~L}}(F)=\{G: \\
& G=F \cup\left\{T: K \in \operatorname{topd}(\lfloor\operatorname{bmax} / \operatorname{mmax}\rfloor)\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{~B}}\right)\right),\right. \\
& \\
& H \in \operatorname{topd}(\operatorname{pmax})\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{n},-, K}\right)\right), \\
& \\
& \left.w \in \operatorname{der}(H), I=\operatorname{depends}(\operatorname{explode}(H),\{w\}), T=I^{\mathrm{TPT}}\right\}, \\
& \operatorname{layer}(G, \operatorname{der}(G)) \leq \operatorname{lmax}\}
\end{aligned}
$$

If the substrate variables are pluri-variate, $\left|V_{A}\right|>1$, the tree of the limitedlayer limited-underlying limited-breadth fud tree searcher has a single path,
$\left|\operatorname{paths}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, \mathrm{~L}}\right)\right)\right|=1$, and a single leaf, $\left|\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, \mathrm{~L}}\right)\right)\right|=1$.
Note that in some cases a partition transform, $I^{\mathrm{TPT}}$, may already exist in the fud, $F$, because only one variable of the tuple, $K$, need be in the fud derived variables, $|K \cap \operatorname{der}(F)| \geq 1$, and so some components of the partition of the tuple may consist of variables in lower layers of the fud, $J \cap \operatorname{der}(F)=\emptyset$ where $J=\operatorname{und}(I) \subset K$. Furthermore, if, after the first layer, a partition $I_{1}^{\mathrm{TP}}$ already exists in the fud, $I_{1}^{\mathrm{TP}} \in \operatorname{vars}(F)$, and is not a derived variable, $I_{1}^{\mathrm{TP}} \notin \operatorname{der}(F)$, it may sometimes be hidden by another variable $I_{2}^{\mathrm{TP}}$. That is, $I_{1}^{\mathrm{TP}} \in \operatorname{vars}\left(\operatorname{depends}\left(F, \operatorname{und}\left(I_{2}\right)\right)\right)$. It is therefore possible that the succeeding fud, $G$, may, in some cases, contain a single derived variable, $|\operatorname{der}(G)|=1$, and consequently be independent, $\operatorname{algn}\left(A * G^{\mathrm{T}}\right)=0$. This limitation is due to the separation of the optimisation into two steps, (i) tuple set list maximisation, followed by (ii) decrementing fuds list maximisation.

Implementations of the neighbourhood function that do not use partition variables, $F \notin \mathcal{F}_{U, \mathrm{P}}$, must explicitly check for uniqueness, $I^{\mathrm{TP}} \notin\left\{T^{\mathrm{P}}: T \in\right.$ $F\}$.

If (i) each content alignment optimised next limited-underlying limited-breadth layer tuple set has cardinality less than or equal to the maximum layer breadth limit, $\left|B_{\mathrm{B}}\right| \leq\lfloor\operatorname{bmax} / \operatorname{mmax}\rfloor$, and (ii) each tuple $K \in B_{\mathrm{B}}$ has contracted decrementing linear non-overlapping fuds list maximiser cardinality of less than or equal to the maximum tuple optimise limit, pmax, then the cardinality of each additional layer of the fuds in the path is less than or equal to the maximum optimise step cardinality, omax $=b \max \times \mathrm{pmax}$. That is, $|\operatorname{der}(F)| \leq$ omax where $F \in \operatorname{elements}\left(Z_{P, A, A_{R}, \mathrm{~L}}\right)$.

If the substrate variables are pluri-variate, $\left|V_{A}\right|>1$, the optimised limitedlayer limited-underlying limited-breadth fud $F_{\mathrm{L}}$ of layer lmax is the leaf

$$
\left\{F_{\mathrm{L}}\right\}=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, \mathrm{~L}}\right)\right) \subset \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}
$$

If the optimised limited-layer limited-underlying limited-breadth fud, $F_{\mathrm{L}}$, exists, it has at least two variables, $\left|\operatorname{vars}\left(F_{\mathrm{L}}\right) \backslash V_{A}\right|>1$.

Now the filtering step is computed by constructing pluri-partition transforms of the fud variables one variable at a time. Define the limited-derived derived variables set list maximiser
$Z_{P, A, A_{R}, F, \mathrm{D}}=\operatorname{maximiseLister}\left(X_{P, A, A_{R}, F, \mathrm{D}}, P_{P, A, A_{R}, F, \mathrm{D}}, \operatorname{top}(\operatorname{omax}), R_{P, A, A_{R}, F, \mathrm{D}}\right)$
where (i) the optimiser function is

$$
\begin{aligned}
& X_{P, A, A_{R}, F, \mathrm{D}}=\left\{\left(K,\left(I_{\mathrm{a}}^{*}\left(A * G^{\mathrm{T}}\right)-I_{\mathrm{a}}^{*}\left(A_{R} * G^{\mathrm{T}}\right)\right) / I_{\mathrm{cvl}}^{*}(G)\right):\right. \\
&K \subseteq \operatorname{vars}(F), K \neq \emptyset, G=\operatorname{depends}(F, K)\}
\end{aligned}
$$

(ii) the neighbourhood function is

$$
\begin{aligned}
& P_{P, A, A_{R}, F, \mathrm{D}}(D)=\left\{\left(J, X_{P, A, A_{R}, F, \mathrm{D}}(J)\right):\right. \\
& (K, \cdot) \in D, w \in \operatorname{vars}(F) \backslash V_{A} \backslash K, \\
& \left.J=K \cup\{w\},\left|J^{\mathrm{C}}\right| \leq \text { wmax, } \operatorname{der}(\operatorname{depends}(F, J))=J\right\}
\end{aligned}
$$

and (iii) the initial subset is

$$
\begin{aligned}
& R_{P, A, A_{R}, F, \mathrm{D}}=\left\{\left(J, X_{P, A, A_{R}, F, \mathrm{D}}(J)\right):\right. \\
& \quad w, u \in \operatorname{vars}(F) \backslash V_{A}, u \neq w, \\
& \left.J=\{w, u\},\left|J^{\mathrm{C}}\right| \leq \operatorname{wmax}, \operatorname{der}(\operatorname{depends}(F, J))=J\right\}
\end{aligned}
$$

The limited-derived derived variables set list maximiser has no elements if the fud is empty, elements $\left(Z_{P, A, A_{R}, \emptyset, \mathrm{D}}\right)=\emptyset$, or if it consists of a single partition transform, $|F|=1$.

The derived variables sets are such that none of the derived variables are nested in the depends fud variables of another derived variable in the same set, $\forall w, u \in J(w \neq u \Longrightarrow u \notin \operatorname{vars}(\operatorname{depends}(F,\{w\})))$, so that $J=$ $\operatorname{der}(\operatorname{depends}(F, J))$. This restriction prevents unnecessary searches in the optimiser where the derived variables of the dependent fud are a proper subset, $\operatorname{der}(\operatorname{depends}(F, J)) \subset J$. However, hidden variables that are excluded in a fud are not necessarily excluded in another lower layer fud that does not contain the dependent variable.

The limited-derived derived variables set list maximiser differs from the limitedunderlying tuple set list maximiser in respect of nested fud variables. The tuple set optimiser allows nested variables in a tuple in preparation for rolling in the subsequent application of the contracted decrementing linear nonoverlapping fuds list maximiser, whereas the depends fuds of the derived variables of the derived variables set optimiser must be limited-models fuds, $\operatorname{depends}(F, K) \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}$.

An upper bound on the expected cardinality of the searched may be computed given the maximum derived dimension, jmax. The upper bound on the expected cardinality for a non-empty $f u d, F \neq \emptyset$, is

$$
\sum_{j \in\{2 \ldots \min (\mathrm{jmax}, r)\}}\binom{r}{j}
$$

where $R=\operatorname{vars}(F) \backslash V_{A}$ and $r=|R|$ and min $=$ minimum.
The maximum derived dimension, jmax, may be approximated from the geometric average valency $d=\left|R^{\mathrm{C}}\right|^{1 / r}$, and the maximum derived volume, wmax,

$$
\operatorname{jmax}=\left\lceil\frac{\ln \operatorname{wmax}}{\ln d}\right\rceil
$$

Like the limited-underlying tuple set list maximiser, $Z_{P, A, A_{R}, F, \mathrm{~B}}$, the limitedderived derived variables set list maximiser, $Z_{P, A, A_{R}, F, \mathrm{D}}$, has an inclusion function defined top (omax) $\in \mathrm{P}\left(X_{P, A, A_{R}, F, \mathrm{D}}\right) \rightarrow \mathrm{P}\left(X_{P, A, A_{R}, F, \mathrm{D}}\right)$. An implementation of the derived variables set list maximiser, $Z_{P, A, A_{R}, F, \mathrm{D}}$, that guarantees no more than omax derived variables sets at each step of the optimiser list, $\forall D \in \operatorname{set}\left(\operatorname{list}\left(Z_{P, A, A_{R}, F, \mathrm{D}}\right)\right)(|D| \leq$ omax), must also have additional inclusion order criteria such as descending sum derived variables layer, -sumlayer $(F, J)$.

The optimised limited-model fuds are

$$
\begin{aligned}
& \left\{\operatorname{depends}\left(F_{\mathrm{L}}, K\right):\right. \\
& \\
& \quad\left\{F_{\mathrm{L}}\right\}=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, \mathrm{~L}}\right)\right), \\
& \\
& \left.K \in \operatorname{maxd}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F_{\mathrm{L}}, \mathrm{D}}\right)\right)\right\} \subset \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}
\end{aligned}
$$

The practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, may then be implemented

$$
\begin{aligned}
& I_{z, \mathrm{csd}, \mathrm{~F}, \infty, \mathrm{q}, P}^{\prime}(A)= \\
& \left\{\left(G, I_{\mathrm{csd}}^{*}\left(\left(A, A_{R}, G\right)\right)\right):\right. \\
& \quad\left|V_{A}\right|>1,\left\{F_{\mathrm{L}}\right\}=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, \mathrm{~L}}\right)\right) \\
& \left.K \in \operatorname{maxd}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F_{\mathrm{L}}, \mathrm{D}}\right)\right), G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\} \cup \\
& \left\{(\emptyset, 0):\left|V_{A}\right| \leq 1\right\}
\end{aligned}
$$

where the shuffle content alignment valency-density computer $I_{\text {csd }} \in$ computers is defined as

$$
I_{\mathrm{csd}}^{*}\left(\left(A, A_{R}, F\right)\right)=\left(I_{\mathrm{a}}^{*}\left(A * F^{\mathrm{T}}\right)-I_{\mathrm{a}}^{*}\left(A_{R} * F^{\mathrm{T}}\right)\right) / I_{\mathrm{cvl}}^{*}(F)
$$

In the case where the substrate histogram, $A$, is scalar or mono-variate, $\left|V_{A}\right| \leq 1$, the practicable fud inducer is stuffed with the empty fud, because the contracted decrementing linear non-overlapping fuds list maximiser, $Z_{P, A, A_{R}, F, \mathrm{n},-, K}$, in the limited-layer limited-underlying limited-breadth fud tree searcher, $Z_{P, A, A_{R}, \mathrm{~L}}$, requires a pluri-variate tuple, $|K|>1$, and so the limitedunderlying tuple set list maximiser, $Z_{P, A, A_{R}, F, \mathrm{~B}}$, requires a pluri-variate substrate, $\left|V_{A}\right|>1$.

A variation of this implementation of practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, is (i) to constrain the derived variables to intersect with the highest layer of the fud and (ii) to terminate the layer search as soon as the shuffle content alignment valency-density decreases. Define the highest-layer limited-derived derived variables set list maximiser
$Z_{P, A, A_{R}, F, \mathrm{D}, \mathrm{d}}=\operatorname{maximiseLister}\left(X_{P, A, A_{R}, F, \mathrm{D}}, P_{P, A, A_{R}, F, \mathrm{D}}, \operatorname{top}(\max ), R_{P, A, A_{R}, F, \mathrm{D}, \mathrm{d}}\right)$
where the initial subset is

$$
\begin{gathered}
R_{P, A, A_{R}, F, \mathrm{D}, \mathrm{~d}}=\left\{\left(J, X_{P, A, A_{R}, F, \mathrm{D}}(J)\right):\right. \\
w \in \operatorname{der}(F), u \in \operatorname{vars}(F) \backslash V_{A} \backslash \operatorname{vars}(\operatorname{depends}(F,\{w\})), \\
\left.J=\{w, u\},\left|J^{\mathrm{C}}\right| \leq \operatorname{wmax}\right\}
\end{gathered}
$$

The upper bound on the expected cardinality for a non-empty $f u d, F \neq \emptyset$, is

$$
\sum_{j \in\{2 \ldots \min (j \max , r)\}}\binom{r}{j}-\binom{r-x}{j}
$$

where $R=\operatorname{vars}(F) \backslash V_{A}$ and $r=|R|, X=\operatorname{der}(F)$ and $x=|X|$.
Define the highest-layer limited-layer limited-underlying limited-breadth fud tree searcher

$$
Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{~d}}=\operatorname{searchTreer}\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}, P_{P, A, A_{R}, \mathrm{~L}, \mathrm{~d}},\{\emptyset\}\right)
$$

where the neighbourhood function returns a singleton

$$
\begin{aligned}
& P_{P, A, A_{R}, \mathrm{~L}, \mathrm{~d}}(F)=\{G: \\
& \quad G \in P_{P, A, A_{R}, \mathrm{~L}}(F) \\
& \left.\quad\left(F \neq \emptyset \Longrightarrow \operatorname{maxr}\left(\mathrm{el}\left(Z_{P, A, A_{R}, F, \mathrm{D}, \mathrm{~d}}\right)\right)<\operatorname{maxr}\left(\mathrm{el}\left(Z_{P, A, A_{R}, G, \mathrm{D}, \mathrm{~d}}\right)\right)\right)\right\}
\end{aligned}
$$

where el $=$ elements.

The practicable highest-layer shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}$, may then be implemented

$$
\begin{aligned}
& I_{z, \mathrm{csd}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}(A)= \\
& \quad\left\{\left(G, I_{\mathrm{csd}}^{*}\left(\left(A, A_{R}, G\right)\right)\right):\right. \\
& \quad\left|V_{A}\right|>1,\left\{F_{\mathrm{L}}\right\}=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{~d}}\right)\right) \\
& \left.\quad K \in \operatorname{maxd}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F_{\mathrm{L}}, \mathrm{D}, \mathrm{~d}}\right)\right), G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\} \cup
\end{aligned}
$$

$$
\left\{(\emptyset, 0):\left|V_{A}\right| \leq 1\right\}
$$

The practicable highest-layer shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}$, assumes that there is one maximum along the layercumulative path of fuds. An advantage of the highest-layer fud inducer is that fuds containing frame full functional transforms, having exactly the same alignment valency-density of lower layer fuds excluding the reframes, will be excluded, avoiding the extra computation and reducing the cardinality of the maximum domain, $\left|\operatorname{maxd}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F_{\mathrm{L}}, \mathrm{D}, \mathrm{d}}\right)\right)\right|$. Note that a computer implementing the highest-layer limited-derived derived variables set list maximiser need not recompute the previous layer highest shuffle content alignment valency-density, $\operatorname{maxr}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{D}, \mathrm{d}}\right)\right)$, but need only to carry it to this layer.

If the inclusion functions of the tuple set list maximiser and the derived variables set list maximiser are further ordered by descending sum derived variables layer the highest-layer fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}$, must be implemented with the limited-derived derived variables set list maximiser, $Z_{P, A, A_{R}, F, \mathrm{D}}$, rather than the highest-layer limited-derived derived variables set list maximiser, $Z_{P, A, A_{R}, F, \mathrm{D}, \mathrm{d}}$. That is, $K \in \operatorname{maxd}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F_{\mathrm{L}}, \mathrm{D}}\right)\right)$. In this way reframe variables at the max inclusion boundary may be replaced by variables below the highest layer.

Another variation of the implementation of practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, is to include the tuple binary partition constraint. Define

$$
Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{~b}}=\operatorname{searchTreer}\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}, P_{P, A, A_{R}, \mathrm{~L}, \mathrm{~b}},\{\emptyset\}\right)
$$

where the neighbourhood function returns a singleton

$$
\begin{aligned}
& P_{P, A, A_{R}, \mathrm{~L}, \mathrm{~b}}(F)=\{G: \\
& G=F \cup\left\{T: K \in \operatorname{topd}(\lfloor\operatorname{bmax} / \operatorname{mmax}\rfloor)\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{~B}}\right)\right),\right. \\
& \\
& H \in \operatorname{topd}(\operatorname{pmax})\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{n}, \mathrm{~b},-, K}\right)\right), \\
& \\
& \left.w \in \operatorname{der}(H), I=\operatorname{depends}(\operatorname{explode}(H),\{w\}), T=I^{\mathrm{TPT}}\right\}, \\
& \operatorname{layer}(G, \operatorname{der}(G)) \leq \operatorname{lmax}\}
\end{aligned}
$$

The practicable tuple-binary-partition shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~b}}^{\prime}$, may then be implemented

$$
\begin{aligned}
& I_{z, \mathrm{csd}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{~b}}^{\prime *}(A)= \\
& \left\{\left(G, I_{\mathrm{csd}}^{*}\left(\left(A, A_{R}, G\right)\right)\right):\right. \\
& \\
& \quad\left|V_{A}\right|>1,\left\{F_{\mathrm{L}}\right\}=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{~b}}\right)\right) \\
& \\
& \left.\quad K \in \operatorname{maxd}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F_{\mathrm{L}}, \mathrm{D}}\right)\right), G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\} \cup
\end{aligned}
$$

$$
\left\{(\emptyset, 0):\left|V_{A}\right| \leq 1\right\}
$$

Another variation of the implementation of practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, is to include the maximum-roll constraint by implementing with the maximum-roll contracted decrementing linear non-overlapping fuds tree maximiser, $Z_{P, A, A_{R}, F, \mathbf{n},-, K, \mathrm{mr}}$. Define

$$
Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{mr}}=\operatorname{searchTreer}\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}, P_{P, A, A_{R}, \mathrm{~L}, \mathrm{mr}},\{\emptyset\}\right)
$$

where the neighbourhood function returns a singleton

$$
\begin{aligned}
& P_{P, A, A_{R}, \mathrm{~L}, \operatorname{mr}}(F)=\{G: \\
& G=F \cup\left\{T: K \in \operatorname{topd}(\lfloor\operatorname{bmax} / \operatorname{mmax}\rfloor)\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{~B}}\right)\right),\right. \\
& H
\end{aligned} \quad \begin{aligned}
& \left\{\operatorname{maxd}(\operatorname{set}(L)): L \in \operatorname{paths}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, F, \mathrm{n},-, K, \mathrm{mr}}\right)\right)\right\}, \\
& \left.w \in \operatorname{der}(H), I=\operatorname{depends}(\operatorname{explode}(H),\{w\}), T=I^{\mathrm{TPT}}\right\}, \\
& \operatorname{layer}(G, \operatorname{der}(G)) \leq \operatorname{lmax}\}
\end{aligned}
$$

The practicable maximum-roll shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{mr}}^{\prime}$, may then be implemented

$$
\begin{aligned}
& I_{z, \text { csd,F, }, \infty, \mathrm{q}, P, \mathrm{mr}}^{\prime *}(A)= \\
& \left\{\left(G, I_{\mathrm{csd}}^{*}\left(\left(A, A_{R}, G\right)\right)\right):\right. \\
& \quad\left|V_{A}\right|>1,\left\{F_{\mathrm{L}}\right\}=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{mr}}\right)\right) \\
& \left.\quad K \in \operatorname{maxd}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F_{\mathrm{L}}, \mathrm{D}}\right)\right), G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\} \cup
\end{aligned}
$$

$$
\left\{(\emptyset, 0):\left|V_{A}\right| \leq 1\right\}
$$

A variation of the implementation of practicable maximum-roll shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{mr}}^{\prime}$, is to include the maximum-roll-by-derived-dimension constraint by implementing with the maximum-roll-by-derived-dimension contracted decrementing linear non overlapping fuds tree maximiser, $Z_{P, A, A_{R}, F, \mathrm{n},-, K, \mathrm{~mm}}$. Define

$$
Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{~mm}}=\operatorname{searchTreer}\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}, P_{P, A, A_{R}, \mathrm{~L}, \mathrm{~mm}},\{\emptyset\}\right)
$$

where the neighbourhood function returns a singleton

$$
\begin{aligned}
& P_{P, A, A_{R}, \mathrm{~L}, \mathrm{~mm}}(F)=\{G: \\
& G=F \cup\left\{T: K \in \operatorname{topd}(\lfloor\operatorname{bmax} / \operatorname{mmax}\rfloor)\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{~B}}\right)\right),\right. \\
& H \in \bigcup\left\{\operatorname{maxd}(\operatorname{set}(L)): L \in \operatorname{paths}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, F, \mathrm{n},-, K, \mathrm{~mm}}\right)\right)\right\}, \\
& \left.\quad w \in \operatorname{der}(H), I=\operatorname{depends}(\operatorname{explode}(H),\{w\}), T=I^{\mathrm{TPT}}\right\}, \\
& \operatorname{layer}(G, \operatorname{der}(G)) \leq \operatorname{lmax}\}
\end{aligned}
$$

The practicable maximum-roll-by-derived-dimension shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~mm}}^{\prime}$, may then be implemented
$I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~mm}}^{\prime *}(A)=$

$$
\left\{\left(G, I_{\mathrm{csd}}^{*}\left(\left(A, A_{R}, G\right)\right)\right):\right.
$$

$$
\left|V_{A}\right|>1,\left\{F_{\mathrm{L}}\right\}=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{~mm}}\right)\right),
$$

$$
\left.K \in \operatorname{maxd}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F_{\mathrm{L}}, \mathrm{D}}\right)\right), G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\} \cup
$$

$$
\left\{(\emptyset, 0):\left|V_{A}\right| \leq 1\right\}
$$

Another variation of the implementation of practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, is to exclude self partitions from the derived variables of the fuds of the limited-layer limited-underlying limited-breadth fud tree searcher, $Z_{P, A, A_{R}, \mathrm{~L}}$. Define the excluded-self limitedlayer limited-underlying limited-breadth fud tree searcher as

$$
Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{xs}}=\operatorname{searchTreer}\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}, P_{P, A, A_{R}, \mathrm{~L}, \mathrm{xs}},\{\emptyset\}\right)
$$

where the neighbourhood function returns a singleton

$$
\begin{aligned}
& P_{P, A, A_{R}, \mathrm{~L}, \mathrm{xs}}(F)=\{G: \\
& \qquad \begin{array}{l}
G=F \cup\left\{P^{\mathrm{T}}: K \in \operatorname{topd}(\lfloor\operatorname{bmax} / \operatorname{mmax}\rfloor)\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{~B}}\right)\right),\right. \\
\\
H \in \operatorname{topd}(\operatorname{pmax})\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{n},-, K}\right)\right), \\
w \in \operatorname{der}(H), I=\operatorname{depends}(\operatorname{explode}(H),\{w\}), \\
\\
\left.P=I^{\mathrm{TP}}, P \neq(\cup P)^{\{ \}}\right\}, \\
\operatorname{layer}(G, \operatorname{der}(G)) \leq \operatorname{lmax}\}
\end{array}
\end{aligned}
$$

The rationale for excluding self partition variables is to reduce the computation necessary to process redundant variables, although note that the self partition variables will no longer appear in the top layer, $(\cup P)^{\{ \}} \notin \operatorname{der}(G)$, and so cannot lift variables below during tuple building.

Also note that if all but one of the derived variables of the top decrementing linear fuds are self partition variables then the new fud $G$ will have a single derived variable, $|\operatorname{der}(G)|=1$, and hence have zero alignment, $\operatorname{algn}\left(A * G^{\mathrm{T}}\right)=0$. If the top decrementing linear fuds contain only self partition derived variables then the neighbourhood function will return the given fud unchanged, $G=F$. That is, in this case no new layer is added.

The practicable excluded-self shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{xs}}^{\prime}$, may then be implemented
$I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{xs}}^{\prime}(A)=$

$$
\left\{\left(G, I_{\mathrm{csd}}^{*}\left(\left(A, A_{R}, G\right)\right)\right):\right.
$$

$$
\left|V_{A}\right|>1,\left\{F_{\mathrm{L}}\right\}=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{xs}}\right)\right),
$$

$\left.K \in \operatorname{maxd}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F_{\mathrm{L}}, \mathrm{D}}\right)\right), G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\} \cup$
$\left\{(\emptyset, 0):\left|V_{A}\right| \leq 1\right\}$
Another variation of the implementation of practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{cs}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, is to include the limitedvalency constraint by implementing with the limited-valency contracted decrementing linear non-overlapping fuds list maximiser, $Z_{P, A, A_{R}, F, \mathrm{n}, \mathrm{w},-, K}$. Define

$$
Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{w}}=\operatorname{searchTreer}\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}, P_{P, A, A_{R}, \mathrm{~L}, \mathrm{w}},\{\emptyset\}\right)
$$

where the neighbourhood function returns a singleton

$$
\begin{aligned}
& P_{P, A, A_{R}, \mathrm{~L}, \mathrm{w}}(F)=\{G: \\
& G=F \cup\left\{T: K \in \operatorname{topd}(\lfloor\operatorname{bmax} / \operatorname{mmax}\rfloor)\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{~B}}\right)\right),\right. \\
& \\
& H \in \operatorname{topd}(\operatorname{pmax})\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{n}, \mathrm{w},-, K}\right)\right), \\
& \\
& \left.w \in \operatorname{der}(H), I=\operatorname{depends}(\operatorname{explode}(H),\{w\}), T=I^{\mathrm{TPT}}\right\}, \\
& \operatorname{layer}(G, \operatorname{der}(G)) \leq \operatorname{lmax}\}
\end{aligned}
$$

The practicable limited-valency shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{w}}^{\prime}$, may then be implemented

$$
\begin{aligned}
& I_{z, \text { csd,F, }, \infty, \mathrm{q}, P, \mathrm{w}}^{\prime *}(A)= \\
& \left\{\left(G, I_{\mathrm{csd}}^{*}\left(\left(A, A_{R}, G\right)\right)\right):\right. \\
& \quad\left|V_{A}\right|>1,\left\{F_{\mathrm{L}}\right\}=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, A A_{R}, \mathrm{~L}, \mathrm{w}}\right)\right) \\
& \\
& \left.\quad K \in \operatorname{maxd}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F_{\mathrm{L}}, \mathrm{D}}\right)\right), G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\} \cup
\end{aligned}
$$

$$
\left\{(\emptyset, 0):\left|V_{A}\right| \leq 1\right\}
$$

In some cases a tuple $K$ returned by the limited-underlying tuple set list maximiser, $Z_{P, A, A_{R}, F, \mathrm{~B}}$, will be rejected by the subsequent limited-valency contracted decrementing linear non-overlapping fuds list maximiser, $Z_{P, A, A_{R}, F, \mathrm{n}, \mathbf{w},-, K}$, because there are no limited-valency tuple partitions, $\forall Y \in \mathrm{~B}(K)((|Y|>$ $\operatorname{mmax}) \vee \neg\left(\forall M \in Y\left(\left|M^{\mathrm{C}}\right| \leq\right.\right.$ umax $\left.\left.)\right)\right)$. To avoid processing a tuple which is destined to fail the limited-valency constraint, a variation of the limitedunderlying tuple set list maximiser checks to ensure there is at least one limited-valency partition of the tuple. Define the checked-valency limitedunderlying tuple set list maximiser

$$
\begin{aligned}
& Z_{P, A, A_{R}, F, \mathrm{~B}, \mathrm{wc}}= \\
& \quad \text { maximiseLister }\left(X_{P, A, A_{R}, F, \mathrm{~B}}, P_{P, A, A_{R}, F, \mathrm{~B}, \mathrm{wc}}, \operatorname{top}(\mathrm{omax}), R_{P, A, A_{R}, F, \mathrm{~B}, \mathrm{wc}}\right)
\end{aligned}
$$

where the neighbourhood function is

$$
\begin{aligned}
& P_{P, A, A_{R}, F, \mathrm{~B}, \mathrm{wc}}(B)=\left\{\left(J, X_{P, A, A_{R}, F, \mathrm{~B}}(J)\right):\right. \\
& \quad(K, \cdot) \in B, w \in \operatorname{vars}(F) \cup V_{A} \backslash K, J=K \cup\{w\},\left|J^{\mathrm{C}}\right| \leq \mathrm{xmax}, \\
& \left.\quad \exists Y \in \mathrm{~B}(J)\left((|Y| \leq \operatorname{mmax}) \wedge\left(\forall M \in Y\left(\left|M^{\mathrm{C}}\right| \leq \operatorname{umax}\right)\right)\right)\right\}
\end{aligned}
$$

and the initial subset is

$$
\begin{aligned}
R_{P, A, A_{R}, \emptyset, \mathrm{~B}, \mathrm{wc}}= & \left\{\left(\{w, u\}, X_{P, A, A_{R}, \emptyset, \mathrm{~B}}(\{w, u\})\right):\right. \\
& w, u \in V_{A}, u \neq w,\left|\{w, u\}^{\mathrm{C}}\right| \leq \mathrm{xmax}, \\
& \left.\left|\{w\}^{\mathrm{C}}\right| \leq \operatorname{umax},\left|\{u\}^{\mathrm{C}}\right| \leq \operatorname{umax}\right\} \\
R_{P, A, A_{R}, F, \mathrm{~B}, \mathrm{wc}}= & \left\{\left(\{w, u\}, X_{P, A, A_{R}, F, \mathrm{~B}}(\{w, u\})\right):\right. \\
& w \in \operatorname{der}(F), u \in \operatorname{vars}(F) \cup V_{A}, u \neq w,\left|\{w, u\}^{\mathrm{C}}\right| \leq \mathrm{xmax}, \\
& \left.\left|\{w\}^{\mathrm{C}}\right| \leq \operatorname{umax},\left|\{u\}^{\mathrm{C}}\right| \leq \operatorname{umax}\right\}
\end{aligned}
$$

Another variation of the implementation of the practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, is to add a cached or common substrate fud $F_{\mathrm{c}} \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}$. For example, a common fud may be supplied from the parent slice fuds of a decomposition.

The common-fud limited-underlying tuple set list maximiser $Z_{P, A, A_{R}, F_{c}, F, \mathrm{~B}}$ can choose tuples from the variables of the common fud, vars $\left(F_{\mathrm{c}}\right)$, as well as from the substrate variables, $V_{A}$, and the variables of the given $f u d$, $\operatorname{vars}(F)$. Define the common-fud limited-underlying tuple set list maximiser

$$
\begin{aligned}
& Z_{P, A, A_{R}, F_{\mathrm{c}}, F, \mathrm{~B}}= \\
& \quad \text { maximiseLister }\left(X_{P, A, A_{R}, F_{c}, F, \mathrm{~B}}, P_{P, A, A_{R}, F_{\mathrm{c}}, F, \mathrm{~B}}, \operatorname{top}(\mathrm{omax}), R_{P, A, A_{R}, F_{c}, F, \mathrm{~B}}\right)
\end{aligned}
$$

where (i) the optimiser function is

$$
\begin{aligned}
& X_{P, A, A_{R}, F_{\mathrm{c}}, F, \mathrm{~B}}= \\
& \quad\left\{\left(K, I_{\mathrm{a}}^{*}\left(\operatorname{apply}\left(V_{A}, K, \operatorname{his}\left(F \cup F_{\mathrm{c}}\right), A\right)\right)-I_{\mathrm{a}}^{*}\left(\operatorname{apply}\left(V_{A}, K, \operatorname{his}\left(F \cup F_{\mathrm{c}}\right), A_{R}\right)\right)\right):\right. \\
& \left.K \in \operatorname{tuples}\left(\operatorname{vars}\left(F_{\mathrm{c}}\right) \cup V_{A}, F\right)\right\}
\end{aligned}
$$

and (ii) the neighbourhood function is

$$
\begin{aligned}
& P_{P, A, A_{R}, F_{c}, F, \mathrm{~B}}(B)=\left\{\left(J, X_{P, A, A_{R}, F_{\mathrm{c}}, F, \mathrm{~B}}(J)\right):\right. \\
& \left.\quad(K, \cdot) \in B, w \in \operatorname{vars}\left(F \cup F_{\mathrm{c}}\right) \cup V_{A} \backslash K, J=K \cup\{w\},\left|J^{\mathrm{C}}\right| \leq \mathrm{xmax}\right\}
\end{aligned}
$$

and (iii) the initial subset is

$$
\begin{aligned}
R_{P, A, A_{R}, F_{\mathrm{c}}, \emptyset, \mathrm{~B}}= & \left\{\left(\{w, u\}, X_{P, A, A_{R}, F_{\mathrm{c}}, \emptyset \mathrm{~B}}(\{w, u\})\right):\right. \\
& \left.w, u \in \operatorname{vars}\left(F_{\mathrm{c}}\right) \cup V_{A}, u \neq w,\left|\{w, u\}^{\mathrm{C}}\right| \leq \operatorname{xmax}\right\} \\
R_{P, A, A_{R}, F_{\mathrm{c}}, F, \mathrm{~B}}= & \left\{\left(\{w, u\}, X_{P, A, A_{R}, F_{\mathrm{c}}, F, \mathrm{~B}}(\{w, u\})\right):\right. \\
& w \in \operatorname{der}(F), u \in \operatorname{vars}\left(F \cup F_{\mathrm{c}}\right) \cup V_{A}, u \neq w, \\
& \left.\left|\{w, u\}^{\mathrm{C}}\right| \leq \operatorname{xmax}\right\}
\end{aligned}
$$

An upper bound on the expected cardinality of the searched may be computed given the maximum underlying dimension, kmax. The upper bound on the expected cardinality in the first layer, $F=\emptyset$, is

$$
\sum_{k \in\{2 \ldots \min (\mathrm{kmax}, s)\}}\binom{s}{k}
$$

where $s=\left|\operatorname{vars}\left(F_{\mathrm{c}}\right) \cup V\right|$ and $\min =$ minimum. In subsequent layers, $F \neq \emptyset$, the upper bound on the expected cardinality is

$$
\sum_{k \in\{2 \ldots \min (\mathrm{kmax}, t)\}}\binom{t}{k}-\binom{t-x}{k}
$$

where $W=\operatorname{vars}\left(F \cup F_{\mathrm{c}}\right) \cup V_{A}, t=|W|, X=\operatorname{der}(F)$ and $x=|X|$.
Define the common-fud limited-layer limited-underlying limited-breadth fud tree searcher

$$
Z_{P, A, A_{R}, F_{c}, \mathrm{~L}}=\operatorname{searchTreer}\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}, P_{P, A, A_{R}, F_{c}, \mathrm{~L}},\{\emptyset\}\right)
$$

where the neighbourhood function returns a singleton

$$
\begin{aligned}
& P_{P, A, A_{R}, F_{\mathrm{c}}, \mathrm{~L}}(F)=\{G: \\
& G=F \cup \bigcup\{ \{T\} \cup \operatorname{depends}\left(F_{\mathrm{c}}, \operatorname{und}(T)\right): \\
& K \in \operatorname{topd}(\lfloor\operatorname{bmax} / \operatorname{mmax}\rfloor)\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F_{\mathrm{c}}, F, \mathrm{~B}}\right)\right), \\
& H \in \operatorname{topd}(\operatorname{pmax})\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F \cup F_{\mathrm{c}}, \mathrm{n},-, K}\right)\right), \\
&\left.w \in \operatorname{der}(H), I=\operatorname{depends}(\operatorname{explode}(H),\{w\}), T=I^{\mathrm{TPT}}\right\}, \\
&\operatorname{layer}(G, \operatorname{der}(G)) \leq \operatorname{lmax}\}
\end{aligned}
$$

Whereas in the limited-layer limited-underlying limited-breadth fud tree searcher, $Z_{P, A, A_{R}, \mathrm{~L}}$, the layers of the fud increment at each step along the path, $\forall(i, G) \in L(\operatorname{layer}(G, \operatorname{der}(G))=i)$ where $L \in \operatorname{paths}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, \mathrm{~L}}\right)\right)$, in the common-fud fud tree searcher, $Z_{P, A, A_{R}, F_{c}, \mathrm{~L}}$, there is no such guarantee.

Note that in some cases a partition transform, $I^{\mathrm{TPT}}$, may already exist in the common fud, $F_{\mathrm{c}}$. Just as in the case of the fud tree searcher, $Z_{P, A, A_{R}, \mathrm{~L}}$, above, the common-fud fud tree searcher, $Z_{P, A, A_{R}, F_{c}, \mathrm{~L}}$, may also hide partition variables, but in this case it may occur in the first step, because the layer need not correspond to the common-fud fud tree searcher path position.

Implementations of the neighbourhood function that do not use partition variables, $F \notin \mathcal{F}_{U, \mathrm{P}}$, must explicitly check for uniqueness, $I^{\mathrm{TP}} \notin\left\{T^{\mathrm{P}}\right.$ : $\left.T \in F_{\mathrm{c}}\right\}$. If the partition transform is in the common fud, $T_{\mathrm{c}} \in F_{\mathrm{c}}$ where $T_{\mathrm{c}}^{\mathrm{P}}=I^{\mathrm{TP}}$, then the common fud's transform should be added to the given fud instead, $F \cup\left\{T_{\mathrm{c}}\right\}$.

The practicable common-fud shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, F_{\mathrm{c}}}^{\prime}$, may then be implemented

```
\(I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, F_{\mathrm{c}}}^{\prime *}(A)=\)
    \(\left\{\left(G, I_{\text {csd }}^{*}\left(\left(A, A_{R}, G\right)\right)\right):\right.\)
    \(\left|V_{A}\right|>1,\left\{F_{\mathrm{L}}\right\}=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, F_{\mathrm{c}}, \mathrm{L}}\right)\right)\),
    \(\left.K \in \operatorname{maxd}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F_{\mathrm{L}}, \mathrm{D}}\right)\right), G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\} \cup\)
    \(\left\{(\emptyset, 0):\left|V_{A}\right| \leq 1\right\}\)
```

Note that the addition of a common fud hint to the common-fud fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, F_{\mathrm{c}}}^{\prime}$, will not necessarily produce the same models as the fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, without the hint. Nor is there necessarily an improvement in computation performance.

Another variation of the implementation of the practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, is to explicitly specify the substrate. Rather than modelling with the given substrate variables, $V_{A}$, level modelling is parameterised by a pair of (i) a set of variables $V_{\mathrm{g}}$, which is a subset of the substrate variables, $V_{\mathrm{g}} \subseteq V_{A}$, and (ii) a level fud $F_{\mathrm{g}} \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}$, which is such that its underlying is also a subset of the substrate variables, $\operatorname{und}\left(F_{\mathrm{g}}\right) \subseteq V_{A}$. Here only the union of (i) the substrate variables subset, $V_{\mathrm{g}}$, and (ii) the derived variables of the given level fud, $\operatorname{der}\left(F_{\mathrm{g}}\right)$, are visible to the tuple maximiser, so the substrate variables, $V_{A}$, are effectively replaced by the level variables, $V_{\mathrm{g}} \cup \operatorname{der}\left(F_{\mathrm{g}}\right)$.

The level fud inducer allows multiple levels to be modelled in sequence, so, for example, large substrates, $V_{A}$, with large underlying volumes, $\left|V_{A}^{\mathrm{C}}\right|$, may be made practicable by (i) partitioning them into components, $V_{\mathrm{g}} \in P$, where $P \in \mathrm{~B}\left(V_{A}\right)$, with smaller underlying volumes, $\left|V_{\mathrm{g}}^{\mathrm{C}}\right|<\left|V_{A}^{\mathrm{C}}\right|$, (ii) inducing a level fud on each component, $V_{\mathrm{g}}$, of the substrate partition, and then (iii) combining these level fuds in a higher level to produce a model with coverage of the whole substrate, $V_{A}$. Another example is to use the level fud inducer in order to exclude mono-valent substrate variables, $V_{\mathrm{g}}=\{w: w \in$ $\left.V_{A},\left|(A \%\{w\})^{\mathrm{F}}\right|>1\right\}$, which might occur near the leaves of a decomposition. Note that higher levels do not necessarily require non-overlapping level fuds.

The level limited-underlying tuple set list maximiser $Z_{P, A, A_{R}, V_{\mathbf{g}}, F_{\mathrm{F}}, F, \mathrm{~B}}$ replaces the substrate variables, $V_{A}$, with the level variables, $V_{\mathrm{g}} \cup \operatorname{der}\left(F_{\mathrm{g}}\right)$. Define the level limited-underlying tuple set list maximiser

$$
\begin{aligned}
& Z_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{g}}, F, \mathrm{~B}}= \\
& \quad \text { maximiseLister }\left(X_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{g}}, F, \mathrm{~B}}, P_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{g}}, F, \mathrm{~B}}, \operatorname{top}(\mathrm{omax}), R_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{g}}, F, \mathrm{~B}}\right)
\end{aligned}
$$

where (i) the optimiser function is

$$
\begin{aligned}
& X_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{g}}, F, \mathrm{~B}}= \\
& \quad\left\{\left(K, I_{\mathrm{a}}^{*}\left(\operatorname{apply}\left(V_{A}, K, \operatorname{his}\left(F \cup F_{\mathrm{g}}\right), A\right)\right)-I_{\mathrm{a}}^{*}\left(\operatorname{apply}\left(V_{A}, K, \operatorname{his}\left(F \cup F_{\mathrm{g}}\right), A_{R}\right)\right)\right):\right. \\
& \left.K \in \operatorname{tuples}\left(V_{\mathrm{g}} \cup \operatorname{der}\left(F_{\mathrm{g}}\right), F\right)\right\}
\end{aligned}
$$

and (ii) the neighbourhood function is

$$
\begin{aligned}
& P_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{g}}, F, \mathrm{~B}}(B)=\left\{\left(J, X_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{g}}, F, \mathrm{~B}}(J)\right):\right. \\
& (K, \cdot) \in B, w \in \operatorname{vars}(F) \backslash \operatorname{vars}\left(F_{\mathrm{g}}\right) \cup V_{\mathrm{g}} \cup \operatorname{der}\left(F_{\mathrm{g}}\right) \backslash K, \\
& \left.J=K \cup\{w\},\left|J^{\mathrm{C}}\right| \leq \operatorname{xmax}\right\}
\end{aligned}
$$

and (iii) the initial subset is

$$
\begin{aligned}
R_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{g}}, \emptyset, \mathrm{~B}}= & \left\{\left(\{w, u\}, X_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{F}}, \emptyset, \mathrm{~B}}(\{w, u\})\right):\right. \\
& \left.w, u \in V_{\mathrm{g}} \cup \operatorname{der}\left(F_{\mathrm{g}}\right), u \neq w,\left|\{w, u\}^{\mathrm{C}}\right| \leq \mathrm{xmax}\right\} \\
R_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{F}}, F, \mathrm{~B}}= & \left\{\left(\{w, u\}, X_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{F}}, F, \mathrm{~B}}(\{w, u\})\right):\right. \\
& w \in \operatorname{der}(F), u \in \operatorname{vars}(F) \backslash \operatorname{vars}\left(F_{\mathrm{g}}\right) \cup V_{\mathrm{g}} \cup \operatorname{der}\left(F_{\mathrm{g}}\right), u \neq w, \\
& \left.\left|\{w, u\}^{\mathrm{C}}\right| \leq \operatorname{xmax}\right\}
\end{aligned}
$$

An upper bound on the expected cardinality of the searched may be computed given the maximum underlying dimension, kmax. The upper bound on the expected cardinality in the first layer, $F=\emptyset$, is

$$
\sum_{k \in\{2 \ldots \min (\operatorname{kmax}, s)\}}\binom{s}{k}
$$

where $s=\left|V_{\mathrm{g}} \cup \operatorname{der}\left(F_{\mathrm{g}}\right)\right|$ and $\min =$ minimum. In subsequent layers, $F \neq \emptyset$, the upper bound on the expected cardinality is

$$
\sum_{k \in\{2 \ldots \min (\mathrm{kmax}, t)\}}\binom{t}{k}-\binom{t-x}{k}
$$

where $W=\operatorname{vars}(F) \backslash \operatorname{vars}\left(F_{\mathrm{g}}\right) \cup V_{\mathrm{g}} \cup \operatorname{der}\left(F_{\mathrm{g}}\right), t=|W|, X=\operatorname{der}(F)$ and $x=|X|$.

Define the level limited-layer limited-underlying limited-breadth fud tree searcher

$$
Z_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{F}}, \mathrm{~L}}=\operatorname{searchTreer}\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}, P_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{F}}, \mathrm{~L}},\{\emptyset\}\right)
$$

where the neighbourhood function returns a singleton

$$
\begin{aligned}
& P_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{g}}, \mathrm{~L}}(F)=\{G: \\
& G=F \cup \bigcup\left\{\{T\} \cup \operatorname{depends}\left(F_{\mathrm{g}}, \operatorname{und}(T)\right):\right. \\
& K \in \operatorname{topd}(\lfloor\operatorname{bmax} / \max \rfloor)\left(\operatorname{elements}\left(Z_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{F}}, F, \mathrm{~B}}\right)\right), \\
& H \\
& H \in \operatorname{topd}(\operatorname{pmax})\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F \cup F_{\mathrm{g}}, \mathrm{n},-, K}\right)\right), \\
& \left.w \in \operatorname{der}(H), I=\operatorname{depends}(\operatorname{explode}(H),\{w\}), T=I^{\mathrm{TPT}}\right\}, \\
& \operatorname{layer}(G, \operatorname{der}(G)) \leq \operatorname{lmax}\}
\end{aligned}
$$

Note that the resultant $f u d$ of the level fud tree searcher, $Z_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{g}}, \mathrm{L}}$, has its underlying variables flattened to the substrate. That is, $\operatorname{und}\left(F_{\mathrm{L}}\right) \subseteq V_{A}$, where $\left\{F_{\mathrm{L}}\right\}=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{g}}, \mathrm{L}}\right)\right)$. So it is not necessary to supply
$F_{\mathrm{g}}$ along with $F_{\mathrm{L}}$.

Whereas in the limited-layer limited-underlying limited-breadth fud tree searcher, $Z_{P, A, A_{R}, \mathrm{~L}}$, the layers of the fud increment at each step along the path, $\forall(i, G) \in L(\operatorname{layer}(G, \operatorname{der}(G))=i)$ where $L \in \operatorname{paths}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, \mathrm{~L}}\right)\right)$, in the level fud tree searcher, $Z_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{g}}, \mathrm{L}}$, there is no such guarantee.

Define the level limited-derived derived variables set list maximiser
$Z_{P, A, A_{R}, F_{\mathrm{g}}, F, \mathrm{D}}=\operatorname{maximiseLister}\left(X_{P, A, A_{R}, F, \mathrm{D}}, P_{P, A, A_{R}, F_{\mathrm{g}}, F, \mathrm{D}}, \operatorname{top}(\max ), R_{P, A, A_{R}, F_{\mathrm{g}}, F, \mathrm{D}}\right)$
where the neighbourhood function is

$$
\begin{aligned}
& P_{P, A, A_{R}, F_{\mathrm{g}}, F, \mathrm{D}}(D)=\left\{\left(J, X_{P, A, A_{R}, F, \mathrm{D}}(J)\right):\right. \\
& \quad(K, \cdot) \in D, w \in \operatorname{vars}(F) \backslash V_{A} \backslash \operatorname{vars}\left(F_{\mathrm{g}}\right) \backslash K \\
& \left.\quad J=K \cup\{w\},\left|J^{\mathrm{C}}\right| \leq \mathrm{wmax}, \operatorname{der}(\operatorname{depends}(F, J))=J\right\}
\end{aligned}
$$

and the initial subset is

$$
\begin{aligned}
& R_{P, A, A_{R}, F_{\mathrm{g}}, F, \mathrm{D}}=\left\{\left(J, X_{P, A, A_{R}, F, \mathrm{D}}(J)\right):\right. \\
& \quad w, u \in \operatorname{vars}(F) \backslash V_{A} \backslash \operatorname{vars}\left(F_{\mathrm{g}}\right), u \neq w \\
& \left.\quad J=\{w, u\},\left|J^{\mathrm{C}}\right| \leq \operatorname{wmax}, \operatorname{der}(\operatorname{depends}(F, J))=J\right\}
\end{aligned}
$$

The practicable level shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, V_{\mathrm{g}}, F_{\mathrm{g}}}^{\prime}$, may then be implemented

$$
\begin{aligned}
& I_{z, \mathrm{csd}, \mathrm{~F}, \infty, \mathrm{q}, P, V_{\mathrm{g}}, F_{\mathrm{g}}}^{\prime *}(A)= \\
& \qquad\left\{\left(G, I_{\mathrm{csd}}^{*}\left(\left(A, A_{R}, G\right)\right)\right):\right. \\
& \quad\left|V_{A}\right|>1,\left\{F_{\mathrm{L}}\right\}=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{g}}, \mathrm{~L}}\right)\right) \\
& \left.\quad K \in \operatorname{maxd}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F_{\mathrm{g}}, F_{\mathrm{L}}, \mathrm{D}}\right)\right), G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\} \cup
\end{aligned}
$$

$$
\left\{(\emptyset, 0):\left|V_{A}\right| \leq 1\right\}
$$

Of the variations described above of the implementation of practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, only the practicable limited-valency shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{w}}^{\prime}$, is potentially unrestricted. That is, the limited-valency inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{w}}^{\prime}$, can perform the same search as the unlimited inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, if the maximum valency is set equal to the maximum underlying volume, umax $=$ xmax. The other variations all have restricted functionality with respect to the unlimited inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, no matter what the parameters.

As shown above, the use of a shuffle histogram, $A_{R}$, is a practicable approximation to the independent, $A^{\mathrm{X}}$, in the practicable shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$. This allows optimisations to avoid a two stage (i) search of possibly overlapping fuds, $\operatorname{select}\left(T_{A}, N_{A}\right) \subset$ $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}$, followed by (ii) filtering of non-overlapping fuds, $\left\{F: F \in \operatorname{select}\left(T_{A}, N_{A}\right), \operatorname{nd}(F)\right\} \subset \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$. The optimisers do this by maximisation of the shuffle content alignment valency-density to construct fuds that approximate loosely to recursively non-overlapping pluri-partition fuds, from which an approximately non-overlapping top transform can be chosen. The same reasoning may be extended to a fud decomposition inducer. Here a shuffle histogram is constructed from each of the slices of the fuds of the decomposition. Each shuffle approximates to the independent of the contingent sample. Redefine the shuffle indices, $R_{A} \subseteq\left\{1 \ldots z_{A}!^{n_{A}}\right\}$, where $A \in \mathcal{A}_{z(A)}, z_{A}=\operatorname{size}(A)$ and $n_{A}=|\operatorname{vars}(A)|$. Redefine the scaled shuffle histogram, $A_{R(A)}=\operatorname{scalar}(1 /|R(A)|) * \sum_{r \in R(A)} L_{A}(r)$ where $X_{A} \in \operatorname{enums}(\operatorname{shuffles}($ history $(A)))$ and $L_{A}=\operatorname{map}\left(\right.$ his, flip $\left.\left(X_{A}\right)\right)$. Then the scaled contingent shuffle histogram is $(A * C)_{R(A * C)} \approx(A * C)^{\mathrm{X}}$, where $(\cdot, C) \in \operatorname{cont}(D)$ and $D \in \mathcal{D}_{\mathrm{F}, \propto, U_{A}, V_{A}}$.

The practicable summed shuffle content alignment valency-density fud decomposition inducer, which, given substrate histogram $A \in \mathcal{A}_{z}$, is constrained

```
\(I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime *}(A) \subseteq\)
    \(\left\{\left(D, I_{\mathrm{Scsd}}^{*}((A, D))\right):\right.\)
        \(D \in \mathcal{D}_{\mathrm{F}, \infty, U_{A}, V_{A}} \cap \operatorname{trees}\left(\mathcal{S} \times \mathcal{F}_{\mathrm{q}}\right)\),
                \(\forall(C, F) \in \operatorname{cont}(D)\)
                        \(\left.\left(I_{\mathrm{a}}^{*}\left(A * C * F^{\mathrm{T}}\right)-I_{\mathrm{a}}^{*}\left((A * C)_{R(A * C)} * F^{\mathrm{T}}\right)>0\right)\right\} \cup\)
    \(\left\{\left(D_{\emptyset}, 0\right)\right\}\)
```

where $D_{\emptyset}=\{((\emptyset, \emptyset), \emptyset)\}$ and the summed shuffle content alignment valencydensity computer $I_{\text {Scsd }} \in$ computers is defined as

$$
\begin{aligned}
& I_{\mathrm{Scsd}}^{*}((A, D))= \\
& \quad \sum\left(I_{\mathrm{a}}^{*}\left(A * C * F^{\mathrm{T}}\right)-I_{\mathrm{a}}^{*}\left((A * C)_{R(A * C)} * F^{\mathrm{T}}\right)\right) / I_{\mathrm{cv1}}^{*}(F):(C, F) \in \operatorname{cont}(D)
\end{aligned}
$$

In some cases the practicable inducer optimisation may be empty. For example, the independent substrate histogram, $A^{\mathrm{X}}$, cannot have non-zero positive summation content alignment. The maximum function, $\operatorname{maxr}\left(I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P}^{*}\left(A^{\mathrm{X}}\right)\right)$, would therefore be undefined for some inducer domain substrate histograms. In order to have well defined maximum correlation, the practicable inducer
is therefore stuffed with the empty decomposition, $D_{\emptyset} \in \mathcal{D}_{\mathrm{F}}$, in the case of empty optimisation.

Each non-zero positive shuffle content alignment valency-density fud decomposition of the application of the practicable fud decomposition inducer, $I_{z, \mathrm{Scs}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, is related to the computation of fuds of the slices in the practicable fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, which is defined in terms of the limitedlayer limited-underlying limited-breadth fud tree searcher, $Z_{P, A, A_{R}, \mathrm{~L}}$, and the limited-derived derived variables set list maximiser, $Z_{P, A, A_{R}, F, \mathrm{D}}$,

$$
\begin{aligned}
& \forall(D, a) \in I_{z, \mathrm{Scss}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P}^{\prime *}(A)(a>0 \Longrightarrow \\
& \quad\left(\forall(C, F) \in \operatorname{cont}(D) \forall F_{\mathrm{L}} \in \operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A * C,(A * C)_{R(A * C)}, \mathrm{L}}\right)\right)\right. \\
& \left.\left.\quad \exists K \in \operatorname{maxd}\left(\operatorname{elements}\left(Z_{P, A * C,(A * C)_{R(A * C)}, F_{\mathrm{L}}, \mathrm{D}}\right)\right)\left(F=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right)\right)\right)
\end{aligned}
$$

Note that the practicable summed shuffle content alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P}^{\prime}$, is defined such that the contingent histogram, $A * C$, is shuffled, $(A * C)_{R(A * C)}$, rather taking the contingent of the shuffled histogram, $A_{R(A)} * C$. If the contingent shuffle histogram were used then any biases for or against the alignment in the shuffle, $A_{R(A)}$, in the parent slice would be safely removed. However, the size of the contingent shuffle histogram is not necessairly equal to that of the contingent sample, $\operatorname{size}\left(A_{R(A)} * C\right) \neq \operatorname{size}(A * C)$, and so scaling is often necessary. This would not be a disadvantage if it were not the case that typically the entropy of the parent derived histogram of the contingent shuffle is greater than that of the sample, and so the contingent shuffle slice size tends to zero much more quickly than the sample slice size. Therefore the scaling factor is often large, making the contingent shuffle less effective as an approximation to the independent slice, $(A * C)^{\mathrm{X}}$.

In section 'Substrate models computation' above, the finite limited-models infinite-layer fud decomposition tree, $\operatorname{tdfiq}(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{D}_{\mathrm{F}, \mathrm{d}} \rightarrow \operatorname{trees}\left(\mathcal{D}_{\mathrm{F}, \mathrm{d}}\right)$, is a tree of immediate super-decompositions of limited-models infinite-layer substrate fuds. The decompositions of the tree are a subset the limited-models infinite-layer substrate fud decompositions

$$
\mathcal{D}_{\mathrm{F}, \propto, U, V} \cap \operatorname{trees}\left(\mathcal{S} \times \mathcal{F}_{\mathrm{q}}\right) \supset \operatorname{elements}(\operatorname{tdfiq}(U)(V))
$$

The limited-models infinite-layer substrate fud decompositions tree searcher chooses a sublist of a path of immediate super-decompositions from the limited-models infinite-layer fud decomposition tree. Define the limited-models infinite-layer substrate fud decompositions tree searcher

$$
Z_{P, A, \mathrm{D}, \mathrm{~F}}=\operatorname{search} \operatorname{Treer}\left(\mathcal{D}_{\mathrm{F}, \infty, U, V} \cap \operatorname{trees}\left(\mathcal{S} \times \mathcal{F}_{\mathrm{q}}\right), P_{P, A, \mathrm{D}, \mathrm{~F}}, R_{P, A, \mathrm{D}, \mathrm{~F}}\right)
$$

where the neighbourhood function returns a singleton

$$
\begin{aligned}
& P_{P, A, \mathrm{D}, \mathrm{~F}}(D)=\{E: \\
& (\cdot, S, G, L) \in \operatorname{maxd}\left(\operatorname { o r d e r } \left(D_{\mathbf{Q} \times S \times \mathcal{X}^{2}},\{(\operatorname{size}(B), S, G, L):\right.\right. \\
& (L, Y) \in \operatorname{places}(D), \\
& R_{L}=\bigcup \operatorname{dom}(\operatorname{set}(L)), H_{L}=\bigcup \operatorname{ran}(\operatorname{set}(L)) \text {, } \\
& (\cdot, F)=L_{|L|}, W=\operatorname{der}(F) \text {, } \\
& S \in W^{\mathrm{CS}} \backslash \operatorname{dom}(\operatorname{dom}(Y)) \text {, } \\
& B=\operatorname{apply}\left(V_{A}, V_{A}, \operatorname{his}\left(H_{L}\right) \cup\left\{\left\{R_{L} \cup S\right\}^{U}\right\}, A\right), \operatorname{size}(B)>0, \\
& F_{\mathrm{L}} \in \operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, B, B_{R(B)}, \mathrm{L}}\right)\right) \text {, } \\
& (K, a) \in \max \left(\operatorname{elements}\left(Z_{P, B, B_{R(B)}, F_{\mathrm{L}}, \mathrm{D}}\right)\right), a>0, \\
& \left.\left.\left.G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\}\right)\right) \text {, } \\
& M=L \cup\{(|L|+1,(S, G))\} \text {, } \\
& E=\operatorname{tree}(\operatorname{paths}(D) \backslash\{L\} \cup\{M\})\}
\end{aligned}
$$

where

$$
\begin{aligned}
R_{P, A, \mathrm{D}, \mathrm{~F}}=\{ & \{((\emptyset, G), \emptyset)\}: \\
G \in & \operatorname{maxd}\left(\operatorname { o r d e r } \left(D_{\mathrm{F}},\{G:\right.\right. \\
& F_{\mathrm{L}} \in \operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, A_{R(A)}, \mathrm{L}}\right)\right), \\
& (K, a) \in \max \left(\operatorname{elements}\left(Z_{P, A, A_{R(A)}, F_{\mathrm{L}}, \mathrm{D}}\right)\right), a>0, \\
& \left.\left.\left.\left.G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\}\right)\right)\right\}
\end{aligned}
$$

The computation of the slice $B$ is a tractable fud application equivalent to the application of the fud's transforms' histograms, his $\left(H_{L}\right)$, multiplied by the slice derived state, $\left\{R_{L} \cup S\right\}^{\mathrm{U}}$, followed by reduction to the substrate, $V_{A}$,
$\operatorname{apply}\left(V_{A}, V_{A}, \operatorname{his}\left(H_{L}\right) \cup\left\{\left\{R_{L} \cup S\right\}^{\mathrm{U}}\right\}, A\right)=A * \prod \operatorname{his}\left(H_{L}\right) *\left\{R_{L} \cup S\right\}^{\mathrm{U}} \% V_{A}$
The neighbourhood function $P_{P, A, \mathrm{D}, \mathrm{F}}(D)$ returns an empty set or a singleton super-decomposition with an additional slice having non-zero positive shuffle content alignment. The order $D_{\mathbf{Q} \times S \times \mathcal{X}^{2}}$ selects by slice size and then arbitrarily. Together the orders $D_{\mathbf{Q} \times \mathrm{S} \times \mathcal{X}^{2}}$ and $D_{\mathrm{F}}$ ensure that the fud decomposition is distinct. The tree of the limited-models infinite-layer substrate fud decompositions tree searcher has at most one path, $\mid$ paths $\left(\operatorname{tree}\left(Z_{P, A, \mathrm{D}, \mathrm{F}}\right)\right) \mid \leq 1$, and hence the tree has at most one leaf, $\mid$ leaves $\left(\operatorname{tree}\left(Z_{P, A, \mathrm{D}, \mathrm{F}}\right)\right) \mid \leq 1$. If the path exists, $\{L\}=\operatorname{paths}\left(\operatorname{tree}\left(Z_{P, A, \mathrm{D}, \mathrm{F}}\right)\right)$, it is in the limited-models infinite-layer fud decomposition tree, $L \in \operatorname{subpaths}\left(\operatorname{tdfiq}\left(U_{A}\right)\left(V_{A}, \emptyset\right)\right)$.

The practicable summed shuffle content alignment valency-density fud decomposition inducer may then be implemented

$$
\begin{aligned}
& I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P}^{\prime *}(A)= \\
& \quad \operatorname{if}\left(Q \neq \emptyset,\left\{\left(D, I_{\text {Scsd }}^{*}((A, D))\right)\right\},\left\{\left(D_{\emptyset}, 0\right)\right\}\right): \\
& \quad Q=\text { leaves }\left(\operatorname{tree}\left(Z_{P, A, \mathrm{D}, \mathrm{~F}}\right)\right),\{D\}=Q
\end{aligned}
$$

The highest-layer limited-models infinite-layer substrate fud decompositions tree searcher, $Z_{P, A, \mathrm{D}, \mathrm{F}, \mathrm{d}}$, is defined exactly the same as the limited-models infinite-layer substrate fud decompositions tree searcher, $Z_{P, A, \mathrm{D}, \mathrm{F}}$, except that it depends instead on the highest-layer limited-layer limited-underlying limitedbreadth fud tree searcher, $Z_{P, B, B_{R}, \mathrm{~L}, \mathrm{~d}}$, and the highest-layer limited-derived derived variables set list maximiser, $Z_{P, B, B_{R}, F_{\mathrm{L}}, \mathrm{D}, \mathrm{d}}$. The practicable highestlayer summed shuffle content alignment valency-density fud decomposition inducer is implemented

$$
\begin{aligned}
& I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime *}(A)= \\
& \operatorname{if}\left(Q \neq \emptyset,\left\{\left(D, I_{\text {Scsd }}^{*}((A, D))\right)\right\},\left\{\left(D_{\emptyset}, 0\right)\right\}\right): \\
& \quad Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{~d}}\right)\right),\{D\}=Q
\end{aligned}
$$

The common-fud limited-underlying tuple set list maximiser, $Z_{P, A, A_{R}, F_{c}, F, \mathrm{~B}}$, and the common-fud limited-layer limited-underlying limited-breadth fud tree searcher, $Z_{P, A, A_{R}, F_{\mathrm{c}}, \mathrm{L}}$, of the practicable common-fud shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, F_{\mathrm{c}}}^{\prime}$, can be used to implement an accumulating fud along the path of immediate super-decompositions of the limited-models infinite-layer fud decomposition tree. An accumulated fud allows children slice fuds to incorporate the lower layers of parent slice fuds in a decomposition tree path, thus reducing computation in some cases. Implementations of fud tree searchers that do not use partition variables, $F \notin \mathcal{F}_{U, \mathrm{P}}$, also avoid unnecessary duplication of partition variables. These implementations can also detect fud symmetries in the decomposition, without the need to compare fuds in different paths explicitly.

An accumulating-fud fud decompositions tree searcher must carry around the accumulating-fud so far. So the searcher domain consists of pairs of decompositions and common-fuds. Define the accumulating-fud limited-models infinite-layer substrate fud decompositions tree searcher

$$
\begin{aligned}
& Z_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{c}}= \\
& \quad \operatorname{search} \operatorname{Treer}\left(\left(\mathcal{D}_{\mathrm{F}, \infty, U, V} \cap \operatorname{trees}\left(\mathcal{S} \times \mathcal{F}_{\mathrm{q}}\right)\right) \times\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}\right),\right. \\
& \left.P_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{c},}, R_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{c}}\right)
\end{aligned}
$$

where the neighbourhood function returns a singleton

$$
\begin{aligned}
& P_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{c}}\left(\left(D, F_{\mathrm{c}}\right)\right)=\left\{\left(E, G_{\mathrm{c}}\right):\right. \\
& \left(\cdot, S, G, L, G_{\mathrm{c}}\right) \in \operatorname{maxd}\left(\operatorname { o r d e r } \left(D_{\mathbf{Q} \times \mathrm{S} \times \mathcal{X}^{2} \times \mathrm{F}},\left\{\left(\operatorname{size}(B), S, G, L, F_{\mathrm{c}} \cup F_{\mathrm{L}}\right):\right.\right.\right. \\
& \\
& \quad(L, Y) \in \operatorname{places}(D), \\
& \\
& R_{L}=\bigcup \operatorname{dom}(\operatorname{set}(L)), H_{L}=\bigcup \operatorname{ran}(\operatorname{set}(L)), \\
& \\
& \quad(\cdot, F)=L_{|L|}, W=\operatorname{der}(F), \\
& \\
& S \in W^{\mathrm{CS}} \backslash \operatorname{dom}(\operatorname{dom}(Y)), \\
& \\
& B=\operatorname{apply}\left(V_{A}, V_{A}, \operatorname{his}\left(H_{L}\right) \cup\left\{\left\{R_{L} \cup S\right\}^{\mathrm{U}}\right\}, A\right), \operatorname{size}(B)>0, \\
& \\
& \quad F_{\mathrm{L}} \in \operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, B, B_{R(B)}, F_{\mathrm{c}}, \mathrm{~L}}\right)\right), \\
& \\
& (K, a) \in \max \left(\operatorname{elements}\left(Z_{P, B, B_{R(B)}, F_{\mathrm{L}}, \mathrm{D}}\right)\right), a>0, \\
& \\
& \left.\left.\left.\quad G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\}\right)\right), \\
& M= \\
& E \cup\{(|L|+1,(S, G))\}, \\
& E= \\
& \operatorname{tree}(\operatorname{paths}(D) \backslash\{L\} \cup\{M\})\}
\end{aligned}
$$

where

$$
\begin{aligned}
R_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{c}}= & \left\{\left(\{((\emptyset, G), \emptyset)\}, F_{\mathrm{L}}\right):\right. \\
(G, & \left.F_{\mathrm{L}}\right) \in \operatorname{maxd}\left(\operatorname { o r d e r } \left(D_{\mathrm{F}^{2}},\left\{\left(G, F_{\mathrm{L}}\right):\right.\right.\right. \\
& F_{\mathrm{L}} \in \operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, A_{R(A)}, \mathrm{L}}\right)\right), \\
& (K, a) \in \max \left(\operatorname{elements}\left(Z_{P, A, A_{R(A)}, F_{\mathrm{L}}, \mathrm{D}}\right)\right), a>0, \\
& \left.\left.\left.\left.G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\}\right)\right)\right\}
\end{aligned}
$$

The practicable accumulating-fud summed shuffle content alignment valencydensity fud decomposition inducer may then be implemented

$$
\begin{aligned}
& I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{c}}^{\prime *}(A)= \\
& \quad \operatorname{if}\left(Q \neq \emptyset,\left\{\left(D, I_{\mathrm{Scsd}}^{*}((A, D))\right)\right\},\left\{\left(D_{\emptyset}, 0\right)\right\}\right): \\
& \quad Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{c}}\right)\right),\{(D, \cdot)\}=Q
\end{aligned}
$$

If the inclusion functions of the tuple set list maximiser and the derived variables set list maximiser in the common-fud fud tree searcher, $Z_{P, A, A_{R}, F_{c}, \mathrm{~L}}$, are further ordered by descending sum derived variables layer in order to exclude redundant reframe variables at the inclusion boundaries, an implementation may also explicitly recursively exclude reframe transforms from the top layer of the common fud, $G_{\mathrm{c}}$, where these do not also appear in the decomposition fud, $G$.

The level limited-layer limited-underlying limited-breadth fud tree searcher, $Z_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{g}}, \mathrm{L}}$, of the practicable level shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, V_{\mathrm{g}}, F_{g}}^{\prime}$, can be used to implement a fud decomposition inducer parameterised by a heritable tree of levels. Let $Z_{\mathrm{g}} \in \operatorname{trees}\left(\mathbf{N}_{>0} \times\right.$ $\mathrm{P}(\mathcal{V}) \times \mathcal{F})$ be the level hierarchy. A node $\left(\left(\operatorname{wmax}_{\mathrm{g}}, V_{\mathrm{g}}, F_{\mathrm{g}}\right), X_{\mathrm{g}}\right) \in \operatorname{nodes}\left(Z_{\mathrm{g}}\right)$ parameterises the node's level fud tree searcher, $Z_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{F}}, \mathrm{L}}$, with (i) the maximum derived volume, waxx $_{\mathrm{g}}$, (ii) the subset of the substrate, $V_{\mathrm{g}}$, and (iii) the union of (a) the level fud, $F_{\mathrm{g}}$, and (b) the level fuds from the application of recursively parameterised level fud tree searchers of the children nodes, $X_{\mathrm{g}}$. The level hierarchy has various uses including (i) the partitioning of a large substrate, for example into local regions implied by an external metric, so that the resultant fud has complete coverage, (ii) allowing multiple overlapping representations of a small substrate, (iii) hinting derived variables of the substrate that are externally known to be in alignments, and (iv) excluding mono-valent substrate variables that sometimes occur near the leaves of a decomposition.

Define the level limited-models infinite-layer substrate fud decompositions tree searcher

$$
Z_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{~g}}=\operatorname{search} \operatorname{Treer}\left(\mathcal{D}_{\mathrm{F}, \infty, U, V} \cap \operatorname{trees}\left(\mathcal{S} \times \mathcal{F}_{\mathrm{q}}\right), P_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{~g}}, R_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{~g}}\right)
$$

where the parameters includes the level hierarchy tree, $Z_{\mathrm{g}} \in \operatorname{set}(P)$, where $Z_{\mathrm{g}} \in \operatorname{trees}\left(\mathbf{N}_{>0} \times \mathrm{P}\left(V_{A}\right) \times\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}\right)\right)$. The neighbourhood function is defined

$$
\begin{aligned}
& P_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{~g}}(D)=\{E: \\
& (\cdot, S, G, L) \in \operatorname{maxd}\left(\operatorname { o r d e r } \left(D_{\mathbf{Q} \times S \times \mathcal{X}^{2}},\{(\operatorname{size}(B), S, G, L):\right.\right. \\
& (L, Y) \in \operatorname{places}(D), \\
& R_{L}=\bigcup \operatorname{dom}(\operatorname{set}(L)), H_{L}=\bigcup \operatorname{ran}(\operatorname{set}(L)) \text {, } \\
& (\cdot, F)=L_{|L|}, W=\operatorname{der}(F) \text {, } \\
& S \in W^{\mathrm{CS}} \backslash \operatorname{dom}(\operatorname{dom}(Y)) \text {, } \\
& B=\operatorname{apply}\left(V_{A}, V_{A}, \operatorname{his}\left(H_{L}\right) \cup\left\{\left\{R_{L} \cup S\right\}^{\mathrm{U}}\right\}, A\right), \operatorname{size}(B)>0, \\
& \left.\left.\left.G=\operatorname{level}\left(B, B_{R(B)}\right)\left(Z_{\mathrm{g}}\right), G \neq \emptyset\right\}\right)\right) \text {, } \\
& M=L \cup\{(|L|+1,(S, G))\} \text {, } \\
& E=\operatorname{tree}(\operatorname{paths}(D) \backslash\{L\} \cup\{M\})\}
\end{aligned}
$$

where

$$
R_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{~g}}=\left\{\{((\emptyset, G), \emptyset)\}: G \in \operatorname{maxd}\left(\operatorname{order}\left(D_{\mathrm{F}}, \operatorname{level}\left(A, A_{R(A)}\right)\left(Z_{\mathrm{g}}\right)\right)\right)\right\}
$$

and level $\left(A, A_{R}\right) \in \operatorname{trees}\left(\mathbf{N}_{>0} \times \mathrm{P}\left(V_{A}\right) \times\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}\right)\right) \rightarrow$ $\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}\right)$ is defined

$$
\begin{aligned}
\operatorname{level}(A, & \left.A_{R}\right)\left(Z_{\mathrm{g}}\right)=\bigcup\{G: \\
& \left(\left(\operatorname{wmax}_{\mathrm{g}}, V_{\mathrm{g}}, F_{\mathrm{g}}\right), X_{\mathrm{g}}\right) \in Z_{\mathrm{g}}, \\
& F_{\mathrm{h}}=\operatorname{level}\left(A, A_{R}\right)\left(X_{\mathrm{g}}\right), \operatorname{wmax}_{\mathrm{g}} \in \operatorname{set}\left(P_{\mathrm{g}}\right), \\
& F_{\mathrm{L}} \in \operatorname{leaves}\left(\operatorname{tree}\left(Z_{P_{\mathrm{g}}, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{F}} \cup F_{\mathrm{h}}, \mathrm{~L}}\right)\right), \\
& (K, a) \in \max \left(\operatorname{elements}\left(Z_{P_{\mathrm{g}}, A, A_{R}, F_{\mathrm{g}} \cup F_{\mathrm{h}}, F_{\mathrm{L}}, \mathrm{D}}\right)\right), a>0, \\
& \left.G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\}
\end{aligned}
$$

The practicable level summed shuffle content alignment valency-density fud decomposition inducer may then be implemented

$$
\begin{aligned}
& I_{z, \mathrm{Scs}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{~g}}^{\prime *}(A)= \\
& \quad \operatorname{if}\left(Q \neq \emptyset,\left\{\left(D, I_{\mathrm{Scsd}}^{*}((A, D))\right)\right\},\left\{\left(D_{\emptyset}, 0\right)\right\}\right): \\
& \quad Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{~g}}\right)\right),\{(D, \cdot)\}=Q
\end{aligned}
$$

The limited-nodes limited-models infinite-layer substrate fud decompositions tree searcher, $Z_{P, A, \mathrm{D}, \mathrm{F}, \mathrm{f}}$, is a variation of the limited-models infinite-layer substrate fud decompositions tree searcher, $Z_{P, A, \mathrm{D}, \mathrm{F}}$, in which the cardinality of the fuds of the decomposition tree is limited to the maximum fuds limit fmax $\in \mathbf{N}_{>0}$. The neighbourhood function $P_{P, A, \mathrm{D}, \mathrm{F}, \mathrm{f}}$ is modified

$$
\begin{aligned}
& P_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{f}}(D)=\{E: \\
& |\operatorname{nodes}(D)|<\mathrm{fmax}, \\
& (\cdot, S, G, L) \in \operatorname{maxd}\left(\operatorname { o r d e r } \left(D_{\mathbf{Q} \times \mathrm{S} \times \mathcal{X}^{2}},\{(\operatorname{size}(B), S, G, L):\right.\right. \\
& \\
& \quad(L, Y) \in \operatorname{places}(D), \\
& \\
& R_{L}=\bigcup \operatorname{dom}(\operatorname{set}(L)), H_{L}=\bigcup \operatorname{ran}(\operatorname{set}(L)), \\
& \\
& \quad(\cdot, F)=L_{|L|}, W=\operatorname{der}(F), \\
& \\
& S \in W^{\mathrm{CS}} \backslash \operatorname{dom}(\operatorname{dom}(Y)), \\
& \\
& B=\operatorname{apply}\left(V_{A}, V_{A}, \operatorname{his}\left(H_{L}\right) \cup\left\{\left\{R_{L} \cup S\right\}^{\mathrm{U}}\right\}, A\right), \operatorname{size}(B)>0, \\
& \\
& \quad F_{\mathrm{L}} \in \operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, B, B_{R(B)}, \mathrm{L}}\right)\right), \\
& \\
& (K, a) \in \max \left(\operatorname{elements}\left(Z_{P, B, B_{R(B)}, F_{\mathrm{L}}, \mathrm{D}}\right)\right), a>0, \\
& \\
& \\
& \left.\left.\left.G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\}\right)\right), \\
& M= \\
& L \cup\{(|L|+1,(S, G))\}, \\
& E= \\
& \operatorname{tree}(\operatorname{paths}(D) \backslash\{L\} \cup\{M\})\}
\end{aligned}
$$

The practicable limited-nodes summed shuffle content alignment valency-density fud decomposition inducer is implemented

$$
\begin{aligned}
& I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P \mathrm{f},}^{\prime *}(A)= \\
& \operatorname{if}\left(Q \neq \emptyset,\left\{\left(D, I_{\mathrm{Scsd}}^{*}((A, D))\right)\right\},\left\{\left(D_{\emptyset}, 0\right)\right\}\right): \\
& \quad Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{f}}\right)\right),\{D\}=Q
\end{aligned}
$$

A further variation of the limited-nodes limited-models infinite-layer substrate fud decompositions tree searcher, $Z_{P, A, \mathrm{D}, \mathrm{F}, \mathrm{f}}$, is to modify the sequence of fud search and the termination condition in order to minimise label entropy. Let the query variables $V_{\mathrm{Q}} \subset V_{A}$ be a proper subset of the substrate variables, $V_{\mathrm{Q}} \neq V_{A}$. The difference forms the label variables $V_{\mathrm{L}}=V_{A} \backslash V_{\mathrm{Q}}$. Here the modelling is restricted to the query variables, $V_{\mathrm{Q}}$, so that the underlying variables of the decomposition $D$ are a subset, $\operatorname{und}(D) \subseteq V_{\mathrm{Q}}$. Given a query histogram $Q \in \mathcal{A}_{U}$ in the query variables, vars $(Q)=V_{Q}$, the modelled transformed conditional product is a probability histogram if $\left(Q * D^{\mathrm{T}}\right)^{\mathrm{F}} \cap\left(A * D^{\mathrm{T}}\right)^{\mathrm{F}} \neq \emptyset$,

$$
\left(Q * D^{\mathrm{T}} * \operatorname{his}\left(D^{\mathrm{T}}\right) * A\right)^{\wedge} \% V_{\mathrm{L}} \in \mathcal{A} \cap \mathcal{P}
$$

where his $=$ histogram.
The slice histogram of the neighbourhood function is restricted to the query variables, $B \% V_{\mathrm{Q}}$, where the slice histogram is $B=\operatorname{apply}\left(V_{A}, V_{A}, \operatorname{his}\left(H_{L}\right) \cup\right.$ $\left.\left\{\left\{R_{L} \cup S\right\}^{\mathrm{U}}\right\}, A\right)$. The sized label entropy of the slice is defined as

$$
\operatorname{size}(B) * \operatorname{entropy}\left(B \% V_{\mathrm{L}}\right)
$$

If the slice is an effective singleton in the label variables, $\left|\left(B \% V_{\mathrm{L}}\right)^{\mathrm{F}}\right|=1$, then the sized label entropy is zero, entropy $\left(B \% V_{\mathrm{L}}\right)=0$.

The label-entropy limited-nodes limited-models infinite-layer substrate fud decompositions tree searcher, $Z_{P, A, \mathrm{D}, \mathrm{F}, \mathrm{f}, \mathrm{e}, V_{\mathrm{L}}}$, is such that (i) the limited-layer limited-underlying limited-breadth fud tree searcher, $Z_{P, A, A_{R}, \mathrm{~L}}$, and the limitedderived derived variables set list maximiser, $Z_{P, A, A_{R}, F, \mathrm{D}}$, are restricted to the query variables, $V_{\mathrm{Q}}$, (ii) the order of fud decomposition is modified to maximise slice label entropy and then slice size, and (iii) the decomposition of a slice with zero label entropy terminates. The neighbourhood function
$P_{P, A, \mathrm{D}, \mathrm{F}, \mathrm{f}, \mathrm{e}, V_{\mathrm{L}}}$ is modified

$$
\begin{aligned}
& P_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{f}, \mathrm{e}, V_{\mathrm{L}}}(D)=\{E: \\
& |\operatorname{nodes}(D)|<\mathrm{fmax}, \\
& (\cdot, S, G, L) \in \operatorname{maxd}\left(\operatorname { o r d e r } \left(D_{\mathbf{Q}^{2} \times \mathrm{S} \times \mathcal{X}^{2}},\left\{\left(\left(e_{B}, z_{B}\right), S, G, L\right):\right.\right.\right. \\
& \\
& (L, Y) \in \operatorname{places}(D), \\
& \\
& \quad R_{L}=\bigcup \operatorname{dom}(\operatorname{set}(L)), H_{L}=\bigcup \operatorname{ran}(\operatorname{set}(L)), \\
& \quad(\cdot, F)=L_{|L|}, W=\operatorname{der}(F), \\
& \quad S \in W^{\mathrm{CS}} \backslash \operatorname{dom}(\operatorname{dom}(Y)), \\
& \\
& B=\operatorname{apply}\left(V_{A}, V_{A}, \operatorname{his}\left(H_{L}\right) \cup\left\{\left\{R_{L} \cup S\right\}^{\mathrm{U}}\right\}, A\right), \\
& \\
& z_{B}=\operatorname{size}(B), e_{B}=z_{B} * \operatorname{entropy}\left(B \% V_{\mathrm{L}}\right), e_{B}>0, \\
& \\
& B^{\prime}=B \%\left(V_{A} \backslash V_{\mathrm{L}}\right), F_{\mathrm{L}} \in \operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, B^{\prime}, B_{R\left(B^{\prime}\right)}^{\prime}, \mathrm{L}}\right)\right), \\
& \\
& \\
& (K, a) \in \max \left(\operatorname{elements}\left(Z_{P, B^{\prime}, B_{R\left(B^{\prime}\right)}^{\prime}, F_{\mathrm{L}}, \mathrm{D}}\right)\right), a>0, \\
& \\
& \left.\left.\left.\quad G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\}\right)\right), \\
& M= \\
& L \cup\{(|L|+1,(S, G))\}, \\
& E= \\
& \operatorname{tree}(\operatorname{paths}(D) \backslash\{L\} \cup\{M\})\}
\end{aligned}
$$

The practicable label-entropy limited-nodes summed shuffle content alignment valency-density fud decomposition inducer is implemented

$$
\begin{aligned}
& I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{f}, \mathrm{e}, V_{\mathrm{L}}}^{\prime *}(A)= \\
& \quad \operatorname{if}\left(Q \neq \emptyset,\left\{\left(D, I_{\mathrm{Scsd}}^{*}((A, D))\right)\right\},\left\{\left(D_{\emptyset}, 0\right)\right\}\right): \\
& \quad Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{f}, \mathrm{e}, V_{\mathrm{L}}}\right)\right),\{D\}=Q
\end{aligned}
$$

A similar method is to modify the sequence of $f u d$ search and the termination condition in order to minimise non-modal label size. The non-modal label size of the slice is defined as

$$
\operatorname{size}(B)-\operatorname{maxr}\left(B \% V_{\mathrm{L}}\right)
$$

The neighbourhood function $P_{P, A, \mathrm{D}, \mathrm{F}, \mathrm{f}, \mathrm{m}, V_{\mathrm{L}}}$ is modified

$$
\begin{aligned}
& P_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{f}, \mathrm{~m}, V_{\mathrm{L}}}(D)=\{E: \\
& |\operatorname{nodes}(D)|<\operatorname{fmax}, \\
& (\cdot, S, G, L) \in \operatorname{maxd}\left(\operatorname { o r d e r } \left(D_{\mathbf{Q}^{2} \times \mathrm{S} \times \mathcal{X}^{2}},\left\{\left(\left(m_{B}, z_{B}\right), S, G, L\right):\right.\right.\right. \\
& \quad(L, Y) \in \operatorname{places}(D), \\
& \quad R_{L}=\bigcup \operatorname{dom}(\operatorname{set}(L)), H_{L}=\bigcup \operatorname{ran}(\operatorname{set}(L)), \\
& \quad(\cdot, F)=L_{|L|}, W=\operatorname{der}(F), \\
& \quad S \in W^{\mathrm{CS}} \backslash \operatorname{dom}(\operatorname{dom}(Y)), \\
& B=\operatorname{apply}\left(V_{A}, V_{A}, \operatorname{his}\left(H_{L}\right) \cup\left\{\left\{R_{L} \cup S\right\}^{\mathrm{U}}\right\}, A\right), \\
& z_{B}=\operatorname{size}(B), m_{B}=z_{B}-\operatorname{maxr}\left(B \% V_{\mathrm{L}}\right), m_{B}>0, \\
& B^{\prime}=B \%\left(V_{A} \backslash V_{\mathrm{L}}\right), F_{\mathrm{L}} \in \operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, B^{\prime}, B_{R\left(B^{\prime}\right)}^{\prime}, \mathrm{L}}\right)\right), \\
& \\
& (K, a) \in \max \left(\operatorname{elements}\left(Z_{P, B^{\prime}, B_{R\left(B^{\prime}\right)}^{\prime}, F_{\mathrm{L}}, \mathrm{D}}\right)\right), a>0, \\
& \\
& \left.\left.\left.\quad G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\}\right)\right), \\
& M= \\
& L \cup\{(|L|+1,(S, G))\}, \\
& E=\operatorname{tree}(\operatorname{paths}(D) \backslash\{L\} \cup\{M\})\}
\end{aligned}
$$

The practicable label-mode limited-nodes summed shuffle content alignment valency-density fud decomposition inducer is implemented

$$
\begin{aligned}
& I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{f}, \mathrm{~m}, V_{\mathrm{L}}}^{\prime *}(A)= \\
& \quad \operatorname{if}\left(Q \neq \emptyset,\left\{\left(D, I_{\text {Scsd }}^{*}((A, D))\right)\right\},\left\{\left(D_{\emptyset}, 0\right)\right\}\right): \\
& \quad Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{f}, \mathrm{~m}, V_{\mathrm{L}}}\right)\right),\{D\}=Q
\end{aligned}
$$

The delabelled limited-models infinite-layer substrate fud decompositions tree searcher, $Z_{P, A, \mathrm{D}, \mathrm{F}, \mathrm{x}, V_{\mathrm{L}}}$, is a variation of the limited-models infinite-layer substrate fud decompositions tree searcher, $Z_{P, A, \mathrm{D}, \mathrm{F}}$, which allows the fud $F$ to be constructed on the entire substrate, $V_{A}$, including label variables, $V_{\mathrm{L}} \subset V_{A}$, but then recursively removes all variables from the fud that directly or indirectly depend on the label variables, $F^{\prime}=\operatorname{depends}(F,\{w: w \in$ $\left.\left.\operatorname{der}(F), \operatorname{vars}(\operatorname{depends}(F,\{w\})) \cap V_{\mathrm{L}}=\emptyset\right\}\right)$. If there are some derived variables of the fud that do not depend on the label variables, then the resultant fud is not empty, $\exists w \in \operatorname{der}(F)\left(\operatorname{vars}(\operatorname{depends}(F,\{w\})) \cap V_{\mathrm{L}}=\emptyset\right) \Longrightarrow F^{\prime} \neq \emptyset$. The underlying variables of the resultant decomposition do not include label variables, und $(D) \cap V_{\mathrm{L}}=\emptyset$. This method allows the fud tree searcher, $Z_{P, A, A_{R}, \mathrm{~L}}$, to detect alignments between label variables and non-label variables, but does not require queries to contain the label variables, for example by expanding with the cartesian, $V_{\mathrm{L}} \subset \operatorname{vars}\left(Q * V_{\mathrm{L}}^{\mathrm{C}}\right)$.

The neighbourhood function $P_{P, A, \mathrm{D}, \mathrm{F}, \mathrm{x}, V_{\mathrm{L}}}$ is modified

$$
\begin{aligned}
& P_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{x}, V_{\mathrm{L}}}(D)=\{E: \\
& (\cdot, S, G, L) \in \operatorname{maxd}\left(\operatorname { o r d e r } \left(D_{\mathbf{Q} \times \mathrm{S} \times \mathcal{X}^{2}},\{(\operatorname{size}(B), S, G, L):\right.\right. \\
& (L, Y) \in \operatorname{places}(D), \\
& R_{L}=\bigcup \operatorname{dom}(\operatorname{set}(L)), H_{L}=\bigcup \operatorname{ran}(\operatorname{set}(L)) \text {, } \\
& (\cdot, F)=L_{|L|}, W=\operatorname{der}(F) \text {, } \\
& S \in W^{\mathrm{CS}} \backslash \operatorname{dom}(\operatorname{dom}(Y)) \text {, } \\
& B=\operatorname{apply}\left(V_{A}, V_{A}, \operatorname{his}\left(H_{L}\right) \cup\left\{\left\{R_{L} \cup S\right\}^{\mathrm{U}}\right\}, A\right), \operatorname{size}(B)>0, \\
& F_{\mathrm{L}} \in \operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, B, B_{R(B)}, \mathrm{L}}\right)\right), \\
& (K, a) \in \max \left(\operatorname{elements}\left(Z_{P, B, B_{R(B)}, F_{\mathrm{L}}, \mathrm{D}}\right)\right), a>0, \\
& G=\operatorname{depends}\left(F_{\mathrm{L}},\left\{w: w \in K, \operatorname{vars}\left(\operatorname{depends}\left(F_{\mathrm{L}},\{w\}\right)\right) \cap V_{\mathrm{L}}=\emptyset\right\}\right), \\
& G \neq \emptyset\}) \text { ), } \\
& M=L \cup\{(|L|+1,(S, G))\} \text {, } \\
& E=\operatorname{tree}(\operatorname{paths}(D) \backslash\{L\} \cup\{M\})\}
\end{aligned}
$$

The practicable delabelled summed shuffle content alignment valency-density fud decomposition inducer is implemented

$$
\begin{aligned}
& I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{x}, V_{\mathrm{L}}}^{\prime *}(A)= \\
& \operatorname{if}\left(Q \neq \emptyset,\left\{\left(D, I_{\mathrm{Scsd}}^{*}((A, D))\right)\right\},\left\{\left(D_{\emptyset}, 0\right)\right\}\right): \\
& \quad Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{x}, V_{\mathrm{L}}}\right)\right),\{D\}=Q
\end{aligned}
$$

The level limited-layer limited-underlying limited-breadth fud tree searcher, $Z_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{g}}, \mathrm{L}}$, of the practicable level shuffle content alignment valency-density fud inducer, $I_{z, \text { csd }, \mathrm{F}, \infty, \mathrm{q}, P, V_{\mathrm{g}}, F_{\mathrm{g}}}^{\prime}$, can also be used to implement a supervised fud decomposition inducer parameterised by (i) a tree of level substrates and (ii) a goodness function. Instead of creating a fud from a hierarchical tree of levels, as in the practicable level summed shuffle content alignment valencydensity fud decomposition inducer, $I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~g}}^{\prime}$, above, the supervised fud decomposition inducer uses the goodness function to select the maximum goodness level substrate and its corresponding fud from the maximum goodness level substrate path. Let $Z_{\mathrm{g}} \in \operatorname{trees}\left(\mathbf{N}_{>0} \times \mathrm{P}(\mathcal{V}) \times \mathcal{F}\right)$ be the level substrate tree. A node $\left(\left(\operatorname{wmax}_{\mathrm{g}}, V_{\mathrm{g}}, F_{\mathrm{g}}\right), X_{\mathrm{g}}\right) \in \operatorname{nodes}\left(Z_{\mathrm{g}}\right)$ parameterises the node's level fud tree searcher, $Z_{P, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{g}}, \mathrm{L}}$, with (i) the maximum derived volume, wmax ${ }_{\mathrm{g}}$, (ii) the subset of the substrate, $V_{\mathrm{g}}$, and (iii) the level fud, $F_{\mathrm{g}}$. Let $\operatorname{good}(U) \in \mathcal{A}_{U} \times \mathcal{A}_{U} \times \mathcal{F}_{U} \rightarrow \mathbf{Q}$ be some goodness function given in the
parameters, good $\in \operatorname{set}(P)$.
Define the goodness limited-models infinite-layer substrate fud decompositions tree searcher

$$
Z_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{p}}=\operatorname{searchTreer}\left(\mathcal{D}_{\mathrm{F}, \infty, U, V} \cap \operatorname{trees}\left(\mathcal{S} \times \mathcal{F}_{\mathrm{q}}\right), P_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{p}}, R_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{p}}\right)
$$

where the parameters includes the level substrate tree, $Z_{\mathrm{g}} \in \operatorname{set}(P)$, where $Z_{\mathrm{g}} \in \operatorname{trees}\left(\mathbf{N}_{>0} \times \mathrm{P}\left(V_{A}\right) \times\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}\right)\right)$. The neighbourhood function is defined

$$
\begin{aligned}
P_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{p}} & (D)= \\
(\cdot, S, S, & E, L) \in \operatorname{maxd}\left(\operatorname { o r d e r } \left(D_{\mathbf{Q} \times \mathrm{S} \times \mathcal{X}^{2}},\{(\operatorname{size}(B), S, G, L):\right.\right. \\
& (L, Y) \in \operatorname{places}(D), \\
& R_{L}=\bigcup \operatorname{dom}(\operatorname{set}(L)), H_{L}=\bigcup \operatorname{ran}(\operatorname{set}(L)), \\
& (\cdot, F)=L_{|L|}, W=\operatorname{der}(F), \\
& S \in W^{\mathrm{CS}} \backslash \operatorname{dom}(\operatorname{dom}(Y)), \\
& B=\operatorname{apply}\left(V_{A}, V_{A}, \operatorname{his}\left(H_{L}\right) \cup\left\{\left\{R_{L} \cup S\right\}^{\mathrm{U}}\right\}, A\right), \operatorname{size}(B)>0, \\
& \left.\left.\left.(\cdot, G)=\operatorname{best}\left(B, B_{R(B)}\right)\left(Z_{\mathrm{g}}\right), G \neq \emptyset\right\}\right)\right), \\
M= & L \cup\{(|L|+1,(S, G))\}, \\
E= & \operatorname{tree}(\operatorname{paths}(D) \backslash\{L\} \cup\{M\})\}
\end{aligned}
$$

where

$$
R_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{p}}=\left\{\{((\emptyset, G), \emptyset)\}:(\cdot, G)=\operatorname{best}\left(A, A_{R(A)}\right)\left(Z_{\mathrm{g}}\right), G \neq \emptyset\right\}
$$

and $\operatorname{best}\left(A, A_{R}\right) \in \operatorname{trees}\left(\mathbf{N}_{>0} \times \mathrm{P}\left(V_{A}\right) \times\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathbf{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}\right)\right) \rightarrow(\mathbf{Q} \times$ $\left.\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}\right)\right)$ is defined

$$
\begin{gathered}
\operatorname{best}\left(A, A_{R}\right)\left(Z_{\mathrm{g}}\right)=\operatorname{if}\left(Q \neq \emptyset, \operatorname{if}\left(\left(G^{\prime} \neq \emptyset\right) \wedge\left(g^{\prime}>g\right),\left(g^{\prime}, G^{\prime}\right),(g, G)\right),(0, \emptyset)\right) \\
Q=\operatorname{maxd}\left(\operatorname { o r d e r } \left(D_{\mathbf{Q} \times \mathcal{F} \times \mathcal{X}},\right.\right. \\
\left\{\left(\operatorname{good}\left(U_{A}\right)\left(A, A_{R}, G\right), G, X_{\mathrm{g}}\right):\left(\left(\operatorname{wmax}_{\mathrm{g}}, V_{\mathrm{g}}, F_{\mathrm{g}}\right), X_{\mathrm{g}}\right) \in Z_{\mathrm{g}},\right. \\
\operatorname{wmax}_{\mathrm{g}} \in \operatorname{set}\left(P_{\mathrm{g}}\right), \\
F_{\mathrm{L}} \in \operatorname{leaves}\left(\operatorname{tree}\left(Z_{P_{\mathrm{g}}, A, A_{R}, V_{\mathrm{g}}, F_{\mathrm{g}}, \mathrm{~L}}\right)\right), \\
(K, a) \in \max \left(\operatorname{elements}\left(Z_{P_{\mathrm{g}}, A, A_{R}, F_{\mathrm{g}}, F_{\mathrm{L}}, \mathrm{D}}\right)\right), a>0, \\
\left.\left.\left.G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\}\right)\right) \\
\left\{\left(g, G, X_{\mathrm{g}}\right)\right\}=Q \\
\left(g^{\prime}, G^{\prime}\right)=\operatorname{best}\left(A, A_{R}\right)\left(X_{\mathrm{g}}\right)
\end{gathered}
$$

The practicable goodness summed shuffle content alignment valency-density fud decomposition inducer may then be implemented

$$
\begin{aligned}
& I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{p}}^{\prime *}(A)= \\
& \operatorname{if}\left(Q \neq \emptyset,\left\{\left(D, I_{\mathrm{Scsd}}^{*}((A, D))\right)\right\},\left\{\left(D_{\emptyset}, 0\right)\right\}\right): \\
& \quad Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{p}}\right)\right),\{(D, \cdot)\}=Q
\end{aligned}
$$

An example of the goodness function is simply shuffle content alignment valency-density computer application,

$$
\operatorname{good}(U)\left(A, A_{R}, F\right)=I_{\mathrm{csd}}^{*}\left(\left(A, A_{R}, F\right)\right)
$$

Another example is a goodness function that minimises label entropy. Let the query variables $V_{\mathrm{Q}} \subset V_{A}$ be a proper subset of the substrate variables, $V_{\mathrm{Q}} \neq V_{A}$. The difference forms the label variables $V_{\mathrm{L}}=V_{A} \backslash V_{\mathrm{Q}}$. Here the level substrates are restricted to the query variables, $\forall\left(\cdot, V_{\mathrm{g}}, \cdot\right) \in$ elements $\left(Z_{\mathrm{g}}\right)\left(V_{\mathrm{g}} \subseteq V_{\mathrm{Q}}\right)$, and $\forall\left(\cdot, \cdot, F_{\mathrm{g}}\right) \in \operatorname{elements}\left(Z_{\mathrm{g}}\right)\left(\operatorname{und}\left(F_{\mathrm{g}}\right) \subseteq V_{\mathrm{Q}}\right)$. The label entropy is the sum of the component label entropies,

$$
\sum_{(\cdot, C) \in\left(F^{\mathrm{T}}\right)^{-1}} \operatorname{size}(A * C) \times \operatorname{entropy}\left(A * C \% V_{\mathrm{L}}\right)
$$

and the goodness function is the negative label entropy computed by histogram application

$$
\begin{aligned}
& \operatorname{good}(U)(A, \cdot, F)=I_{\approx \mathbf{R}}^{*}\left(-\sum \operatorname{size}(B) \times \operatorname{entropy}\left(B \% V_{\mathrm{L}}\right):\right. \\
& \left.\quad R \in\left(A * F^{\mathrm{T}}\right)^{\mathrm{FS}}, B=\operatorname{apply}\left(V_{A}, V_{A}, \operatorname{his}(F) \cup\left\{\{R\}^{\mathrm{U}}\right\}, A\right)\right)
\end{aligned}
$$

A similar example is a goodness function that minimises non-modal label size. The non-modal label size is the sum of the component non-modal label sizes,

$$
\sum_{(\cdot, C) \in\left(F^{\mathrm{T}}\right)^{-1}} \operatorname{size}(A * C)-\operatorname{maxr}\left(A * C \% V_{\mathrm{L}}\right)
$$

and the goodness function is the negative non-modal label size computed by histogram application

$$
\begin{aligned}
& \operatorname{good}(U)(A, \cdot, F)=-\sum \operatorname{size}(B)-\operatorname{maxr}\left(B \% V_{\mathrm{L}}\right): \\
& \quad R \in\left(A * F^{\mathrm{T}}\right)^{\mathrm{FS}}, B=\operatorname{apply}\left(V_{A}, V_{A}, \operatorname{his}(F) \cup\left\{\{R\}^{\mathrm{U}}\right\}, A\right)
\end{aligned}
$$

### 4.22.4 Implementation

The implementation of practicable inducers must exclude partition variables because they are impracticable. In the following computers none of the instantiated variables are partition variables.

In order to implement the limited-underlying tuple set list maximiser, $Z_{P, A, A_{R}, F, \mathrm{~B}}$, define the limited-underlying tuple set list builder $I_{P, U, \mathrm{~B}} \in$ computers such that (i) the domain is domain $\left(I_{P, U, \mathrm{~B}}\right)=\mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{F}_{U, 1} \times \mathcal{A}_{U} \times \mathcal{A}_{U}$, (ii) the range is range $\left(I_{P, U, \mathrm{~B}}\right)=\mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{A}_{U} \times \mathcal{A}_{U} \rightarrow \mathbf{Q}$, and (iii) the application is

$$
\begin{gathered}
I_{P, U, \mathrm{~B}}^{*}\left(\left(V, \emptyset, X, X_{R}\right)\right)=\operatorname{topd}(\lfloor\operatorname{bmax} / \operatorname{mmax}\rfloor)\left(\operatorname{buildb}\left(V, X, X_{R}, \operatorname{init}(V), \emptyset\right)\right) \\
I_{P, U, \mathrm{~B}}^{*}\left(\left(V, F, X, X_{R}\right)\right)=\operatorname{topd}(\lfloor\text { bmax } / \operatorname{mmax}\rfloor)\left(\operatorname { b u i l d b } \left(\operatorname{vars}(F) \cup V, X, X_{R},\right.\right. \\
\operatorname{init}(\operatorname{der}(F)), \emptyset))
\end{gathered}
$$

where $\operatorname{init}(V):=\{(((\{w\}, \emptyset, \emptyset), 0), 0): w \in V\}$, buildt $=\left(\left(\mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{A}_{U} \times\right.\right.$ $\left.\left.\mathcal{A}_{U}\right) \times \mathbf{Q}\right) \times(\mathbf{Q} \times \mathbf{N} \times \mathbf{Q} \times \mathbf{N} \times \mathbf{N})$ and buildb $\in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{A}_{U} \times \mathcal{A}_{U} \times$ buildt $\times$ buildt $\rightarrow$ buildt is defined

$$
\begin{aligned}
& \operatorname{buildb}\left(W, X, X_{R}, Q, N\right)= \\
& \qquad \begin{aligned}
& \operatorname{if}\left(M \neq \emptyset, \operatorname{buildb}\left(W, X, X_{R}, M, N \cup M\right), \operatorname{final}(N)\right): \\
& P=\{J:(((K, \cdot \cdot), \cdot), \cdot) \in Q, w \in W \backslash K, J=K \cup\{w\}\}, \\
& M= \operatorname{top}(\operatorname{omax})\left(\left\{\left(\left(\left(J, B, B_{R}\right), a_{1}-b_{1}\right),\right.\right.\right. \\
&\left.\quad\left(a_{1}-a_{2}-b_{1}+b_{2},-l,-b_{1}+b_{2},-u, D_{\mathcal{X}}(J)\right)\right): \\
& \quad J \in P, u=\mid J^{\mathrm{C}}, u \leq \operatorname{xmax}, l=\operatorname{sumlayer}(F, J), \\
& B=I_{\%}^{*}((J, X)), B_{R}=I_{\%}^{*}\left(\left(J, X_{R}\right)\right), \\
& a_{1}=I_{\mathrm{S} \approx \ln !}^{*}(B), a_{2}=I_{\mathrm{S} \approx \ln !}^{*}\left(I_{\mathrm{X}}^{*}(B)\right), \\
&\left.\left.b_{1}=I_{\mathrm{S} \approx \ln !}^{*}\left(B_{R}\right), b_{2}=I_{\mathrm{S} \approx \ln !}^{*}\left(I_{\mathrm{X}}^{*}\left(B_{R}\right)\right)\right\}\right)
\end{aligned}
\end{aligned}
$$

where $\operatorname{final}(N):=\{(((K, A, B), y), a):(((K, A, B), y), a) \in N,|K|>1\}$, $D_{\mathcal{X}} \in \operatorname{enums}(\mathcal{X})$ is an arbitrary order, sumlayer $\in \mathcal{F} \times \mathrm{P}(\mathcal{V}) \rightarrow \mathbf{N}$, the reducer $I_{\%}=$ reducer $\in$ computers, the independenter $I_{\mathrm{X}}=$ independenter $\in$ computers is such that $I_{\mathrm{X}}^{*}(A)=A^{\mathrm{X}}$, and $I_{\mathrm{S} \approx \ln !}=$ sumlogfactorialer $\in$ computers is defined

$$
I_{\mathrm{S} \approx \ln !}^{*}(A)=\sum_{S \in A^{\mathrm{FS}}} I_{\approx \mathrm{n}!}^{*}\left(A_{S}\right)
$$

where $I_{\approx \ln !}=\log$ factorialer $\in$ computers is defined $I_{\approx \operatorname{nn}!}^{*}(x) \approx \ln \Gamma_{!} x$.
The tuples of the limited-underlying tuple set list builder $I_{P, U, \mathrm{~B}}$, are plurivariate, $\forall((K, \cdot \cdot \cdot), \cdot) \in I_{P, U, \mathrm{~B}}^{*}\left(\left(V, F, X, X_{R}\right)\right)(|K|>1)$.

The buildb function argument histograms, $X, X_{R}$, have the same variables, $\operatorname{vars}(X)=\operatorname{vars}\left(X_{R}\right)$. The argument variables, $W$, are a subset of the argument histograms variables, $W \subseteq \operatorname{vars}(X)$. It is sufficient that the system, $U$,
contains the variables of the argument histograms, $\operatorname{vars}(X) \subseteq \operatorname{vars}(U)$.
The argument histograms, $X, X_{R}$, are in a list representation or binary map representation, because in some cases the volume, $\left|\operatorname{vars}(X)^{\mathrm{C}}\right|$, is impracticably large for an array representation. The resultant histograms, $B, B_{R}$, may be in array representation because their volume cannot exceed the given limit, $\left|B^{\mathrm{C}}\right| \leq$ xmax, which is chosen to be practicable.

The limited-underlying tuple set list builder implements the limited-underlying tuple set list maximiser, insofar as the inclusion boundaries are the same, $\operatorname{dom}\left(I_{P, U, \mathrm{~B}}^{*}\left(\left(V, F, A, A_{R}\right)\right) \subseteq \operatorname{top}(\lfloor\operatorname{bmax} / \operatorname{mmax}\rfloor)\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{~B}}\right)\right)\right.$.

The tuple set list builder never returns more than $\lfloor\operatorname{bmax} / \mathrm{mmax}\rfloor$ tuples, because of the trailing arbitrary ordering of the tuples, $D_{\mathcal{X}}(J)$.

Although inducers are defined only for substrate histograms, $A \in \mathcal{A}_{z}$, which are constrained such that the independent sample histogram is completely effective, $A^{\mathrm{XF}}=A^{\mathrm{C}}$, the implementation of induction computers here only requires that the argument histogram, $X$, be in the system $U, X \in \mathcal{A}_{U}$.

The limited-underlying tuple set list builder returns the non-independent content sum factorial, $a_{1}-b_{1}=I_{\mathrm{S} \approx \operatorname{nn}!}^{*}(B)-I_{\mathrm{S}}^{*} \approx \ln !\left(B_{R}\right)$, to avoid unnecessary recomputation subsequently in the partitioner.

The computation of sumlayer $(F, J)$ is costly so some implementations may exclude it, especially as it only affects tuples in the inclusion boundary. If the layerer (see later) is subject to the excluded-self restriction then it is less likely that there will be duplicate tuple alignments, so the inclusion bouundary is more likely to be a singleton.

Another performance improvement is to restrict the builder to variables that are multi-effective, $\left\{u: u \in V,\left|(X \%\{u\})^{\mathrm{F}}\right|>1\right\}$. This prevents some variables from being included in the tuple that are necessarily independent of the other variables in the tuple.

To implement the highest-layer limited-derived derived variables set list maximiser, $Z_{P, A, A_{R}, F, \mathrm{D}, \mathrm{d}}$, define the highest-layer limited-derived derived variables set builder $I_{P, U, \mathrm{D}, \mathrm{d}} \in$ computers such that (i) the domain is domain $\left(I_{P, U, \mathrm{D}, \mathrm{d}}\right)=$ $\mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{F}_{U, 1} \times \mathcal{A}_{U} \times \mathcal{A}_{U}$, (ii) the range is range $\left(I_{P, U, \mathrm{D}, \mathrm{d}}\right)=\left(\mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{A}_{U} \times\right.$
$\left.\mathcal{A}_{U}\right) \rightarrow \mathbf{Q}$, and (iii) the application is
$I_{P, U, \mathrm{D}, \mathrm{d}}^{*}\left(\left(V, F, X, X_{R}\right)\right)=\operatorname{maxd}\left(\operatorname{buildd}\left(\operatorname{vars}(F) \backslash V, X, X_{R}, \operatorname{init}(\operatorname{der}(F)), \emptyset\right)\right)$
where buildd $\in \mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{A}_{U} \times \mathcal{A}_{U} \times$ buildt $\times$ buildt $\rightarrow$ buildt is defined

$$
\begin{aligned}
& \operatorname{buildd}\left(W, X, X_{R}, Q, N\right)= \\
& \qquad \begin{array}{r}
\operatorname{if}\left(M \neq \emptyset, \operatorname{buildb}\left(W, X, X_{R}, M, N \cup M\right), \text { final }(N)\right): \\
P=\{J:(((K, \cdot \cdot \cdot), \cdot) \cdot) \in Q, w \in W \backslash K, J=K \cup\{w\}\}, \\
M= \\
\operatorname{top}(\operatorname{omax})\left(\left\{\left(\left(\left(J, B, B_{R}\right),(a-b) / c\right),\right.\right.\right. \\
\left.\quad\left((a-b) / c,-l,-b / c,-u, D_{\mathcal{X}}(J)\right)\right): \\
\\
J \in P, u=\left|J^{\mathrm{C}}\right|, u \leq \operatorname{wmax}, \operatorname{der}(\operatorname{depends}(F, J))=J, \\
\\
m=|J|, l=\operatorname{sumlayer}(F, J), \\
\\
B=I_{\%}^{*}((J, X)), B_{R}=I_{\%}^{*}\left(\left(J, X_{R}\right)\right), \\
\\
\left.\left.a=I_{\mathrm{a}}^{*}(B), b=I_{\mathrm{a}}^{*}\left(B_{R}\right), c=I_{\approx \text { pow }}^{*}((u, 1 / m))\right\}\right)
\end{array}
\end{aligned}
$$

where the power approxer $I_{\approx \text { pow }} \in$ computers is such that $I_{\approx \text { pow }}^{*}((x, y)) \approx x^{y}$, and the alignmenter $I_{\mathrm{a}}=$ alignmenter $\in$ computers is such that $I_{\mathrm{a}}^{*}(A) \approx$ $\operatorname{algn}(A)$.

The tuples of the highest-layer limited-derived derived variables set builder $I_{P, U, \mathrm{D}, \mathrm{d}}$, are pluri-variate, $\forall((K, \cdot \cdot \cdot), \cdot) \in I_{P, U, \mathrm{D}, \mathrm{d}}^{*}\left(\left(V, F, X, X_{R}\right)\right)(|K|>1)$.

The buildd function argument histograms, $X, X_{R}$, have the same variables, $\operatorname{vars}(X)=\operatorname{vars}\left(X_{R}\right)$. The argument variables, $W$, are a subset of the argument histograms variables, $W \subseteq \operatorname{vars}(X)$. It is sufficient that the system, $U$, contains the variables of the argument histograms, $\operatorname{vars}(X) \subseteq \operatorname{vars}(U)$.

The argument histograms, $X, X_{R}$, are in a list representation or binary map representation, because in some cases the volume, $\left|\operatorname{vars}(X)^{\mathrm{C}}\right|$, is impracticably large for an array representation. The resultant histograms, $B, B_{R}$, may be in array representation because their volume cannot exceed the given limit, $\left|B^{\mathrm{C}}\right| \leq$ wmax, which is chosen to be practicable.

If the fud is a non-empty substrate fud, $F \in \mathcal{F}_{U_{A}, V_{A}} \backslash\{\emptyset\}$, the highestlayer limited-derived derived variables set builder implements the highestlayer limited-derived derived variables set list maximiser, insofar as the inclusion boundaries are the same,

$$
\operatorname{dom}\left(I_{P, U, \mathrm{D}, \mathrm{~b}}^{*}\left(\left(V, F, A, A_{R}\right)\right)\right) \subseteq \operatorname{top}(\lfloor\operatorname{bmax} / \operatorname{mmax}\rfloor)\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{D}, \mathrm{~b}}\right)\right)
$$

Similarly to the tuple builder above, some implementations may drop the computation of sumlayer $(F, J)$, especially if the layerer is subject to the excluded-self restriction.

Also, some implementations may drop the exclusion of hidden variables $J=\operatorname{der}(\operatorname{depends}(F, J))$. This computation is costly, but dropping may in some cases lead to tuple rolls that result in a single derived variable. However, this is also true of the excluded-self restriction which is applied in the layerer (see later).

In order to implement the limited-valency contracted decrementing linear non-overlapping fuds list maximiser initial set, $R_{P, A, A_{R}, F, \mathrm{n}, \mathrm{w},-, K}$, the tuple partitioner $I_{P, U, \mathrm{~K}} \in$ computers is defined such that (i) domain $\left(I_{P, U, \mathrm{~K}}\right)=$ $\left(\mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{A}_{U} \times \mathcal{A}_{U}\right) \times \mathbf{Q}$, (ii) range $\left(I_{P, U, \mathrm{~K}}\right)=\mathrm{P}\left(\mathcal{L}\left(\mathcal{S}_{U} \rightarrow \mathbf{N}\right) \times \mathcal{A}_{U} \times \mathcal{A}_{U}\right)$, and (iii) the application is

$$
\begin{aligned}
& I_{P, U, \mathrm{~K}}^{*}\left(\left(\left(K, B, B_{R}\right), y_{1}\right)\right)= \\
& \quad \operatorname{topd}(\operatorname{pmax})\left(\left\{\left(\left(N, C, C_{R}\right),\left(\left(y_{1}-a_{2}+b_{2}\right) / c, b_{2} / c,-m, D_{\mathcal{X}}(J)\right)\right):\right.\right. \\
& \quad m \in\{2 \ldots \operatorname{mmax}\}, Y \in \mathrm{~S}(K, m),\left(\forall J \in Y\left(\left|J^{\mathrm{C}}\right| \leq u \max \right)\right), \\
& \quad N=\left\{\left(i, \operatorname{order}\left(D_{\mathrm{S}}, J^{\mathrm{CS}}\right)\right):(J, i) \in \operatorname{order}\left(D_{\mathrm{P}(\mathcal{V})}, Y\right)\right\}, \\
& \quad T=\left(\left\{\bigcup\{S \cup\{(w, u)\}:(w,(S, u)) \in L\}: L \in \prod N\right\}^{\mathrm{U}},\{1 \ldots m\}\right), \\
& \quad C=I_{* \mathrm{~T}}^{*}((T, B)), C_{R}=I_{* \mathrm{~T}}^{*}\left(\left(T, B_{R}\right)\right), \\
& \\
& \left.\left.a_{2}=I_{\mathrm{S} \approx \ln !}^{*}\left(I_{\mathrm{X}}^{*}(C)\right), b_{2}=I_{\mathrm{S} \approx \ln !}^{*}\left(I_{\mathrm{X}}^{*}\left(C_{R}\right)\right), c=I_{\approx \text { pow }}^{*}((v, 1 / m))\right\}\right)
\end{aligned}
$$

where $v=\left|K^{\mathrm{C}}\right|, \operatorname{vars}(U) \cap \mathbf{N}=\emptyset, D_{\mathrm{S}} \in \operatorname{enums}\left(\mathcal{S}_{U}\right), D_{\mathrm{P}(\mathcal{V})} \in \operatorname{enums}\left(\mathrm{P}\left(\mathcal{V}_{U}\right)\right)$, and the transformer $I_{* \mathrm{~T}}=$ transformer $\in$ computers is such that $I_{* \mathrm{~T}}^{*}((T, A))=$ $A * T$.

The tuple partitioner has non-empty application if $|K| \geq 2$. The resultant histograms, $C, C_{R}$ where $\left(\cdot, C, C_{R}\right) \in I_{P, U, K}^{*}\left(\left(K, B, B_{R}, y_{1}\right)\right)$, should be in array representation, suitable for succeeding value roll computers. The tuple partitioner assumes that the array index variables are not system variables, $\operatorname{vars}(U) \cap \mathbf{N}=\emptyset$.

Because (i) the alignmenter equals the difference in the non-independent sum $\log$ factorialer and the independent sum log factorialer, $I_{\mathrm{a}}^{*}(A)=I_{\mathrm{S} \approx \mathrm{nn}!}^{*}(A)-$ $I_{\mathrm{S} \approx \mathrm{nn}!}^{*}\left(A^{\mathrm{X}}\right)$, and (ii) the non-independent terms are constant, $\sum_{S \in C^{\mathrm{S}}} \ln \Gamma_{!} C_{S}=$ $\sum_{S \in B^{\mathrm{S}}} \ln \Gamma_{!} B_{S}$, so only the independent terms, $\sum_{S \in C^{\mathrm{xS}}} \ln \Gamma_{!} C_{S}^{\mathrm{X}}$, need be computed for each of the possible partitions. Thus the non-independent part of
the computation of the difference in alignments, $I_{\mathrm{a}}^{*}(C)-I_{\mathrm{a}}^{*}\left(C_{R}\right)$, need not be re-computed, but can be carried from the tuple builder.

In order to implement the maximum-roll-by-derived-dimension limitedvalency contracted decrementing linear non-overlapping fuds list maximiser initial set, $R_{P, A, A_{R}, F, \mathrm{n}, \mathrm{w},-, K, \mathrm{~mm}}$, the maximum-roll-by-derived-dimension tuple partitioner $I_{P, U, \mathrm{~K}, \mathrm{~mm}} \in$ computers is defined such that (i) domain $\left(I_{P, U, \mathrm{~K}, \mathrm{~mm}}\right)=$ $\left(\mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{A}_{U} \times \mathcal{A}_{U}\right) \times \mathbf{Q},($ ii $) \operatorname{range}\left(I_{P, U, \mathrm{~K}, \mathrm{~mm}}\right)=\mathrm{P}\left(\mathcal{L}\left(\mathcal{S}_{U} \rightarrow \mathbf{N}\right) \times \mathcal{A}_{U} \times \mathcal{A}_{U}\right)$, and (iii) the application is

$$
\begin{aligned}
& I_{P, U, \mathrm{~K}, \mathrm{~mm}}^{*}\left(\left(\left(K, B, B_{R}\right), y_{1}\right)\right)= \\
& \bigcup\left\{\operatorname { t o p d } ( \operatorname { p m a x } ) \left(\left\{\left(\left(N, C, C_{R}\right),\left(\left(y_{1}-a_{2}+b_{2}\right) / c, b_{2} / c,-m, D_{\mathcal{X}}(J)\right)\right):\right.\right.\right. \\
& \quad Y \in \mathrm{~S}(K, m),\left(\forall J \in Y\left(\left|J^{\mathrm{C}}\right| \leq \operatorname{umax}\right)\right), \\
& \quad N=\left\{\left(i, \operatorname{order}\left(D_{\mathrm{S}}, J^{\mathrm{CS}}\right)\right):(J, i) \in \operatorname{order}\left(D_{\mathrm{P}(\mathcal{V})}, Y\right)\right\}, \\
& \quad T=\left(\left\{\bigcup\{S \cup\{(w, u)\}:(w,(S, u)) \in L\}: L \in \prod N\right\}^{\mathrm{U}},\{1 \ldots m\}\right), \\
& \quad C=I_{* \mathrm{~T}}^{*}((T, B)), C_{R}=I_{* \mathrm{~T}}^{*}\left(\left(T, B_{R}\right)\right), \\
& \left.\left.a_{2}=I_{\mathrm{S} \approx \ln !}^{*}\left(I_{\mathrm{X}}^{*}(C)\right), b_{2}=I_{\mathrm{S} \approx \ln !}^{*}\left(I_{\mathrm{X}}^{*}\left(C_{R}\right)\right), c=I_{\approx \mathrm{pow}}^{*}((v, 1 / m))\right\}\right): \\
& m \in\{2 \ldots \operatorname{mmax}\}\}
\end{aligned}
$$

After constructing the initial set in a tuple partitioner, $I_{P, U, \mathrm{~K}}$, the remainder of the limited-valency contracted decrementing linear non-overlapping fuds list maximiser, $Z_{P, A, A_{R}, F, \mathrm{n}, \mathrm{w},-, K}$, is implemented by means of value roll computers, defined in section 'Value roll computers', above. The tuplepartition value roller $I_{P, U, \mathrm{R}} \in$ computers is defined such that (i) the domain is domain $\left(I_{P, U, \mathrm{R}}\right)=\mathrm{P}\left(\mathcal{L}\left(\mathcal{S}_{U} \rightarrow \mathbf{N}\right) \times \mathcal{A}_{U} \times \mathcal{A}_{U}\right)$, (ii) the range is $\operatorname{range}\left(I_{P, U, \mathrm{R}}\right)=\mathrm{P}\left(\mathcal{L}\left(\mathcal{S}_{U} \rightarrow \mathbf{N}\right)\right)$, and (iii) the application is

$$
\begin{aligned}
& I_{P, U, \mathrm{R}}^{*}(Q)= \\
& \qquad \begin{array}{l}
\left\{N^{\prime}:\right. \\
M=\left\{\left(\left(N, R_{A}, R_{B}\right),(a-b) / c\right):\right. \\
\quad(N, A, B) \in Q \\
a=I_{\mathrm{a}}^{*}(A), b=I_{\mathrm{a}}^{*}(B), \\
\quad w=\prod_{(\cdot, I) \in N}|\operatorname{ran}(I)|, m=|N|, c=I_{\approx \operatorname{pow}}^{*}((w, 1 / m)), \\
\left.R_{A}=\left(a, A, I_{\mathrm{X}}^{*}(A)\right), R_{B}=\left(b, B, I_{\mathrm{X}}^{*}(B)\right)\right\}, \\
\left.\left(N^{\prime}, \cdot, \cdot\right) \in \operatorname{topd}(\operatorname{pmax})(\operatorname{rollb}(M, M))\right\}
\end{array}
\end{aligned}
$$

where rollb $\in$ rollbt $\times$ rollbt $\rightarrow$ rollbt, where rollbt $=\mathcal{L}\left(\mathcal{S}_{U} \rightarrow \mathbf{N}\right) \times(\mathbf{Q} \times$ $\left.\mathcal{A}_{U} \times \mathcal{A}_{U}\right)^{2} \rightarrow \mathbf{Q}$, is defined

$$
\begin{aligned}
& \operatorname{rollb}(Q, P)= \\
& \qquad \begin{aligned}
& \operatorname{if}(M \neq \emptyset, \operatorname{rollb}(M, P \cup M), P): \\
& M= \operatorname{top}(\operatorname{pmax})\left(\left\{\left(\left(N^{\prime}, R_{A}^{\prime}, R_{B}^{\prime}\right),\left(a^{\prime}-b^{\prime}\right) / c^{\prime}\right):\right.\right. \\
&\left(\left(N, R_{A}, R_{B}\right), \cdot\right) \in Q, \\
& V=\operatorname{dom}(N),\left(\cdot, A, A_{\mathrm{X}}\right)=R_{A},\left(\cdot, B, B_{\mathrm{X}}\right)=R_{B}, \\
& Y_{A}=\operatorname{rals}\left(N, A, A_{\mathrm{X}}\right), Y_{B}=\operatorname{rals}\left(N, B, B_{\mathrm{X}}\right), \\
&(v, I) \in N,|\operatorname{ran}(I)|>2, s, t \in \operatorname{ran}(I), s>t, \\
& N^{\prime}=N \backslash\{(v, I)\} \cup\{(v,\{(s, t)\} \circ I)\}, \\
& R_{A}^{\prime}=I_{\mathrm{R}, \mathrm{a}}^{*}\left(\left((V, v, s, t), Y_{A}, R_{A}\right)\right), \\
& R_{B}^{\prime}=I_{\mathrm{R}, \mathrm{a}}^{*}\left(\left((V, v, s, t), Y_{B}, R_{B}\right)\right), \\
&\left(a^{\prime}, \cdot, \cdot\right)=R_{A}^{\prime},\left(b^{\prime}, \cdot \cdot \cdot\right)=R_{B}^{\prime}, \\
&\left.\left.w=\prod_{\left(\cdot, I^{\prime}\right) \in N^{\prime}}\left|\operatorname{ran}\left(I^{\prime}\right)\right|, m=|V|, c^{\prime}=I_{\approx \mathrm{pow}}^{*}((w, 1 / m))\right\}\right)
\end{aligned}
\end{aligned}
$$

where $I_{\mathrm{R}, \mathrm{a}}=$ rollValueAlignmenter $\in$ computers and rals $\in \mathcal{L}\left(\mathcal{S}_{U} \rightarrow \mathbf{N}\right) \times$ $\mathcal{A} \times \mathcal{A} \rightarrow(\mathcal{V} \rightarrow(\mathcal{S} \rightarrow \mathbf{Q}))$ is defined as

$$
\begin{aligned}
& \operatorname{rals}\left(N, A, A_{\mathrm{X}}\right):= \\
& \qquad \begin{array}{l}
\left\{\left(w,\left\{\left(S, \sum\left(I_{\approx \operatorname{nn}!}^{*}(A(T)): T \in A^{\mathrm{S}}, T \supseteq S\right)-\right.\right.\right.\right. \\
\left.\sum\left(I_{\approx \ln !}^{*}\left(A_{\mathrm{X}}(T)\right): T \in A_{\mathrm{X}}^{\mathrm{S}}, T \supseteq S\right)\right): \\
\left.\left.\left.\quad u \in \operatorname{ran}\left(N_{w}\right), S=\{(w, u)\}\right\}\right): w \in \operatorname{dom}(N)\right\}
\end{array}
\end{aligned}
$$

The roll value alignmenter, $I_{\mathrm{R}, \mathrm{a}}$, requires that all histograms are implemented in array histogram representations on ordered list state representations.

The value roll compositions do not necessarily lead to a contiguous set, so in some cases $\operatorname{ran}(I) \neq\{1 \ldots|\operatorname{ran}(I)|\}$. In some implementations, however, a source value may be completely removed from the representation, rather than simply zeroed out. In these cases the value roll compositions must also value roll by one all values higher than the source values. That is, instead of $\{(s, t)\} \circ I$ the composition is $\{(r, r-1): r \in \operatorname{ran}(I), r>s\} \circ\{(s, t)\} \circ I$.

The operation to take the top (pmax) at each step requires that the value roll list composition, $I$, be computed for each value roll because different value roll lists can have the same composition. However, the computation is costly,
so some implementations may simply take the top value roll lists rather than the top value roll list compositions. The functionality is only equivalent with respect to value roll list compositions when $\operatorname{pmax}=1$. An alternative is to implement the limited-valency maximum-roll contracted decrementing linear non-overlapping fuds tree maximiser, $Z_{P, A, A_{R}, F, \mathrm{n}, \mathrm{w},-, K, \mathrm{mr}}$, which only applies the pmax parameter to the initial set. The tuple partitioner, $I_{P, U, \mathrm{~K}}$, is unchanged and the tuple-partition value roller, $I_{P, U, \mathrm{R}}$, is modified to use the max inclusion function instead of top $(\mathrm{pmax})$. The maximum-roll tuple-partition value roller $I_{P, U, \mathrm{R}, \mathrm{mr}} \in$ computers is defined such that (i) the domain is domain $\left(I_{P, U, \mathrm{R}, \mathrm{mr}}\right)=\mathcal{L}\left(\mathcal{S}_{U} \rightarrow \mathbf{N}\right) \times \mathcal{A}_{U} \times \mathcal{A}_{U}$, (ii) the range is $\operatorname{range}\left(I_{P, U, \mathrm{R}, \mathrm{mr}}\right)=\mathrm{P}\left(\mathcal{L}\left(\mathcal{S}_{U} \rightarrow \mathbf{N}\right)\right)$, and (iii) the application is

$$
\begin{aligned}
& I_{P, U, \mathrm{R}, \mathrm{mr}}^{*}((N, A, B))= \\
& \left\{\begin{array}{c}
\left\{N^{\prime}:\right. \\
M=\left\{\left(\left(N, R_{A}, R_{B}\right),(a-b) / c\right):\right. \\
a=I_{\mathrm{a}}^{*}(A), b=I_{\mathrm{a}}^{*}(B), \\
w=\prod_{(\cdot, I) \in N}|\operatorname{ran}(I)|, m=|N|, c=I_{\approx \operatorname{pow}}^{*}((w, 1 / m)), \\
\left.R_{A}=\left(a, A, I_{\mathrm{X}}^{*}(A)\right), R_{B}=\left(b, B, I_{\mathrm{X}}^{*}(B)\right)\right\}, \\
\left.\left(N^{\prime}, \cdot, \cdot\right) \in \operatorname{maxd}(\operatorname{rollb}(M, M))\right\}
\end{array}\right.
\end{aligned}
$$

and

$$
\begin{aligned}
& \operatorname{rollb}(Q, P)= \\
& \qquad \begin{aligned}
\operatorname{if}(M \neq \emptyset, & \operatorname{rollb}(M, P \cup M), P): \\
M= & \max \left(\left\{\left(\left(N^{\prime}, R_{A}^{\prime}, R_{B}^{\prime}\right),\left(a^{\prime}-b^{\prime}\right) / c^{\prime}\right):\right.\right. \\
& \left(\left(N, R_{A}, R_{B}\right), \cdot\right) \in Q \\
& V=\operatorname{dom}(N),\left(\cdot, A, A_{\mathrm{X}}\right)=R_{A},\left(\cdot, B, B_{\mathrm{X}}\right)=R_{B}, \\
& Y_{A}=\operatorname{rals}\left(N, A, A_{\mathrm{X}}\right), Y_{B}=\operatorname{rals}\left(N, B, B_{\mathrm{X}}\right), \\
& (v, I) \in N,|\operatorname{ran}(I)|>2, s, t \in \operatorname{ran}(I), s>t, \\
& N^{\prime}=N \backslash\{(v, I)\} \cup\{(v,\{(s, t)\} \circ I)\}, \\
& R_{A}^{\prime}=I_{\mathrm{R}, \mathrm{a}}^{*}\left(\left((V, v, s, t), Y_{A}, R_{A}\right)\right), \\
& R_{B}^{\prime}=I_{\mathrm{R}, \mathrm{a}}^{*}\left(\left((V, v, s, t), Y_{B}, R_{B}\right)\right), \\
& \left(a^{\prime}, \cdot, \cdot\right)=R_{A}^{\prime},\left(b^{\prime}, \cdot, \cdot\right)=R_{B}^{\prime}, \\
& \left.\left.w=\prod_{\left(\cdot, I^{\prime}\right) \in N^{\prime}}\left|\operatorname{ran}\left(I^{\prime}\right)\right|, m=|V|, c^{\prime}=I_{\approx \operatorname{pow}}^{*}((w, 1 / m))\right\}\right)
\end{aligned}
\end{aligned}
$$

Next, the functionality of (i) the highest-layer limited-layer limited-underlying limited-breadth fud tree searcher, $Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{~d}}$, and (ii) the highest-layer limited-
derived derived variables set list maximiser, $Z_{P, A, A_{R}, F, \mathrm{D}, \mathrm{d}}$, is implemented in the highest-layer layerer $I_{P, U, \mathrm{~L}, \mathrm{~d}} \in$ computers, which is defined such that (i) the domain is domain $\left(I_{P, U, \mathrm{~L}, \mathrm{~d}}\right)=\mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{A}_{U} \times \mathcal{A}_{U} \times \mathbf{N}$, (ii) the range is $\operatorname{range}\left(I_{P, U, \mathrm{~L}, \mathrm{~d}}\right)=\mathcal{U} \times \mathcal{F} \times(\mathrm{P}(\mathcal{V}) \rightarrow \mathbf{Q})$, and (iii) the application is

$$
I_{P, U, \mathrm{~L}, \mathrm{~d}}^{*}\left(\left(V, A, A_{R}, f\right)\right)=\operatorname{layer}\left(V, U, \emptyset, \emptyset, A, A_{R}, f, 1\right)
$$

where layer $\in \mathrm{P}(\mathcal{V}) \times \mathcal{U} \times \mathcal{F} \times((\mathrm{P}(\mathcal{V}) \times \mathcal{A} \times \mathcal{A}) \rightarrow \mathbf{Q}) \times \mathcal{A} \times \mathcal{A} \times \mathbf{N} \times \mathbf{N} \rightarrow$ $(\mathcal{U} \times \mathcal{F} \times(\mathrm{P}(\mathcal{V}) \rightarrow \mathbf{Q}))$ is defined

$$
\begin{aligned}
& \operatorname{layer}\left(V, U, F, M, X, X_{R}, f, l\right)= \\
& \text { if }((l \leq\operatorname{lax}) \wedge(H \neq \emptyset) \wedge\left(M \neq \emptyset \Longrightarrow \operatorname{maxr}\left(M^{\prime}\right)>\operatorname{maxr}(M)\right), \\
& \operatorname{layer}\left(V, U^{\prime}, F \cup H, M^{\prime}, X^{\prime}, X_{R}^{\prime}, f, l+1\right), \\
&(U, F, M)): \\
& L=\{(b,(T,(w, \operatorname{ran}(I)))): \\
&((\cdot, I), b) \in \operatorname{order}\left(D_{\mathrm{L}},\{(v, I):\right. \\
& Q \in I_{P, U, \mathrm{~B}}^{*}\left(\left(V, F, X, X_{R}\right)\right), \\
& N \in I_{P, U, \mathrm{R}}^{*}\left(I_{P, U, \mathrm{~K}}^{*}(Q)\right), \\
&(v, I) \in N\}), \\
&w=(f, l, b), T=(\{S \cup\{(w, k)\}:(S, k) \in I\},\{w\})\}, \\
& L^{\prime}=\{(i,(T,(w, W))):(i,(T,(w, W))) \in L, \\
&\left.\forall\left(i^{\prime},\left(T^{\prime},\left(w^{\prime}, W^{\prime}\right)\right)\right) \in L\left(i>i^{\prime} \Longrightarrow T^{\mathrm{P}} \neq T^{\prime \mathrm{P}}\right)\right\}, \\
& H= \operatorname{dom}\left(\operatorname{set}\left(L^{\prime}\right)\right), U^{\prime}=U \cup \operatorname{ran}\left(\operatorname{set}\left(L^{\prime}\right)\right), \\
& X^{\prime}= I_{* \mathrm{X}}^{*}((H, X)), X_{R}^{\prime}=I_{* \mathrm{X}}^{*}\left(\left(H, X_{R}\right)\right), \\
& M^{\prime}= I_{P, U^{\prime}, \mathrm{D}, \mathrm{~d}}^{*}\left(\left(V, F \cup H, X^{\prime}, X_{R}^{\prime}\right)\right)
\end{aligned}
$$

where $I_{* \mathrm{X}}=$ applier $\in$ computers.
Here the order $D_{\mathrm{L}}$ is some enumeration of the layer fud representation, $D_{\mathrm{L}} \in \operatorname{enums}\left(\mathbf{N} \times\left(\mathcal{S}_{U} \rightarrow \mathbf{N}\right)\right)$.

The new variable, $w=(f, l, b)$, is constructed from the fud identifier, $f$, the layer identifier, $l$, and the position within the breadth of the layer fud, $b$. The new variable, $w$, is added to a new system, $U^{\prime}$. The values of the new variable are cardinal numbers, $U^{\prime}(w) \subset \mathbf{N}_{>0}$, such that $1 \in U^{\prime}(w)$. The values are not necessarily contiguous, unless the implementation completely removes source values, in which case $U^{\prime}(w)=\left\{1 \ldots\left|U^{\prime}(w)\right|\right\}$.

The layer list, $L$, potentially contains duplicate transform partitions, $\mid\left\{T^{\mathrm{P}}\right.$ :
$(\cdot,(T, \cdot)) \in L\}\left|\leq|L|\right.$. These duplicates are stripped from the list $L^{\prime}$ by crossing each new variable with all previous and checking that the transforms differ. Note that implementations may improve the performance of the check by testing the valency and underlying variables before testing the partition, $\forall\left(i^{\prime},\left(T^{\prime},\left(w^{\prime}, W^{\prime}\right)\right)\right) \in L\left(i>i^{\prime} \Longrightarrow|W| \neq\left|W^{\prime}\right| \wedge \operatorname{und}(T) \neq\right.$ $\left.\operatorname{und}\left(T^{\prime}\right) \wedge T^{\mathrm{P}} \neq T^{\prime \mathrm{P}}\right)$.

A variation of the highest-layer layerer, $I_{P, U, \mathrm{~L}, \mathrm{~d}}$, is to implement the limitedvalency maximum-roll contracted decrementing linear non-overlapping fuds tree maximiser, $Z_{P, A, A_{R}, F, \mathrm{n}, \mathrm{w},-, K, \mathrm{mr}}$, by means of the maximum roll tuple partition value roller, $I_{P, U, \mathrm{R}, \mathrm{mr}}$. The highest-layer maximum-roll layerer $I_{P, U, \mathrm{~L}, \mathrm{mr}, \mathrm{d}} \in$ computers is defined such that the application is

$$
I_{P, U, \mathrm{~L}, \mathrm{mr}, \mathrm{~d}}^{*}\left(\left(V, A, A_{R}, f\right)\right)=\operatorname{layer}\left(V, U, \emptyset, \emptyset, A, A_{R}, f, 1\right)
$$

and

$$
\begin{aligned}
& \operatorname{layer}\left(V, U, F, M, X, X_{R}, f, l\right)= \\
& \operatorname{if}((l \leq\operatorname{lmax}) \wedge(H \neq \emptyset) \wedge\left(M \neq \emptyset \Longrightarrow \operatorname{maxr}\left(M^{\prime}\right)>\operatorname{maxr}(M)\right), \\
& \operatorname{layer}\left(V, U^{\prime}, F \cup H, M^{\prime}, X^{\prime}, X_{R}^{\prime}, f, l+1\right), \\
&(U, F, M)): \\
& L=\{(b,(T,(w, \operatorname{ran}(I)))): \\
&((\cdot, I), b) \in \operatorname{order}\left(D_{\mathrm{L}},\{(v, I):\right. \\
& Q \in I_{P, U, \mathrm{~B}}^{*}\left(\left(V, F, X, X_{R}\right)\right), \\
& P \in I_{P, U, \mathrm{~K}}^{*}(Q), N \in I_{P, U, \mathrm{R}, \mathrm{mr}}^{*}(P), \\
&(v, I) \in N\}) \\
&w=(f, l, b), T=(\{S \cup\{(w, k)\}:(S, k) \in I\},\{w\})\}, \\
& L^{\prime}=\{(i,(T,(w, W))):(i,(T,(w, W))) \in L, \\
&\left.\quad \forall\left(i^{\prime},\left(T^{\prime},\left(w^{\prime}, W^{\prime}\right)\right)\right) \in L\left(i>i^{\prime} \Longrightarrow T^{\mathrm{P}} \neq T^{\prime \mathrm{P}}\right)\right\}, \\
& H== \operatorname{dom}\left(\operatorname{set}\left(L^{\prime}\right)\right), U^{\prime}=U \cup \operatorname{ran}\left(\operatorname{set}\left(L^{\prime}\right)\right), \\

M^{\prime}= \\
I_{P, U^{\prime}, \mathrm{D}, \mathrm{~d}}^{*}\left(\left(V, F \cup H, X^{\prime}, X_{R}^{\prime}\right)\right)
\end{gathered}
$$

The functionality of the practicable highest-layer shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}$, is implemented in the highest-layer fud induction computer $I_{P, U, Z, \mathrm{~F}, \mathrm{~d}} \in$ computers, which is defined such that (i) the domain is domain $\left(I_{P, U, Z, \mathrm{~F}, \mathrm{~d}}\right)=\mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{A}_{U} \times \mathcal{A}_{U} \times \mathrm{N}$, (ii) the range is $\operatorname{range}\left(I_{P, U, \mathrm{Z}, \mathrm{F}, \mathrm{d}}\right)=\mathcal{F} \rightarrow \mathbf{Q}$, and (iii) the application is

$$
\begin{aligned}
& I_{P, U, \mathrm{Z}, \mathrm{~F}, \mathrm{~d}}^{*}\left(\left(V, A, A_{R}, f\right)\right)= \\
& \{(G, a): \\
& \quad(\cdot, F, N)=I_{P, U, \mathrm{~L}, \mathrm{~d}}^{*}\left(\left(V, A, A_{R}, f\right)\right), \\
& \quad(K, a) \in N, G=\operatorname{depends}(F, K)\}
\end{aligned}
$$

The fud identifier, $f$, is used to construct the new variables in the new system. The fud identifier should be such that $\forall i, j \in \mathbf{N}_{>0}((f, i, j) \notin \operatorname{vars}(U))$.

The fuds of the fud induction computer, $I_{P, U, \mathrm{Z}, \mathrm{F}, \mathrm{d}}$, are not partition fuds, $\forall\left(U^{\prime}, F, \cdot\right) \in I_{P, U, \mathrm{~L}, \mathrm{~d}}^{*}\left(\left(V, A, A_{R}, f\right)\right)\left(F \notin \mathcal{F}_{U^{\prime}, \mathrm{P}}\right)$, so the fud induction computer is not a literal implementation of the fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}$. However, the fuds flatten to the same substrate partition transforms, $\forall A \in$ $\mathcal{A}_{z}\left(\left\{\left(F^{\mathrm{TPT}}, a\right):(F, a) \in I_{P, U_{A}, \mathrm{Z}, \mathrm{F}, \mathrm{b}, \mathrm{d}}^{*}\left(\left(V_{A}, A, A^{\mathrm{X}}, f\right)\right)\right\}=\left\{\left(F^{\mathrm{TPT}}, a\right):(F, a) \in\right.\right.$ $\left.\left.I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime *}(A)\right\} \subset\left(\mathcal{T}_{U_{A}, V_{A}} \rightarrow \mathbf{Q}\right)\right)$. Thus, an inducer implemented with
the fud induction computer, $I_{P, U, Z, \mathrm{~F}, \mathrm{~d}}$, after suitable conversion of the fuds to substrate models, would have the same inducer correlation as the fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d} \cdot}^{\prime}$. That is, $\operatorname{maxr}\left(I_{P, U, \mathrm{Z}, \mathrm{F}, \mathrm{d}}^{*}\left(\left(V, A, A^{\mathrm{X}}, f\right)\right)\right)=\operatorname{maxr}\left(I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{*}(A)\right)$.

Now consider the yet more restricted functionality of the practicable highestlayer excluded-self maximum-roll shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{mr}, \mathrm{xs}, \mathrm{d}}^{\prime}$, is implemented in the highest-layer maximumroll excluded-self fud induction computer $I_{P, U, \mathrm{Z}, \mathrm{F}, \mathrm{mr}, \mathrm{xs}, \mathrm{d}} \in$ computers, which is defined such that the application is

$$
\begin{aligned}
& I_{P, U, \mathrm{Z}, \mathrm{~F}, \mathrm{mr}, \mathrm{xs}, \mathrm{~d}}^{*}\left(\left(V, A, A_{R}, f\right)\right)= \\
& \{(G, a): \\
& \quad(\cdot, F, N)=I_{P, U, \mathrm{~L}, \mathrm{mr}, \mathrm{xs}, \mathrm{~d}}^{*}\left(\left(V, A, A_{R}, f\right)\right), \\
& \quad(K, a) \in N, G=\operatorname{depends}(F, K)\}
\end{aligned}
$$

Finally, the maximum-roll variation functionality of the practicable highestlayer excluded-self maximum-roll-by-derived-dimension shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~mm}, \mathrm{xs}, \mathrm{d}}^{\prime}$, is implemented in the highest-layer maximum-roll-by-derived-dimension excluded-self fud induction computer $I_{P, U, \mathrm{Z}, \mathrm{F}, \mathrm{mm}, \mathrm{xs}, \mathrm{d}} \in$ computers, which is defined such that the application is

$$
\begin{aligned}
& I_{P, U, \mathrm{Z}, \mathrm{~F}, \mathrm{~mm}, \mathrm{xs}, \mathrm{~d}}^{*}\left(\left(V, A, A_{R}, f\right)\right)= \\
& \{(G, a): \\
& \quad(\cdot, F, N)=I_{P, U, \mathrm{~L}, \mathrm{~mm}, \mathrm{xs}, \mathrm{~d}}^{*}\left(\left(V, A, A_{R}, f\right)\right), \\
& \quad(K, a) \in N, G=\operatorname{depends}(F, K)\}
\end{aligned}
$$

Now consider the practicable highest-layer summed shuffle content alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}$, implemented by means of induction computers. The implementation of the practicable fud decomposition inducer in terms of optimisers is described above in section 'Optimisation'. The functionality of the highest-layer limited-models infinitelayer substrate fud decompositions tree searcher, $Z_{P, A, \mathrm{D}, \mathrm{F}, \mathrm{d}}$, is implemented in the highest-layer fud decomper $I_{P, U, \mathrm{D}, \mathrm{F}, \mathrm{d}} \in$ computers, which is defined such that (i) the domain is domain $\left(I_{P, U, \mathrm{D}, \mathrm{F}, \mathrm{d}}\right)=\mathrm{P}\left(\mathcal{V}_{U}\right) \times \mathcal{A}_{U}$, (ii) the range is $\operatorname{range}\left(I_{P, U, \mathrm{D}, \mathrm{F}, \mathrm{d}}\right)=\mathcal{U} \times \mathcal{D}_{\mathrm{F}, \mathrm{d}}$, and (iii) the application is

$$
I_{P, U, \mathrm{D}, \mathrm{~F}, \mathrm{~d}}^{*}((V, A))=\operatorname{decomp}(V, A, U, \emptyset, 1, \emptyset)
$$

where decomp $\in \mathrm{P}(\mathcal{V}) \times \mathcal{A} \times \mathcal{U} \times \mathcal{D}_{\mathrm{F}, \mathrm{d}} \times \mathrm{N} \times \mathrm{P}(\mathcal{L}(\mathcal{S} \times \mathcal{F}) \times \mathcal{S}) \rightarrow\left(\mathcal{U} \times \mathcal{D}_{\mathrm{F}, \mathrm{d}}\right)$ is defined as

$$
\begin{aligned}
& \operatorname{decomp}(V, A, U, D, f, Z)= \\
& \text { if }(Q \neq \emptyset, \\
& \text { if }(N \neq \emptyset \wedge \operatorname{maxr}(N)>0, \\
& \operatorname{decomp}\left(V, A, U^{\prime}, E, f+1, Z^{\prime}\right) \text {, } \\
& \left.\operatorname{decomp}\left(V, A, U, D, f, Z^{\prime}\right)\right) \text {, } \\
& (U, D)) \text { : } \\
& Q=\operatorname{maxd}\left(\operatorname { o r d e r } \left(D_{\mathbf{Q} \times \mathrm{S} \times \mathcal{X}^{3}},\left\{\left(z_{B}, S, L, B\right):\right.\right.\right. \\
& (L, Y) \in \operatorname{places}(D) \text {, } \\
& (\cdot, F)=L_{|L|}, W=\operatorname{der}(F) \text {, } \\
& S \in W^{\mathrm{CS}} \backslash \operatorname{dom}(\operatorname{dom}(Y)) \text {, } \\
& (L, S) \notin Z, \\
& R_{L}=\bigcup \operatorname{dom}(\operatorname{set}(L)), H_{L}=\bigcup \operatorname{ran}(\operatorname{set}(L)), \\
& B=I_{\%}^{*}\left(\left(V, I_{*}^{*}\left(\left(I_{* \mathrm{X}}^{*}\left(\left(H_{L}, A\right)\right),\left\{R_{L} \cup S\right\}^{\mathrm{U}}\right)\right)\right)\right) \text {, } \\
& \left.\left.\left.z_{B}=\operatorname{size}(B), z_{B}>0\right\}\right)\right), \\
& \{(\cdot, S, L, B)\}=Q \text {, } \\
& Z^{\prime}=Z \cup\{(L, S)\} \text {, } \\
& \left(U^{\prime}, F, N\right)=I_{P, U, \mathrm{~L}, \mathrm{~d}}^{*}\left(\left(V, B, B_{R(B)}, f\right)\right), \\
& \{K\}=\operatorname{maxd}\left(\operatorname{order}\left(D_{\mathrm{K}}, \operatorname{dom}(N)\right)\right) \text {, } \\
& G=\operatorname{depends}(F, K) \text {, } \\
& M=L \cup\{(|L|+1,(S, G))\} \text {, } \\
& E=\operatorname{tree}(\operatorname{paths}(D) \backslash\{L\} \cup\{M\})\}
\end{aligned}
$$

and

$$
\begin{aligned}
& \operatorname{decomp}( V, A, U, \emptyset, f, Z)= \\
& \operatorname{if}(N \neq \emptyset \wedge \operatorname{maxr}(N)>0, \\
& \operatorname{decomp}\left(V, A, U^{\prime}, D, f+1, \emptyset\right), \\
&\left.\left(U, D_{\emptyset}\right)\right): \\
&\left(U^{\prime}, F, N\right)=I_{P, U, \mathrm{~L}, \mathrm{~d}}^{*}\left(\left(V, A, A_{R(A)}, f\right)\right), \\
&\left.\{K\}=\operatorname{maxd}\left(\operatorname{order}\left(D_{\mathrm{K}}, \operatorname{dom}(N)\right)\right)\right), \\
& G= \operatorname{depends}(F, K), \\
& D=\{((\emptyset, G), \emptyset)\}
\end{aligned}
$$

The fuds of the decomposition in the fud decomposition induction computer, $I_{P, U, \mathrm{D}, \mathrm{F}, \mathrm{d}}$, are not partition fuds, $\forall F \in \operatorname{fuds}(D)\left(F \notin \mathcal{F}_{U^{\prime}, \mathrm{P}}\right)$ where $\left(U^{\prime}, D\right)=$ $\operatorname{decomp}(V, A, U, \emptyset, 1, \emptyset)$, so the fud decomposition induction computer is not a literal implementation of the fud decomposition inducer, $I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}$. However, the fuds flatten to the same substrate partition transforms, so an inducer implemented with the fud decomposition induction computer, $I_{P, U, \mathrm{D}, \mathrm{F}, \mathrm{d}}$, after suitable conversion of the fuds to substrate models, would have the same maximum function correlation as the fud decomposition inducer, $I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}$. That is, $I_{\mathrm{Scsd}}^{*}((A, D))=\operatorname{maxr}\left(I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime *}(A)\right)$, where $D=I_{P, U, \mathrm{D}, \mathrm{F}, \mathrm{d}}^{*}((V, A))$.

The practicable highest-layer excluded-self maximum-roll summed shuffle content alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{mr}, \mathrm{xs}, \mathrm{d}}^{\prime}$, is implemented in the highest-layer excluded-self maximum-roll fud decomper $I_{P, U, \mathrm{D}, \mathrm{F}, \mathrm{mr}, \mathrm{xs}, \mathrm{d}} \in$ computers exactly as in the highest-layer fud decomper $I_{P, U, \mathrm{D}, \mathrm{F}, \mathrm{d}}$, above, except that the highest-layer maximum-roll excluded-self fud induction computer, $I_{P, U, \mathrm{Z}, \mathrm{F}, \mathrm{mr}, \mathrm{xs}, \mathrm{d}}$, replaces the highest-layer fud induction computer, $I_{P, U, \mathrm{Z}, \mathrm{F}, \mathrm{d}}$.

The practicable highest-layer excluded-self maximum-roll-by-derived-dimension summed shuffle content alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~mm}, \mathrm{xs}, \mathrm{d}}^{\prime}$, is implemented in the highest-layer excluded-self maximum-roll-by-derived-dimension fud decomper $I_{P, U, \mathrm{D}, \mathrm{F}, \mathrm{mm}, \mathrm{xs}, \mathrm{d}} \in$ computers exactly as in the highest-layer fud decomper $I_{P, U, \mathrm{D}, \mathrm{F}, \mathrm{d}}$, above, except that the highestlayer maximum-roll-by-derived-dimension excluded-self fud induction computer, $I_{P, U, \mathrm{Z}, \mathrm{F}, \mathrm{mm}, \mathrm{xs}, \mathrm{d}}$, replaces the highest-layer fud induction computer, $I_{P, U, \mathrm{Z}, \mathrm{F}, \mathrm{d}}$.

## 5 Induction

This section considers how tractable and practicable induction is related to (a) structure and compression, and (b) likelihood and sensitivity.

A variable or structure is defined as known below if (a) its type or containing class is defined, and (b) its instance of the type is specified. For example, it is known if (i) it is finite and can be explicitly constructed in a first order formula, or (ii) it is countably enumerable and can be defined recursively/algorithmically. An unknown variable or structure may be subject to known constraints. That is, the variable or structure is partially known. At the least, the type of an unknown is usually defined.

First review the definitions of the degree of structure and compression.
Let $U$ be a non-empty finite system, $U \in \mathcal{U}=\mathcal{V} \rightarrow(\mathrm{P}(\mathcal{W}) \backslash\{\emptyset\})$ such that $0<|U|<\infty$ and $\forall(\cdot, W) \in U(|W|<\infty)$. Let $X \subset \mathcal{X}$ be a non-empty unknown finite set of event identifiers, $0<|X|<\infty$. Let $\mathcal{H}_{U, X}$ be the nonempty unknown finite set of histories in system $U$ having event identifiers $X$,

$$
\mathcal{H}_{U, X}=\bigcup\left\{X \rightarrow W^{\mathrm{CS}}: W \subseteq \operatorname{vars}(U)\right\} \subset \mathcal{H}_{U} \subset \mathcal{X} \rightarrow \mathcal{S}_{U}
$$

and $0<\left|\mathcal{H}_{U, X}\right|<\infty$.
Let $P \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$ be an unknown history probability function in the histories $\mathcal{H}_{U, X}$. The expected space of a history $\operatorname{coder} C \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$ is greater than or equal to the entropy of the history probability function,

$$
\begin{aligned}
\operatorname{expected}(P)\left(C^{\mathrm{s}}\right) & =\sum_{H \in \mathcal{H}_{U, X}} P_{H} \times C^{\mathrm{s}}(H) \\
& \geq-\sum\left(P_{H} \ln P_{H}: H \in \mathcal{H}_{U, X}, P_{H}>0\right) \\
& =\operatorname{entropy}(P)
\end{aligned}
$$

The expected space of a history coder $C \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$ may also be compared to the canonical space which is the lesser space of the canonical history coders, (i) index history coder, $C_{\mathrm{H}}$, and (ii) classification history coder, $C_{\mathrm{G}}$. The expected canonical space is defined canonical $(U, X) \in\left(\left(\mathcal{H}_{U, X}: \rightarrow\right.\right.$ $\left.\left.\mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}\right) \rightarrow \mathbf{Q}_{\geq 0} \ln \mathbf{N}_{>0}$ as

$$
\operatorname{canonical}(U, X)(P):=\operatorname{expected}(P)\left(\operatorname{minimum}\left(C_{\mathrm{H}}^{\mathrm{s}}, C_{\mathrm{G}}^{\mathrm{s}}\right)\right)
$$

The expected canonical space is also always greater than or equal to the entropy of the history probability function, canonical $(U, X)(P) \geq$ entropy $(P)$.

The degree of structure is defined for probability function $P \in\left(\mathcal{H}_{U, X}: \rightarrow\right.$ $\left.\mathrm{Q}_{\geq 0}\right) \cap \mathcal{P}$ with respect to a history coder $C \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$ in terms of a relationship between (i) the expected space, expected $(P)\left(C^{\mathrm{s}}\right)$, (ii) the expected canonical space, canonical $(U, X)(P)$, and (iii) the entropy, entropy $(P)$. The degree of structure is defined in section 'Derived history space', structure $(U, X) \in$ $\left(\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}\right) \times \operatorname{coders}\left(\mathcal{H}_{U, X}\right) \rightarrow \mathbf{Q} \ln \mathbf{Q}_{>0} / \ln \mathbf{Q}_{>0}$ as

$$
\text { structure }(U, X)(P, C):=\frac{\operatorname{canonical}(U, X)(P)-\operatorname{expected}(P)\left(C^{\mathrm{s}}\right)}{\operatorname{canonical}(U, X)(P)-\operatorname{entropy}(P)}
$$

The compression of coder $C$ with respect to probability function $P$ is a synonym for the degree of structure of probability function $P$ with respect to the
coder $C$.
The degree of structure, or compression, is defined for any history coder, $\operatorname{coders}\left(\mathcal{H}_{U, X}\right)$. The derived history coders are a special case of history coders. Given a transform $T$, the expanded specialising derived history coder $C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}(T) \in$ $\operatorname{coders}\left(\mathcal{H}_{U, X}\right)$ is derived from the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$. It expands the transform to the history variables, $V_{H}$, where the set of history variables is a superset of the underlying variables, $V=\operatorname{und}(T)$, and otherwise defaults to an index coder,

$$
\begin{aligned}
C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H)= & \left(C_{\mathrm{G}, V_{H}, \mathrm{~T}, \mathrm{H}}\left(T^{\mathrm{P} V_{H} \mathrm{~T}}\right)^{\mathrm{s}}(H)+s_{\left|V_{H}\right|}: V_{H} \supseteq V\right)+ \\
& \left(C_{\mathrm{H}}^{\mathrm{s}}(H): V_{H} \nsupseteq V\right)
\end{aligned}
$$

where $s_{n}=\operatorname{spaceVariables}(U)(n)$ and the specialising derived substrate history coder is
$C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)=\operatorname{coderHistorySubstrateDerivedSpecialising}\left(U, X, T, D_{\mathrm{S}}, D_{\mathrm{X}}\right)$
The specialising degree of structure of the probability function $P$ with respect to the expanded specialising derived history coder for some transform $T$ is

$$
\operatorname{structure}(U, X)\left(P, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}(T)\right) \in \mathbf{Q} \ln \mathbf{Q}_{>0} / \ln \mathbf{Q}_{>0}
$$

In section 'Derived history space', above, the specialising-canonical space difference, $2 C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, of history $H \in \mathcal{H}_{U, X}$ is characterised for given transform $T$ in terms of (i) the component size cardinality relative entropy,

$$
\text { entropyRelative }\left(A_{H} * T, V^{\mathrm{C}} * T\right)
$$

(ii) the possible derived volume space, $w^{\prime}$, where $w^{\prime}=\left|T^{-1}\right|$, and (iii) the expected component entropy,

$$
\text { entropyComponent }\left(A_{H}, T\right)
$$

The specialising-canonical space difference is minimised by varying the transform such that (i) the derived entropy is low, (ii) the possible derived volume is small, (iii) the underlying components have high entropy and (iv) high counts are in low cardinality components and high cardinality components have low counts. The canonical space terms, $C_{\mathrm{H}, V}^{\mathrm{s}}(H)$ and $C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, do not depend on the transform, $T$, and so the minimisation of the specialisingcanonical space difference is also the minimisation of the specialising derived substrate history coder space, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H)$.

Now review substrate structure alignment.
The substrate transforms set in system $U$ and variables $V$ is defined

$$
\mathcal{T}_{U, V}=\left\{F^{\mathrm{T}}: F \subseteq\left\{P^{\mathrm{T}}: P \in \mathrm{~B}\left(V^{\mathrm{CS}}\right)\right\}\right\}
$$

The set of complete congruent integral substrate histograms of size $z$ is defined

$$
\mathcal{A}_{U, \mathrm{i}, V, z}=\left\{A: A \in \mathcal{A}_{U, \mathrm{i}}, A^{\mathrm{U}}=V^{\mathrm{C}}, \operatorname{size}(A)=z\right\}
$$

Given $T \in \mathcal{T}_{U, V}$, the integral iso-transform-independents is derived from the formal-abstract pair valued function of the complete congruent integral substrate histograms,

$$
Y_{U, \mathbf{i}, T, z}=\left\{\left(A,\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
$$

The integral iso-transform-independents given transform $T \in \mathcal{T}_{U, V}$ for integral substrate histogram $A \in \mathcal{A}_{U, i, V, z}$ are abbreviated

$$
\begin{aligned}
\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A) & =Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \\
& =\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{X}} * T=A^{\mathrm{x}} * T,(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{X}}\right\}
\end{aligned}
$$

The integral iso-transform-independents, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)$, are equivalently the subset of integral substrate histograms which are both iso-formal and isoabstract with respect to substrate histogram $A, \forall B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\left(\left(B^{\mathrm{X}} * T=\right.\right.$ $\left.\left.A^{\mathrm{X}} * T\right) \wedge\left((B * T)^{\mathrm{X}}=(A * T)^{\mathrm{X}}\right)\right)$.

The generalised multinomial probability distribution of draw $(E, z) \in \mathcal{A}_{U, V, z_{E}} \times$ $\mathbf{N}$ is defined $\hat{Q}_{\mathrm{m}, U}(E, z) \in\left(\mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{Q}_{U} \cap \mathcal{Q}_{z} \cap \mathcal{P}$. The generalised multinomial probability for integral substrate histogram $A \in \mathcal{A}_{U, \mathrm{i}, V, z}$ is

$$
\hat{Q}_{\mathrm{m}, U}(E, z)(A)=\frac{z!}{\prod_{S \in A^{\mathrm{s}}} A_{S}!} \prod_{S \in A^{\mathrm{s}}}\left(\frac{E_{S}}{z_{E}}\right)^{A_{S}}
$$

The set of sized cardinal substrate histograms $\mathcal{A}_{z}$ is the finite set of complete integral cardinal substrate histograms of size $z$ and dimension less than or equal to the size such that the independent is completely effective,

$$
\mathcal{A}_{z}=\left\{A: A \in \mathcal{A}_{\mathrm{c}} \cap \mathcal{A}_{\mathrm{i}}, \operatorname{size}(A)=z,\left|V_{A}\right| \leq z, A^{\mathrm{U}}=A^{\mathrm{XF}}=A^{\mathrm{C}}\right\}
$$

where $A^{\mathrm{CS}}=\operatorname{cartesian}\left(U_{A}\right)\left(V_{A}\right)$ and $U_{A}=\operatorname{implied}(\operatorname{implied}(A))$ and $V_{A}=$ $\operatorname{vars}(A)$.

The subset of the sized cardinal substrate histograms, $\mathcal{A}_{z}$, for which the independent, $A^{\mathrm{X}}$, is integral, is the set of integral-independent substrate histograms,

$$
\mathcal{A}_{z, \mathrm{xi}}=\left\{A: A \in \mathcal{A}_{z}, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right\}
$$

The independent-sample-distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate ideal formal-abstract transform search set, also known as the alignment-bounded iso-transform space ideal transform search set, is defined $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}} \in \mathcal{A}_{z, \mathrm{xi}} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow\right.$ $\left.\ln \mathbf{Q}_{>0}\right)$ as

$$
\begin{aligned}
X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)= & \left\{\left(T,-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(B)}\right):\right. \\
& \left.T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}
\end{aligned}
$$

The derived alignment integral-independent substrate ideal formal-abstract transform search set is defined $X_{z, \mathrm{x}, \mathrm{T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime} \in \mathcal{A}_{z, \mathrm{xi}} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow \ln \mathrm{Q}_{>0}\right)$ as

$$
\begin{aligned}
X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}(A)= & \{(T, \operatorname{algn}(A * T)): \\
& \left.T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{x}} * T=(A * T)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}
\end{aligned}
$$

In section 'Substrate structures alignment', above, it is conjectured that the alignment-bounded iso-transform space ideal transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}$, is correlated with the derived alignment integralindependent substrate ideal formal-abstract transform maximum function, $\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j},}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}\right) \geq 0\right)
$$

where $\operatorname{cov}(z)(F, G):=\operatorname{covariance}\left(\hat{R}_{z}\right)(F, G)$ and the renormalised geometryweighted probability function is $\hat{R}_{z}=$ normalise $\left(\left\{\left(A, 1 /\left(\left|V_{A}\right|!\prod_{w \in V_{A}}\left|U_{A}(w)\right|!\right)\right)\right.\right.$ : $A \in \operatorname{dom}(F)\})$.

Now review the definition of induction. First inducers and literal inducers are defined.

The set of inducers is defined in section 'Tractable alignment-bounding', above. The inducers are computers $I_{z} \in \operatorname{inducers}(z) \subset$ computers such that (i) the domain is a set of substrate histograms which are at least a superset of the integral-independent substrate histograms, $\mathcal{A}_{z, \mathrm{xi}} \subseteq$ domain $\left(I_{z}\right) \subseteq \mathcal{A}_{z}$, (ii) the finite time and space application returns a rational-valued function
of the substrate models set, $I_{z}^{*}(A) \in \mathcal{M}_{U_{A}, V_{A}} \rightarrow \mathbf{Q}$, and (iii) the maximum of the inducer application, maxr $\circ I_{z}^{*}$, is positively correlated with the finite alignment-bounded iso-transform space ideal transform maximum function, $\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ I_{z}^{*}\right) \geq 0\right)
$$

That is, the induction correlation of inducer $I_{z}$ is positive.
The literal derived alignment integral-independent substrate ideal formal-abstract transform inducer $I_{z, \mathrm{a}, \mathrm{l}}^{\prime} \in \operatorname{inducers}(z)$ is a literal finite approximation to the derived alignment integral-independent substrate ideal formal-abstract transform search set, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}(A)$,

$$
\begin{aligned}
I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}(A)= & \left\{\left(T, I_{\approx \ln \mathbf{Q}}^{*}(\operatorname{algn}(A * T))\right):\right. \\
& \left.T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}
\end{aligned}
$$

The induction correlation of the literal derived alignment inducer is conjectured to be positive,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}\right) \geq 0\right)
$$

Now consider the definition of the class of tractable inducers.
Although the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, is finitely computable and faster than a literal implementation of the alignment-bounded iso-transform space ideal transform search set, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}$, it is nonetheless intractable. Section 'Tractable alignment-bounding' discusses the various intractabilities and the classes of limits and constraints on the structures of more tractable inducers.

First, the substrate volume is intractable. The application of the transformer $I_{* \mathrm{~T}}$, in the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, to a substrate histogram, $A$, and a substrate transform, $T \in \mathcal{T}_{U_{A}, V_{A}}$, is $I_{* T}^{*}((T, A))=A * T$. The volume, $\left|V_{A}^{\mathrm{C}}\right|$, grows exponentially with underlying dimension $n=\left|V_{A}\right|$, and so the space complexity of the transformer, $I_{* \mathrm{~T}}$, is exponential with respect to underlying dimension, $n$. To address this (i) the inducer models of the literal derived alignment inducer are expanded from substrate transforms, $\mathcal{T}_{U_{A}, V_{A}}$, to substrate fuds, $\mathcal{F}_{U_{A}, V_{A}}$, and (ii) the substrate fuds are then limited by intersecting with one of the class of limited-underlying subsets of the functional definition sets $\mathcal{F}_{\mathbf{u}} \subset \mathcal{F}$. A set of limited-underlying fuds, $\mathcal{F}_{\mathrm{u}}$, is defined such
that a fud $F \in \mathcal{F}_{\mathbf{u}}$ is such that its transforms, $F \subset \mathcal{T}$, are each tractably computable. For example the underlying volume of the transforms may be limited by a maximum underlying volume limit xmax $\in \mathbf{N}_{\geq 4}$. The set of inducer models is $\mathcal{F}_{U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}}$.

Next, the derived volume is intractable. Both the computation time and computation space of the alignmenter applied to the transformed sample histogram, $I_{\mathrm{a}}^{*}(A * T) \approx \operatorname{algn}(A * T)$, in the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, vary with the derived volume, $w=\left|W^{\mathrm{C}}\right|$, where $W=\operatorname{der}(T)$. The derived volume, $w$, grows exponentially with derived dimension $m=|W|$ and so the time and space complexities are exponential, and therefore intractable, with respect to derived dimension, $m$. This is also the case where the implementation uses a fuder, $I_{* \mathrm{~F}}$, in a limited-underlying derived alignment fud inducer, because the application of a fud $F \in \mathcal{F}_{U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}}$ must still compute $(A * F)^{\mathrm{X}}$ in an independenter, $I_{\mathrm{X}}$, in order to compute derived alignment, $\operatorname{algn}(A * F)$. So a further compromise is made by intersecting the substrate fuds with one of the class of limited-derived subsets of the functional definition sets $\mathcal{F}_{\mathrm{d}} \subset \mathcal{F}$. A set of limited-derived fuds, $\mathcal{F}_{\mathrm{d}}$, is defined such that a fud $F \in \mathcal{F}_{\mathrm{d}}$ is such that the independent derived of the fud is tractable. For example the derived volume of the fud may be limited by a maximum derived volume limit of $\operatorname{wmax} \in \mathbf{N}_{\geq 4}$.

Although the limited-variables substrate fuds, $\mathcal{F}_{U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{d}}$, has coverage of the entire substrate even when the substrate volume, $v$, is greater than the underlying volume limit, for example $v>$ xmax, the derived volume is still strictly limited, $w \leq$ wmax. In section 'Summation aligned decomposition inducers', above, it is conjectured that a summation aligned decomposition $D \in \mathcal{D}_{\Sigma}(A)$ is such that the content alignment equals the summation alignment, $\operatorname{algn}\left(A * D^{\mathrm{T}}\right)-\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)=\operatorname{alignmentSum}(A, D)$, where alignmentSum $(A, D)=\sum \operatorname{algn}(A * C * T):(C, T) \in \operatorname{cont}(D)$ and cont $=$ elements $\circ$ contingents. Thus, insofar as the content alignment approximates to the derived alignment, summing the derived alignments of the contingent fuds avoids the computation of the nullable transform, $D^{\mathrm{T}}$, which may have intractable derived volume, for example $w>$ wmax, where $w=\left|W^{\mathrm{C}}\right|$ and $W=\operatorname{der}\left(D^{\mathrm{T}}\right)$. Just as above where the set of inducer models is increased from substrate transforms, $\mathcal{T}_{U_{A}, V_{A}}$, to substrate fuds, $\mathcal{F}_{U_{A}, V_{A}}$, the inducer models is again expanded to the substrate fud decompositions $\mathcal{D}_{\mathrm{F}, U_{A}, V_{A}}$. The set of inducer models is then the limited-variables substrate fud decompositions, $\mathcal{D}_{\mathrm{F}, U_{A}, V_{A}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{d}}\right)\right)$. Given a limitedvariables substrate fud decomposition $D \in \mathcal{D}_{\mathrm{F}, U_{A}, V_{A}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{d}}\right)\right)$, the inducer computes the tractable sum of the contingent derived alignments,

$$
\sum \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right):(C, F) \in \operatorname{cont}(D) .
$$

Third, the computation of the search set models is intractable for two reasons, (i) fud flattening, and (ii) layer variables cardinality. The computation of the finite substrate fud set, $\mathcal{F}_{U_{A}, V_{A}}$, requires the exclusion of duplicate nested partitions. This is done by checking for the uniqueness of the flattened partitions. This check is intractable so the substrate fud set, $\mathcal{F}_{U_{A}, V_{A}}$, is replaced by the intersection of (i) the infinite-layer substrate fud set $\mathcal{F}_{\infty, U_{A}, V_{A}}$, which dispenses with the check, and (ii) one of the class of the sets of limitedlayer fuds, $\mathcal{F}_{\mathrm{h}}$. The limited-layer substrate fuds, $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{h}}$, places a limit on the number of layers, for example, a maximum layer limit of $\operatorname{lmax} \in \mathbf{N}_{>0}$.

The layer variables cardinality intractability is because of exponential time complexity of the computation of the layers of the fuds. This is addressed by defining one of the class of the sets of limited-breadth fuds, $\mathcal{F}_{\mathrm{b}}$. For example a maximum layer breadth limit of bmax $\in \mathbf{N}_{>0}$. Together the classes of limits are intersected together to form the class of limited-models $\mathcal{F}_{\mathrm{q}}=\mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{d}} \cap \mathcal{F}_{\mathrm{h}} \cap \mathcal{F}_{\mathrm{b}}$. The set of inducer models is then the limited-models infinite-layer fud decompositions, $\mathcal{D}_{\mathrm{F}, \infty, U_{A}, V_{A}} \cap \operatorname{trees}\left(\mathcal{S} \times \mathcal{F}_{\mathrm{q}}\right)$.

Last, the computation of the literal substrate model inclusion is intractable. The derivation of the conjectured induction correlation of the literal derived alignment inducer,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{f}, \mathrm{j},}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}\right) \geq 0\right)
$$

is described in section 'Derived alignment and conditional probability'. The derivation imposes several constraints, (i) integral independent histogram, $A \in \mathcal{A}_{\mathrm{xi}} \Longrightarrow A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, (ii) the formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, and (iii) the transform is ideal, $A=A * T * T^{\dagger A}$. Formal-abstract equality implies independent formal, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}=$ $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$. Together with integral independent histogram, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, this implies that the independent is an integral iso-transform-independent,

$$
A^{\mathrm{X}} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)=Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)
$$

and the lifted integral iso-transform-independents contains the abstract histogram

$$
(A * T)^{\mathrm{x}} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)=\left\{B * T: B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right\}
$$

Then, given the minimum alignment conjecture, it can be shown that the alignment-bounded lifted iso-transform space is bounded by the derived align-
ment,

$$
\begin{aligned}
& \leq \quad\left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{x}} * T, z\right)(A * T)}{\sum_{B^{\prime} \in \mathcal{A}_{U, i, \mathrm{y}, T,, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}} * T, z\right)\left(B^{\prime}\right)}:\right. \\
& \left.\quad E^{\mathrm{x}} * T=\left(E^{\mathrm{x}} * T\right)^{\mathrm{x}}, E^{\mathrm{XF}} \geq A^{\mathrm{xF}}, A^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{x}} * T=(A * T)^{\mathrm{x}}\right) \\
& \leq \operatorname{algn}(A * T)+\ln \left|\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right|
\end{aligned}
$$

The corresponding alignment-bounded iso-transform space is

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)(B)}:\right. \\
& \left.E^{\mathrm{X}} * T=\left(E^{\mathrm{X}} * T\right)^{\mathrm{X}}, E^{\mathrm{XF}} \geq A^{\mathrm{XF}}, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{x}}\right) \in \ln \mathbf{Q}_{>0}
\end{aligned}
$$

The formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, and so each derived histogram maps to exactly one set of iso-transform-independents,

$$
\begin{aligned}
& \left.\left\{\left(A * T, Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{x}}\right)\right)\right)\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{x}}\right\} \\
\in & \mathcal{A}_{U, \mathrm{i}, W, z} \rightarrow \mathrm{P}\left(\mathcal{A}_{U, \mathrm{i}, V, z}\right)
\end{aligned}
$$

Thus the alignment-bounded lifted iso-transform space is correlated with the alignment-bounded iso-transform space.

The derivation goes on to conjecture that when independent-sample distributed, $E^{\mathrm{X}}=A^{\mathrm{X}}$, the correlation is highest when the transform is ideal, $A=A * T * T^{\dagger A}$. That is, the alignment-bounded lifted iso-transform space is correlated with the alignment-bounded iso-transform idealisation space,

$$
\begin{aligned}
& \left(-\ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)\left(A * T * T^{\dagger A}\right)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \hat{Q}_{\mathrm{m}, U}\left(A^{\mathrm{X}}, z\right)(B)}:\right. \\
& \left.A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}, A * T * T^{\dagger A} \in \mathcal{A}_{\mathrm{i}}\right) \in \ln \mathbf{Q}_{>0}
\end{aligned}
$$

Therefore the derived alignment, $\operatorname{algn}(A * T)$, is conjectured to be correlated with the alignment-bounded iso-transform idealisation space, hence the literal derived alignment inducer correlation.

The constraint that the independent histogram is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, is sometimes not the case if the sample histogram, $A$, is a given. As noted in section 'Tractable alignment-bounding', the inducer correlation, $\operatorname{cov}(z)($ maxr o $\left.X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{f}, \mathrm{j},}, \operatorname{maxr} \circ I_{z}^{*}\right)$, is restricted to the intersection of the domains of the argument functions, which is the integral-independent substrate histograms, $\mathcal{A}_{z, \mathrm{xi}}$. However, in the case of non-integral-independent substrate histograms, $\mathcal{A}_{z} \backslash \mathcal{A}_{z, \mathrm{xi}}$, an inducer defined in terms of the generalised multinomial probability distribution $\hat{Q}_{\mathrm{m}, U}(E, z) \in \mathcal{A}_{U, \mathrm{i}, V, z} \rightarrow \mathbf{Q}_{\geq 0}$ can be extended by interpolating instead with the multinomial probability density function, $\operatorname{mpdf}(U)(E, z) \in$ $\mathcal{A}_{U, V, z} \rightarrow \mathbf{R}_{\geq 0}$,

$$
\operatorname{mpdf}(U)(E, z)(A):=\frac{\Gamma_{!} z}{\prod_{S \in A^{\mathrm{S}}} \Gamma_{!} A_{S}} \prod_{S \in A^{\mathrm{S}}}\left(\frac{E_{S}}{z_{E}}\right)^{A_{S}}
$$

The multinomial probability density function is defined in terms of the unittranslated gamma function, $\Gamma_{!} \in \mathbf{R} \rightarrow \mathbf{R}$. An inducer defined in terms of alignment is already extended to the non-integral-independent substrate histograms, algn $\in \mathcal{A} \rightarrow \mathbf{R}$ is defined as $\operatorname{algn}(A):=\sum_{S \in A^{\mathrm{s}}} \ln \Gamma_{!} A_{S}-$ $\sum_{S \in A^{\mathrm{XS}}} \ln \Gamma!A_{S}^{\mathrm{X}}$.

The substrate histograms, $\mathcal{A}_{z}$, defined in section 'Substrate structures alignment', are such that the independent is completely effective, $A^{\mathrm{XF}}=A^{\mathrm{C}}$. Hence, if the size, $z$, is less than the volume, $v=\left|A^{\mathrm{C}}\right|$, the independent is necessarily non-integral, $z<v \Longrightarrow A^{\mathrm{X}} \notin \mathcal{A}_{\mathfrak{i}}$. For this reason, any volume limits, for example, xmax $\in \mathbf{N}_{\geq 4}$, should be chosen such that they are less than or equal to the size, xmax $\leq z$. This is also more likely to avoid the region of negative logarithm unit-translated gamma function, $\forall x \in \mathbf{R}(0<x<1 \Longrightarrow 0>\ln \Gamma!x<0)$.

Consider the remaining two constraints, (i) formal-abstract equality, $A^{\mathrm{X}} * T=$ $(A * T)^{\mathrm{X}}$, and (ii) ideal transform, $A=A * T * T^{\dagger A}$. As described in section 'Intractable literal substrate model inclusion', both of these inclusion tests of the model are intractable with respect to substrate volume. The section considers how inducers can be made tractable while adhering to these constraints as closely as possible.

First, the formal-abstract equality is weakened to the independent-formal constraint, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, in the derived alignment substrate ideal independent-formal transform inducer, $I_{z, \mathrm{a}, \mathrm{fx}, \mathrm{j}}^{\prime}$. This constraint is still intractable, so it is replaced by constraining the transforms to be non-overlapping,
$\neg \operatorname{overlap}(T) \Longrightarrow A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, in the derived alignment substrate ideal non-overlapping transform inducer, $I_{z, \mathrm{a}, \mathrm{n}, \mathrm{j}}^{\prime}$. If the ideality inclusion test is dropped and the inducer model set of substrate transforms, $\mathcal{T}_{U_{A}, V_{A}}$, is replaced by the limited-models infinite-layer substrate fuds, $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}$, then the tractable limited-models derived alignment substrate non-overlapping infinitelayer fud inducer $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime} \in \operatorname{inducers}(z)$, given substrate histogram $A \in \mathcal{A}_{z}$, can be defined

$$
\begin{aligned}
& I_{z, \mathrm{a}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)= \\
& \quad\left\{\left(F, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}\left(A * F^{\mathrm{T}}\right)\right)\right): F \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right\}
\end{aligned}
$$

Although this inducer is tractable, the non-overlapping constraint is weaker than the formal-abstract equality constraint and the ideality constraint has been dropped altogether. The entropy of the doubly-independent formal independent histogram, entropy $\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right)$, is expected to be greater than the entropy of the abstract histogram, entropy $\left((A * T)^{\mathrm{X}}\right)$, whereas if the formalabstract equality constraint holds then the entropies would be equal. The abstract-non-formal entropy substrate ideal independent-formal transform inducer, $I_{z, \mathrm{e}, \mathrm{fx}, \mathrm{j}}^{\prime} \in \operatorname{inducers}(z)$, maximises the entropy difference between the abstract and the formal independent. The inducer is defined

$$
\begin{aligned}
& I_{z, \mathrm{e}, \mathrm{fx}, \mathrm{j}}^{\prime *}(A)= \\
& \quad\left\{\left(T, I_{\approx \ln \mathbf{Q}}^{*}\left(\operatorname{entropy}\left((A * T)^{\mathrm{X}}\right)-\operatorname{entropy}\left(\left(A^{\mathrm{x}} * T\right)^{\mathrm{X}}\right)\right)\right):\right. \\
& \left.\quad T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}}, A=A * T * T^{\dagger A}\right\}
\end{aligned}
$$

Derived alignment approximates to the sized entropy difference between the abstract histogram and the derived histogram,

$$
\operatorname{algn}(A * T) \approx z \times\left(\operatorname{entropy}\left((A * T)^{\mathrm{X}}\right)-\operatorname{entropy}(A * T)\right)
$$

so the abstract-non-formal entropy inducer, $I_{z, \mathrm{e}, \mathrm{fx}, \mathrm{j}}^{\prime}$, weakly maximises the derived alignment.

The abstract-non-formal entropy inducer is defined in terms of the entropies of histograms in the derived variables, entropy $\left((A * T)^{\mathrm{X}}\right)$ and entropy $\left(\left(A^{\mathrm{X}} *\right.\right.$ $\left.T)^{\mathrm{X}}\right)$, and so ignores the entropies of the underlying components, $\{(C$, entropy $(A *$ $\left.C)):(\cdot, C) \in T^{-1}\right\} \in \mathrm{P}\left(V_{A}^{\mathrm{CS}}\right) \rightarrow \ln \mathbf{Q}_{>0}$. The discussion considers the actualisations, which alter the relative independence of the derived and underlying, and then proposes an inducer that maximises the midisation pseudoalignment, $\operatorname{algn}(A)-\operatorname{algn}\left(A * T * T^{\dagger A}\right)-\operatorname{algn}\left((A * T)^{\mathrm{X}} * T^{\odot A}\right)$. However, the ideality constraint restricts the midisation pseudo-alignment to be equal to
the negative surrealisation alignment, so the ideality constraint is dropped. The midisation pseudo-alignment substrate independent-formal transform inducer $I_{z, \mathrm{~m}, \mathrm{fx}} \in \operatorname{inducers}(z)$, given substrate histogram $A \in \mathcal{A}_{z}$, is defined

$$
\begin{aligned}
& I_{z, \mathrm{~m}, \mathrm{fx}}^{*}(A)= \\
& \quad\left\{\left(T, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}(A)-\operatorname{algn}\left(A * T * T^{\dagger A}\right)-\operatorname{algn}\left((A * T)^{\mathrm{x}} * T^{\odot A}\right)\right)\right):\right. \\
& \left.T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{x}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}}\right\}
\end{aligned}
$$

The computation of midisation is intractable, so a further approximation is required. Maximisation of midisation tends to move component alignments from off-diagonal states to on-diagonal states, balancing the high derived alignment of longer diagonals with the high on-diagonal component alignments of shorter diagonals. Thus the midisation pseudo-alignment varies with the derived alignment valency density. The derived alignment valencydensity substrate independent-formal transform inducer $I_{z, \mathrm{ad,fx}}^{\prime} \in \operatorname{inducers}(z)$, given substrate histogram $A \in \mathcal{A}_{z}$, is defined

$$
\begin{aligned}
& I_{z, \mathrm{ad}, \mathrm{fx}}^{\prime *}(A)= \\
& \quad\left\{\left(T, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}(A * T) / w^{1 / m}\right)\right): T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right\}
\end{aligned}
$$

If the independent formal constraint is replaced by constraining the transforms to be non-overlapping, and the inducer model set of substrate transforms, $\mathcal{T}_{U_{A}, V_{A}}$, is replaced by the limited-models infinite-layer substrate fuds, $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{q}}$, then the tractable limited-models derived alignment valencydensity substrate non-overlapping infinite-layer fud inducer $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime} \in$ inducers $(z)$, given substrate histogram $A \in \mathcal{A}_{z}$, can be defined as

$$
\begin{aligned}
& I_{z, \mathrm{ad}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)= \\
& \quad\left\{\left(F, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}\left(A * F^{\mathrm{T}}\right) / w^{1 / m}\right)\right): F \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathbf{n}} \cap \mathcal{F}_{\mathrm{q}}\right\}
\end{aligned}
$$

This derived alignment valency-density fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, addresses the formal-abstract equality constraint, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, but ignores the ideal transform constraint, $A=A * T * T^{\dagger A}$. As described above, intractable derived volume can be addressed by expanding the inducer models to the substrate fud decompositions, $\mathcal{D}_{\mathrm{F}, U_{A}, V_{A}}$, and summing the derived alignments of the contingent fuds, $\sum \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right):(C, F) \in \operatorname{cont}(D)$. Using a similar method, sections 'Decomposition alignment' and 'Tractable decomposition inducers' show how maximising the sum of the contingent alignment valencydensities, $\sum \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}}:(C, F) \in \operatorname{cont}(D)$, of limited-models non-overlapping infinite-layer fud decompositions, $\mathcal{D}_{\mathrm{F}, \infty, U_{A}, V_{A}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{n}} \cap\right.\right.$ $\left.\mathcal{F}_{\mathrm{q}}\right)$ ), removes alignments along the decomposition path and tends to independent leaf components. When fully decomposed the nullable transform of
the decomposition is ideal, $A * D^{\mathrm{T}} * D^{\mathrm{T} \dagger A}=A$. The tractable limited-models summed alignment valency-density substrate aligned non-overlapping infinitelayer fud decomposition inducer, given non-independent substrate histogram $A \in \mathcal{A}_{z} \backslash\left\{A^{\mathrm{X}}\right\}$, is defined

$$
\begin{aligned}
& I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)= \\
& \qquad\left\{\left(D, I_{\approx \mathbf{R}}^{*}\left(\sum \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}}:(C, F) \in \operatorname{cont}(D)\right)\right):\right. \\
& D \in \mathcal{D}_{\mathrm{F}, \infty, U_{A}, V_{A}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right), \\
& \left.\forall(C, F) \in \operatorname{cont}(D)\left(\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)>0\right)\right\}
\end{aligned}
$$

where $W_{F}=\operatorname{der}(F), w_{F}=\left|W_{F}^{\mathrm{C}}\right|$ and $m_{F}=\left|W_{F}\right|$. The summed alignment valency-density decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is conjectured to have positive induction correlation. That is, it is positively correlated with the alignment-bounded iso-transform space ideal transform maximum function,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}\right) \geq 0\right)
$$

In section 'Tractable decomposition inducers', above, it is shown that, although the maximisation of the midisation alignment tends to minimise the mid component size cardinality relative entropy, the subsequent maximisation of the idealisation alignment tends to restore the relative entropy so that the maximal relative entropy of the tractable limited-models summed alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is (a) greater than that of the corresponding model in the tractable derived alignment valencydensity fud inducer, $I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$,

$$
\text { entropyRelative }\left(A * D^{\mathrm{T}}, V_{A}^{\mathrm{C}} * D^{\mathrm{T}}\right)>\operatorname{entropyRelative}\left(A * F_{\mathrm{ad}}^{\mathrm{T}}, V_{A}^{\mathrm{C}} * F_{\mathrm{ad}}^{\mathrm{T}}\right)
$$

where $D \in \operatorname{maxd}\left(I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)\right)$ and $F_{\text {ad }} \in \operatorname{maxd}\left(I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}(A)\right)$, and (b) comparable to that of the corresponding model in the tractable derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$,

$$
\operatorname{entropyRelative}\left(A * D^{\mathrm{T}}, V_{A}^{\mathrm{C}} * D^{\mathrm{T}}\right) \approx \operatorname{entropyRelative}\left(A * F_{\mathrm{a}}^{\mathrm{T}}, V_{A}^{\mathrm{C}} * F_{\mathrm{a}}^{\mathrm{T}}\right)
$$

where $F_{\mathrm{a}} \in \operatorname{maxd}\left(I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)\right)$.
In order to investigate the constraints necessary to make tractable inducers practicable, section 'Practicable alignment-bounding', above, considers how the limited-models non-overlapping infinite-layer substrate fuds, $\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}$, may be constructed. Section 'Optimisation' goes on to consider the explicit definitions of the (i) limited-models constraints, and (ii)
layer-ordered limited-underlying limited-breadth infinite-layer substrate fuds trees, in order to define a finite search for a practicable inducer.

Let $A$ be a substrate histogram, $A \in \mathcal{A}_{z}$. The scaled shuffle histogram, $A_{R}$, is defined $A_{R}=\operatorname{scalar}(1 /|R|) * \sum_{r \in R} L_{r}$ where $X \in \operatorname{enums}($ shuffles $($ history $(A)))$, $L=\operatorname{map}(\operatorname{his}, \operatorname{flip}(X)), R \subseteq\left\{1 \ldots z!^{n}\right\}$ and $n=\left|V_{A}\right|$.

The practicable highest-layer shuffle content alignment valency-density fud inducer, $I_{z, \mathrm{csd}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}$, is defined,

$$
\begin{aligned}
& I_{z, \mathrm{csd}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime *}(A)= \\
& \quad\left\{\left(G, I_{\mathrm{csd}}^{*}\left(\left(A, A_{R}, G\right)\right)\right):\right. \\
& \quad\left|V_{A}\right|>1,\left\{F_{\mathrm{L}}\right\}=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{~d}}\right)\right) \\
& \left.\quad K \in \operatorname{maxd}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F_{\mathrm{L}}, \mathrm{D}, \mathrm{~d}}\right)\right), G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\} \cup
\end{aligned}
$$

$$
\left\{(\emptyset, 0):\left|V_{A}\right| \leq 1\right\}
$$

where (i) the shuffle content alignment valency-density computer is

$$
I_{\mathrm{csd}}^{*}\left(\left(A, A_{R}, F\right)\right)=\left(I_{\mathrm{a}}^{*}\left(A * F^{\mathrm{T}}\right)-I_{\mathrm{a}}^{*}\left(A_{R} * F^{\mathrm{T}}\right)\right) / I_{\mathrm{cvl}}^{*}(F)
$$

(ii) the valency capacity computer is

$$
I_{\mathrm{cv1}}^{*}(F):=\left(I_{\approx \mathrm{pow}}^{*}((w, 1 / m)): W=\operatorname{der}(F), w=\left|W^{\mathrm{C}}\right|, m=|W|\right)
$$

(iii) the highest-layer limited-layer limited-underlying limited-breadth fud tree searcher is

$$
Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{~d}}=\operatorname{searchTreer}\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}, P_{P, A, A_{R}, \mathrm{~L}, \mathrm{~d}},\{\emptyset\}\right)
$$

(iv) the highest-layer limited-layer limited-underlying limited-breadth fud tree searcher neighbourhood function is

$$
\begin{aligned}
& P_{P, A, A_{R}, \mathrm{~L}, \mathrm{~d}}(F)=\{G: \\
& \quad G \in P_{P, A, A_{R}, \mathrm{~L}}(F) \\
& \left.\quad\left(F \neq \emptyset \Longrightarrow \operatorname{maxr}\left(\mathrm{el}\left(Z_{P, A, A_{R}, F, \mathrm{D}, \mathrm{~d}}\right)\right)<\operatorname{maxr}\left(\mathrm{el}\left(Z_{P, A, A_{R}, G, \mathrm{D}, \mathrm{~d}}\right)\right)\right)\right\}
\end{aligned}
$$

(v) the limited-layer limited-underlying limited-breadth fud tree searcher neighbourhood function is

$$
\begin{aligned}
& P_{P, A, A_{R}, \mathrm{~L}}(F)= \\
& \qquad=\{G: \\

\end{aligned}
\end{aligned}
$$

and (v) the highest-layer limited-models infinite-layer substrate fud decompositions tree searcher initial subset is

$$
\begin{aligned}
R_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{~d}}= & \{\{((\emptyset, G), \emptyset)\}: \\
G \in & \operatorname{maxd}\left(\operatorname { o r d e r } \left(D_{\mathrm{F}},\{G:\right.\right. \\
& F_{\mathrm{L}} \in \operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, A_{R(A)}, \mathrm{L}, \mathrm{~d}}\right)\right), \\
& (K, a) \in \max \left(\operatorname{elements}\left(Z_{P, A, A_{R(A)}, F_{\mathrm{L}}, \mathrm{D}, \mathrm{~d}}\right)\right), a>0, \\
& \left.\left.\left.\left.G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right)\right\}\right)\right)\right\}
\end{aligned}
$$

### 5.1 Inducers and Compression

Now consider how substrate structure alignment and inducers relate to derived history coders.

The fud decomposition minimum space specialising derived search function for history $H \in \mathcal{H}_{U, X}$ is defined in terms of the expanded specialising derived history coder, $C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}(T) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$, as

$$
Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}(H)=\left\{\left(D,-C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(D^{\mathrm{T}}\right)^{\mathrm{s}}(H)\right): D \in \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}\right\}
$$

The summed alignment valency-density decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, application also defines a fud decomposition search function, but restricted to the limited-models non-overlapping fud decompositions, $\mathcal{D}_{\mathrm{F}, U, \mathrm{P}} \cap \operatorname{trees}(\mathcal{S} \times$ $\left.\left(\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right) \subseteq \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}$. Define the limited-models summed alignment valencydensity aligned non-overlapping fud decomposition search function

$$
\begin{aligned}
& Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)= \\
& \qquad \begin{array}{l}
\left\{\left(D, I_{\approx \mathbf{R}}^{*}\left(\sum \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}}:(C, F) \in \operatorname{cont}(D)\right)\right):\right. \\
D \in \mathcal{D}_{\mathrm{F}, U, \mathrm{P}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right), \operatorname{und}(D) \subseteq V, \\
\left.\forall(C, F) \in \operatorname{cont}(D)\left(\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)>0\right)\right\} \cup
\end{array}
\end{aligned}
$$

$$
\left\{\left(D_{\mathrm{u}}, 0\right)\right\}
$$

where $V=\operatorname{vars}(H), A=\operatorname{histogram}(H)$, the unary fud decomposition $D_{\mathrm{u}}=$ $\left\{\left(\left(\emptyset,\left\{T_{\mathrm{u}}\right\}\right), \emptyset\right)\right\}$, and the unary transform $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$. The addition of the unary fud decomposition ensures that the search is not empty, as it would otherwise be in the case, say, of independent history, $A=A^{\mathrm{X}}$. The domain of the inducer search function is a subset of the minimum space search function,

$$
\operatorname{dom}\left(Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)\right) \subseteq \operatorname{dom}\left(Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}(H)\right)=\mathcal{D}_{\mathrm{F}, U, \mathrm{P}}
$$

The definition of the subset depends on the instance of the class of limitedmodels, $\mathcal{F}_{\mathrm{q}}$.

Although the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, is defined completely separately of the notions of alignment and independence, the properties of the minimum coder space are similar in many ways to the properties of the maximum summed alignment valency-density of the tractable midising/idealising fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, as is discussed below. Conjecture that in some cases, the maximum decompositions intersect,

$$
\left|\operatorname{maxd}\left(Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)\right) \cap \operatorname{maxd}\left(Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}(H)\right)\right| \geq 0
$$

More formally, conjecture that for all finite systems and finite event identifier sets there exists a class of limited-models fuds such that the search functions are positively correlated for uniform history probability function,

$$
\begin{aligned}
& \forall U \in \mathcal{U} \forall X \subset \mathcal{X}\left(\left|\mathcal{H}_{U, X}\right|<\infty \Longrightarrow\right. \\
& \quad \exists \mathcal{F}_{\mathrm{q}} \subset \mathcal{F}\left(\operatorname{covariance}\left(\mathcal{H}_{U, X} \times\left\{1 /\left|\mathcal{H}_{U, X}\right|\right\}\right)\right. \\
& \left.\left.\quad\left(\operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}, \operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}\right) \geq 0\right)\right)
\end{aligned}
$$

The fud decomposition minimum space specialising derived search function for history $H \in \mathcal{H}_{U, X}$ is

$$
Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}(H)=\left\{\left(D,-C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(D^{\mathrm{T}}\right)^{\mathrm{s}}(H)\right): D \in \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}\right\}
$$

It is maximised by finding the fud decomposition $D \in \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}$ which minimises the specialising derived substrate history coder space, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(D^{\mathrm{PVT}}\right)^{\mathrm{s}}(H)$ where $V=\operatorname{vars}(H)$.

The minimisation of the specialising derived substrate history coder space, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(D^{\mathrm{P} V \mathrm{~T}}\right)^{\mathrm{s}}(H)$, occurs where (i) the derived entropy is low, (ii) the possible derived volume is small, (iii) the underlying components have high entropy and (iv) high counts are in low cardinality components and high cardinality components have low counts. The minimisation of the specialising derived substrate history coder space, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(D^{\mathrm{PVT}}\right)^{\mathrm{s}}(H)$, also minimises the specialising-canonical space difference, $2 C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(D^{\mathrm{PVT}}\right)^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)-$ $C_{\mathrm{G}, V}^{\mathrm{s}}(H)$. History probability functions that have high specialising degree of structure, structure $(U, X)\left(P, C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}\left(D^{\mathrm{T}}\right)\right)$, are expected to have encodings with these properties because the degree of structure is defined relative to the canonical coders.

The limited-models summed alignment valency-density aligned non-overlapping fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)$, is maximised by searching
for the fud decomposition $D \in \operatorname{maxd}\left(Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)\right) \subset \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}$, which maximises summed alignment valency-density, algnValDensSum $(U)\left(A, D^{\mathrm{D}}\right)=$ $\sum \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}}:(C, F) \in \operatorname{cont}(D)$, where $A=\operatorname{histogram}(H)$ and ()$^{\mathrm{D}} \in \mathcal{D}_{\mathrm{F}} \rightarrow \mathcal{D}$.

In order to compare the properties of the minimum space search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$, and the summed alignment valency-density search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, first consider the correlation between summed alignment valencydensity, algnValDensSum $(U)\left(A, D^{\mathrm{D}}\right)$, and derived entropy, entropy $\left(A * D^{\mathrm{T}}\right)$. Clearly the summed alignment valency-density is correlated with its numerator, summed alignment, $\operatorname{algnSum}(U)\left(A, D^{\mathrm{D}}\right)=\sum \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right):(C, F) \in$ cont $(D)$,

$$
\sum_{(C, F) \in \operatorname{cont}(D)} \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}} \sim \sum_{(C, F) \in \operatorname{cont}(D)} \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)
$$

Within the degree to which Stirling's approximation holds, the contingent derived alignment is approximately equal to the sized difference between the contingent abstract entropy and the contingent derived entropy,
$\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) \approx z \times \operatorname{entropy}\left(\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{X}}\right)-z \times \operatorname{entropy}\left(A * C * F^{\mathrm{T}}\right)$
So the summed alignment varies against the summed derived entropy

$$
\sum_{(C, F) \in \operatorname{cont}(D)} \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) \sim-\sum_{(C, F) \in \operatorname{cont}(D)} \operatorname{entropy}\left(A * C * F^{\mathrm{T}}\right)
$$

So summed alignment valency-density, algnValDensSum $(U)\left(A, D^{\mathrm{D}}\right)$, maximisation in the summed alignment valency-density search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, tends to minimise the summed derived entropy,

$$
\sum_{(C, F) \in \operatorname{cont}(D)} \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}} \sim-\sum_{(C, F) \in \operatorname{cont}(D)} \operatorname{entropy}\left(A * C * F^{\mathrm{T}}\right)
$$

As the cardinality of the decomposition tree increases the summed derived entropy decreases, because the slices are aligned, $\forall(C, F) \in \operatorname{cont}(D)(\operatorname{algn}(A *$ $\left.C * F^{\mathrm{T}}\right)>0$ ).

The summed alignment valency-density, algnValDensSum $(U)\left(A, D^{\mathrm{D}}\right)$, also varies against the derived entropy of the nullable transform, entropy $\left(A * D^{\mathrm{T}}\right)$. If it so happens that the decomposition is also a summation aligned decomposition, $D^{\mathrm{D}} \in \mathcal{D}_{\Sigma}(A)$, then the decomposition is contingently diagonalised,
$\forall(C, T) \in \operatorname{cont}\left(D^{\mathrm{D}}\right)(\operatorname{diagonal}(A * C * T))$, and contingently formal-abstract equivalent, $\forall(C, T) \in \operatorname{cont}\left(D^{\mathrm{D}}\right)\left(A^{\mathrm{X}} * C * T=(A * C * T)^{\mathrm{X}}\right)$. In section 'Summation aligned decomposition inducers', above, it is conjectured that the content alignment of a summation aligned decomposition, $D^{\mathrm{D}}$, equals the summation alignment, $\operatorname{algn}\left(A * D^{\mathrm{T}}\right)-\operatorname{algn}\left(A^{\mathrm{X}} * D^{\mathrm{T}}\right)=\operatorname{algnSum}(U)\left(A, D^{\mathrm{D}}\right)$. So, in the case of a summation aligned decomposition, the summation alignment varies with the nullable transform derived alignment and against the nullable transform derived entropy,

$$
\begin{aligned}
\sum_{(C, F) \in \operatorname{cont}(D)} \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) & \sim \operatorname{algn}\left(A * D^{\mathrm{T}}\right) \\
& \sim-\operatorname{entropy}\left(A * D^{\mathrm{T}}\right)
\end{aligned}
$$

Hence for a summation aligned decomposition, $D^{\mathrm{D}} \in \mathcal{D}_{\Sigma}(A)$,

$$
\sum_{(C, F) \in \operatorname{cont}(D)} \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}} \sim-\operatorname{entropy}\left(A * D^{\mathrm{T}}\right)
$$

The limited-models summed alignment valency-density aligned non-overlapping fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)$, constrains the fuds to be non-overlapping and its maximisation tends to increase slice midisation. This is consistent with the contingently formal-abstract equivalence constraint of the summation aligned decompositions, $\mathcal{D}_{\Sigma}(A)$. The maximisation of the slice alignment valency-density tends to contingent diagonalisation, which is also consistent with summation aligned decompositions. Therefore conjecture that, even in the cases where the decomposition is not a summation aligned decomposition, $D^{\mathrm{D}} \notin \mathcal{D}_{\Sigma}(A)$, the maximisation of summed alignment valency-density, algnValDensSum $(U)\left(A, D^{\mathrm{D}}\right)$, tends to minimise the derived entropy of the nullable transform, entropy $\left(A * D^{\mathrm{T}}\right)$,

$$
\sum_{(C, F) \in \operatorname{cont}(D)} \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}} \sim-\operatorname{entropy}\left(A * D^{\mathrm{T}}\right)
$$

However, this anti-correlation between the summed alignment valency-density, algnValDensSum $(U)\left(A, D^{\mathrm{D}}\right)$, and the derived entropy, entropy $\left(A * D^{\mathrm{T}}\right)$, is not perfect. One of the reasons is that maximising the contingent derived alignment, $\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)$, also tends to maximise the sized contingent abstract entropy, $z \times \operatorname{entropy}\left(\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{X}}\right)$. As discussed in section 'Maximum alignment', above, maximum alignment, alignmentMaximum $(U)\left(W, z_{A * C}\right)$ where $W=\operatorname{der}(F)$, is obtained when the histogram is uniformly diagonalised. In this case maximum alignment occurs when the contingent derived histogram is diagonalised, diagonal $\left(A * C * F^{\mathrm{T}}\right)$, and uniform, $\left|\operatorname{ran}\left(\operatorname{trim}\left(A * C * F^{\mathrm{T}}\right)\right)\right|=1$.

In the case of regular derived variables of dimension $m=|W|$ and valency $\{d\}=\left\{\left|U_{w}\right|: w \in W\right\}$, the maximum alignment approximates to

$$
\operatorname{alignmentMaximum}(U)\left(W, z_{A * C}\right) \approx z_{A * C}(m-1) \ln d
$$

That is, maximum alignment increases weakly with increasing diagonal, $d$. Entropy, on the other hand, is minimised when the histogram is a singleton, entropy $(\{(\cdot, 1)\})=0$, so near maximum alignment the entropy no longer decreases, but instead increases as the diagonal becomes more uniform. However, in the limited-models summed alignment valency-density aligned non-overlapping fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)$, it is the contingent alignment valency-density that is maximimised, so the maximum alignment valency-density for regular derived histogram approximates to

$$
\operatorname{alignmentMaximum}(U)\left(W, z_{A * C}\right) / d \approx z_{A * C}(m-1)(\ln d) / d
$$

Thus the diagonals tend to shorten to bivalent, $d=2$. Although the diagonals cannot shorten to singletons, the derived entropy, entropy $\left(A * D^{\mathrm{T}}\right)$, is lower in order to minimise valency-capacity, $d$. In any case, the space of the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, is sometimes minimised where there are two effective derived states, $\left|\left(A * D^{\mathrm{T}}\right)^{\mathrm{F}}\right|=2$, depending on the partition events space, as described in section 'Derived history space', above.

In the case where the decomposition, $D \in \operatorname{maxd}\left(Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)\right) \subset \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}$, is also a summation aligned decomposition, $D^{\mathrm{D}} \in \mathcal{D}_{\Sigma}(A)$, then the decomposition is contingently diagonalised,

$$
\forall(C, T) \in \operatorname{cont}\left(D^{\mathrm{D}}\right)(\operatorname{diagonal}(A * C * T))
$$

and so there exists a skeletal reduction,

$$
\exists D_{\mathrm{s}}^{\mathrm{D}} \in \operatorname{reductions}\left(A, D^{\mathrm{D}}\right)\left(\operatorname{skeletal}\left(A * D_{\mathrm{s}}^{\mathrm{DT}}\right)\right)
$$

The summed derived entropy is unchanged,

$$
\sum_{(C,\{T\}) \in \operatorname{cont}\left(D_{\mathrm{s}}\right)} \operatorname{entropy}(A * C * T)=\sum_{(C, F) \in \operatorname{cont}(D)} \operatorname{entropy}\left(A * C * F^{\mathrm{T}}\right)
$$

because the off-diagonal derived states of the contingently diagonalised decomposition's fuds are ineffective and do not contribute to the derived entropy. So, with respect to summed derived entropy, the skeletal reductions of a summation aligned decomposition of singleton fuds are equally well correlated with the minimum space search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$, than is the
case without reduction.
In the special case of full functional fud decomposition $D_{\mathrm{f}}=\left\{\left(\left(\emptyset,\left\{T_{\mathrm{f}}\right\}\right), \emptyset\right)\right\}$, where $T_{\mathrm{f}}=\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in V\right\}^{\mathrm{T}}$, the derived alignment equals the histogram alignment, $\operatorname{algn}\left(A * D_{\mathrm{f}}^{\mathrm{T}}\right)=\operatorname{algn}(A)$, and the derived entropy equals the histogram entropy, entropy $\left(A * D_{\mathrm{f}}^{\mathrm{T}}\right)=\operatorname{entropy}(A)$. Note that the full functional decomposition, $D_{\mathrm{f}}$, is not necessarily a limited-models fud decomposition, $\operatorname{trees}\left(\mathcal{S} \times \mathcal{F}_{\mathrm{q}}\right)$, depending on the definition of limited-models fuds, $\mathcal{F}_{\mathrm{q}}$, and so the full functional decomposition may not be in the domain of the limited-models summed alignment valency-density aligned non-overlapping fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)$. At the other extreme of unary fud decomposition $D_{u}=\left\{\left(\left(\emptyset,\left\{T_{\mathrm{u}}\right\}\right), \emptyset\right)\right\}$, where $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$, the derived alignment is zero, $\operatorname{algn}\left(A * D_{\mathrm{u}}^{\mathrm{T}}\right)=0$, and the derived entropy is zero, $\operatorname{entropy}\left(A * D_{\mathrm{u}}^{\mathrm{T}}\right)=0$.

To continue the comparison of the properties of the minimum space search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$, and the summed alignment valency-density search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, now consider the correlation between summed alignment valency-density, algnValDensSum $(U)\left(A, D^{\mathrm{D}}\right)$, and component size cardinality relative entropy, entropyRelative $\left(A * D^{\mathrm{T}}, V^{\mathrm{C}} * D^{\mathrm{T}}\right)$, where $D \in$ $\operatorname{maxd}\left(Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)\right) \subset \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}, H \in \mathcal{H}_{U, X}, A=\operatorname{histogram}(H), V=$ $\operatorname{vars}(H), v=\left|V^{\mathrm{C}}\right|$ and $z=\operatorname{size}(A)$.

The minimisation of the specialising derived substrate history coder space, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(D^{\mathrm{P} V \mathrm{~T}}\right)^{\mathrm{s}}(H)$, in the minimum space search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}(H)$, maximises the component size cardinality relative entropy so that high counts tend to be in low cardinality components and high cardinality components tend to have low counts. The component size cardinality relative entropy can be expressed in terms of components,

$$
\begin{aligned}
& \text { entropyRelative }\left(A * D^{\mathrm{T}}, V^{\mathrm{C}} * D^{\mathrm{T}}\right)= \\
& \qquad \sum\left(\operatorname{size}\left(A * C^{\mathrm{U}}\right) / z\right) \ln \frac{\operatorname{size}\left(A * C^{\mathrm{U}}\right) / z}{|C| / v}: C \in D^{\mathrm{P}}, \operatorname{size}\left(A * C^{\mathrm{U}}\right)>0
\end{aligned}
$$

The limited-models summed alignment valency-density aligned non-overlapping fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)$, is maximised by searching for the fud decomposition $D \in \operatorname{maxd}\left(Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)\right) \subset \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}$, which maximises summed alignment valency-density, algnValDensSum $(U)\left(A, D^{\mathrm{D}}\right)=$ $\sum \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}}:(C, F) \in \operatorname{cont}(D)$. The limited-models summed alignment valency-density substrate aligned non-overlapping infinite-layer fud decomposition inducer maximum function, maxr $\circ I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}$, is correlated
with the midisation pseudo-alignment substrate independent-formal transform inducer maximum function, maxr $I_{z, \mathrm{~m}, \mathrm{fx}}^{*}$, which maximises the midisation pseudo-alignment. The alignment valency-density of a contingent fud of the decomposition, $\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}}$, where $(C, F) \in \operatorname{cont}(D)$, varies with the midisation pseudo-alignment,

$$
\begin{aligned}
& \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}} \sim \\
& \left.\quad \operatorname{algn}(A * C)-\operatorname{algn}\left(A * C * F^{\mathrm{T}} * F^{\mathrm{T} \dagger A * C}\right)-\operatorname{algn}\left(\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{x}} * F^{\mathrm{T} \odot A * C}\right)\right)
\end{aligned}
$$

Maximisation of midisation tends to move component alignments from offdiagonal states to on-diagonal states. That is, if not fully decomposed, the on-diagonal states have high component alignment, $\operatorname{algn}\left(A * C * C^{\prime}\right)>0$ where $\left(R^{\prime}, C^{\prime}\right) \in\left(F^{\mathrm{T}}\right)^{-1}$ and $\left(A * C * F^{\mathrm{T}}\right)_{R^{\prime}}=\operatorname{size}\left(A * C * C^{\prime}\right)>0$, while offdiagonal states have (i) low component alignment, $\operatorname{algn}\left(A * C * C^{\prime}\right) \approx 0$ where $\left(A * C * F^{\mathrm{T}}\right)_{R^{\prime}} \approx 0$, or (ii) are independent, $\operatorname{algn}\left(A * C * C^{\prime}\right)=0 \Longleftrightarrow A * C *$ $C^{\prime}=\left(A * C * C^{\prime}\right)^{\mathrm{X}}$, or (iii) are ineffective, $\left(A * C * F^{\mathrm{T}}\right)_{R^{\prime}}=0$. If the contingent derived histogram is diagonalised, diagonal $\left(A * C * F^{\mathrm{T}}\right)$, then the off-diagonal components are necessarily ineffective, $\left(A * C * F^{\mathrm{T}}\right)_{R^{\prime}}=\operatorname{size}\left(A * C * C^{\prime}\right)=0$.

Although the maximisation of the midisation alignment tends to minimise the mid component size cardinality relative entropy, entropyRelative $(A * C *$ $\left.F^{\mathrm{T}}, C * F^{\mathrm{T}}\right) \approx 0$, the subsequent maximisation of the idealisation alignment in the super-decomposition tends to restore it. The increase in relative entropy was conjectured, in section 'Likely histograms', above, to occur where the idealisation is integral, because the logarithm of the cardinality of integral independent histograms varies against the volume. It is shown below that, regardless of whether the idealisation is integral or not, the relative entropy also increases during decomposition because of the tendency to diagonalise as the midisation alignment of the slice is maximised. The maximisation of summed alignment valency-density, algnValDensSum $(U)\left(A, D^{\mathrm{D}}\right)$, tends to maximise the relative entropy of the nullable transform,

$$
\sum_{(C, F) \in \operatorname{cont}(D)} \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}} \sim \text { entropyRelative }\left(A * D^{\mathrm{T}}, V^{\mathrm{C}} * D^{\mathrm{T}}\right)
$$

Choose a node of the decomposition $((C, F), X) \in$ contingents $(D)$. In the case of a sub-decomposition $E \in \operatorname{subtrees}(D)$ which is such that the component, $C$, is a component of the decomposition partition, $C^{\mathrm{S}} \in E^{\mathrm{P}}$, the contribution of $C$ to the relative entropy of $E$ is

$$
(\operatorname{size}(A * C) / z) \ln \frac{\operatorname{size}(A * C) / z}{|C| / v}
$$

where $\operatorname{size}(A * C)>0$. In the super-decomposition, $D$, however, the component, $C$, is further decomposed so that in the case where the node has no children, $X=\emptyset$, the contribution to the relative entropy is instead

$$
\begin{aligned}
& \sum\left(\operatorname{size}\left(A * C * C^{\prime}\right) / z\right) \ln \frac{\operatorname{size}\left(A * C * C^{\prime}\right) / z}{\left|C * C^{\prime}\right| / v}: \\
& \quad\left(\cdot, C^{\prime}\right) \in\left(F^{\mathrm{T}}\right)^{-1}, \operatorname{size}\left(A * C * C^{\prime}\right)>0
\end{aligned}
$$

The fud, $F$, is chosen such that the midisation is maximised and so in some cases the relative entropy increases,

$$
\begin{aligned}
& (\operatorname{size}(A * C) / z) \ln \frac{\operatorname{size}(A * C) / z}{|C| / v} \\
& \leq \sum\left(\operatorname{size}\left(A * C * C^{\prime}\right) / z\right) \ln \frac{\operatorname{size}\left(A * C * C^{\prime}\right) / z}{\left|C * C^{\prime}\right| / v}: \\
& \quad\left(\cdot, C^{\prime}\right) \in\left(F^{\mathrm{T}}\right)^{-1}, \operatorname{size}\left(A * C * C^{\prime}\right)>0
\end{aligned}
$$

In the special case where the decomposed slice has uniform sub-slice sizes, $\forall\left(\cdot, C^{\prime}\right) \in\left(F^{\mathrm{T}}\right)^{-1}\left(\operatorname{size}\left(A * C * C^{\prime}\right)=\operatorname{size}(A * C) /\left|\left(F^{\mathrm{T}}\right)^{-1}\right|\right)$, then the relative entropy must increase if the sub-components do not all have the same cardinality, $\exists\left(\cdot, C^{\prime}\right) \in\left(F^{\mathrm{T}}\right)^{-1}\left(\left|C^{\prime}\right| \neq|C| /\left|\left(F^{\mathrm{T}}\right)^{-1}\right|\right)$, because then

$$
\exists\left(\cdot, C^{\prime}\right) \in\left(F^{\mathrm{T}}\right)^{-1}\left(\frac{\operatorname{size}\left(A * C * C^{\prime}\right) / z}{\left|C * C^{\prime}\right| / v} \neq \frac{\operatorname{size}(A * C) / z}{|C| / v}\right)
$$

In the case where there are ineffective components, $\operatorname{size}\left(A * C * C^{\prime}\right)=0$, the relative entropy necessarily increases because the effective underlying volume decreases,

$$
\left|\bigcup\left\{C * C^{\prime}:\left(\cdot, C^{\prime}\right) \in\left(F^{\mathrm{T}}\right)^{-1}, \operatorname{size}\left(A * C * C^{\prime}\right)>0\right\}\right|<|C|
$$

whereas the size of the slice $A * C$ is conserved,

$$
\sum \operatorname{size}\left(A * C * C^{\prime}\right):\left(\cdot, C^{\prime}\right) \in\left(F^{\mathrm{T}}\right)^{-1}=\operatorname{size}(A * C)
$$

Viewed as an optimising process, decomposition consists of successive alternating maximisations of midisation pseudo-alignment and then idealisation alignment. Alignments are removed along the decomposition paths so that a fully decomposed decomposition is ideal, $\operatorname{ideal}\left(A, D^{\mathrm{T}}\right)$. In the case where the node, $((C, F), X) \in$ contingents $(D)$, has children, $X \neq \emptyset$, a child slice $A * C_{2} \subset A * C$, where $\left(C_{2}, F_{2}\right) \in \operatorname{dom}(X)$, which cannot contain the parent alignment, $\operatorname{algn}\left(A * C_{2} * F^{\mathrm{T}}\right)=0$, again has its fud, $F_{2}$, chosen to maximise
midisation from the remaining alignment, tending to diagonalise the derived histogram, $A * C_{2} * F_{2}^{\mathrm{T}}$. Again, ineffective components and independent components are removed from subsequent slices, so the contribution to relative entropy, which was

$$
\left(\operatorname{size}\left(A * C_{2}\right) / z\right) \ln \frac{\operatorname{size}\left(A * C_{2}\right) / z}{\left|C_{2}\right| / v}=\left(\operatorname{size}\left(A * C * C^{\prime}\right) / z\right) \ln \frac{\operatorname{size}\left(A * C * C^{\prime}\right) / z}{\left|C * C^{\prime}\right| / v}
$$

where $\left(\cdot, C^{\prime}\right) \in\left(F^{\mathrm{T}}\right)^{-1}$ and $C * C^{\prime}=C_{2}$, is such that now, in some cases, the relative entropy again increases,

$$
\begin{aligned}
& \left(\operatorname{size}\left(A * C_{2}\right) / z\right) \ln \frac{\operatorname{size}\left(A * C_{2}\right) / z}{\left|C_{2}\right| / v} \\
& \qquad \begin{array}{l}
\leq \sum\left(\operatorname{size}\left(A * C_{2} * C^{\prime \prime}\right) / z\right) \ln \frac{\operatorname{size}\left(A * C_{2} * C^{\prime \prime}\right) / z}{\left|C_{2} * C^{\prime \prime}\right| / v} \\
\\
\left(\cdot, C^{\prime \prime}\right) \in\left(F_{2}^{\mathrm{T}}\right)^{-1}, \operatorname{size}\left(A * C_{2} * C^{\prime \prime}\right)>0
\end{array}
\end{aligned}
$$

The decomposition tends to concentrate events into smaller and smaller components along the decomposition path as the idealisation is maximised, because of the asymmetric distribution of events in the contingent fuds' slice partitions as midisation is maximised, thus increasing the component size cardinality relative entropy. However, the correlation between the minimum space search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$, and the summed alignment valencydensity search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, in this respect, is not perfect. A reason is that when any effective component, $\operatorname{size}\left(A * C * C^{\prime}\right)>0$, is independent, $A * C * C^{\prime}=\left(A * C * C^{\prime}\right)^{\mathrm{X}}$, the decomposition is ideal with respect to it, and no further slicing of the component can take place, $\left(C * C^{\prime}\right)^{\mathrm{S}} \in D^{\mathrm{P}}$.

On the other hand, the alignment of the components varies weakly with the component cardinality if the component volume is a proper cartesian subvolume, $\left|C * C^{\prime}\right| \leq\left|\left(C * C^{\prime}\right)^{\mathrm{XF}}\right|<\left|V^{\mathrm{C}}\right|$. In the on-diagonal case where the component alignments may be high, algn $\left(A * C * C^{\prime}\right)>0$, the maximum alignment varies approximately with the logarithm of the component cardinality, $\ln \left|\left(C * C^{\prime}\right)^{\mathrm{XF}}\right|^{(n-1) / n}$. (See the section 'Maximum alignment', above, where it is shown that alignmentMaximum $(U)(V, z) \approx z \ln v^{(n-1) / n}$.) In the offdiagonal case where the component alignments are low, $\operatorname{algn}\left(A * C * C^{\prime}\right) \approx 0$, the expected alignment varies with the logarithm of the component cardinality, $\ln \left|\left(C * C^{\prime}\right)^{\mathrm{XF}}\right|$. (See the section 'Minimum alignment', above, where it is conjectured that expected alignment varies approximately with the logarithm of the volume, $\ln v$ where $z \ll v$.) In both cases if the component is a proper cartesian sub-volume, $\left|\left(C * C^{\prime}\right)^{\mathrm{XF}}\right|<\left|V^{\mathrm{C}}\right|$, the alignment, $\operatorname{algn}\left(A * C * C^{\prime}\right)$,
varies weakly with the component cardinality, $\left|C * C^{\prime}\right|$. Hence the further decomposition of these non-independent slices decomposes larger cardinalities, tending to increase the relative entropy.

However, as shown in section 'Tractable decomposition inducers', above, the fraction of derived histograms of a given derived geometry that are diagonalised, $\mid\left\{A: A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right.$, diagonal $\left.(A)\right\}\left|/\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right|\right.$, increases as the diagonals shorten. Maximisation of alignment valency-density or midisation tends to shorten the diagonals, so the probability of off-diagonal states being completely ineffective is higher than would otherwise be the case. The probability of effective independent off-diagonal derived states that cannot be further decomposed is lower. In addition, maximisation of valency-density does not necessarily decrease the derived dimension where this does not lengthen the diagonal, so the fraction of the derived volume may be low, which tends to reduce the total volume of effective underlying components.

In the section above, which considers the correlation between the summed alignment valency-density, algnValDensSum $(U)\left(A, D^{\mathrm{D}}\right)$, and the derived entropy, entropy $\left(A * D^{\mathrm{T}}\right)$, it was shown that if it is the case that the decomposition $D \in \operatorname{maxd}\left(Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)\right)$ is a summation aligned decomposition, $D^{\mathrm{D}} \in \mathcal{D}_{\Sigma}(A)$, and also such that the fuds are all singletons, $\forall F \in$ fuds $(D)(|F|=1)$, then the summed derived entropy of the skeletal reduction $D_{\mathrm{s}}^{\mathrm{D}} \in \operatorname{reductions}\left(A, D^{\mathrm{D}}\right)$ is unchanged, $\sum \operatorname{entropy}(A * C * T):(C,\{T\}) \in$ $\operatorname{cont}\left(D_{\mathrm{s}}\right)=\sum \operatorname{entropy}\left(A * C * F^{\mathrm{T}}\right):(C, F) \in \operatorname{cont}(D)$. While the summation aligned decomposition, $D^{\mathrm{D}}$, may have high component size cardinality relative entropy because of the contingent diagonalisation, in the skeletal reduction, $D_{\mathrm{s}}^{\mathrm{D}}$, the fuds are mono-derived-variate, $\forall F \in \operatorname{fuds}\left(D_{\mathrm{s}}\right)(|\operatorname{der}(F)|=$ $1)$, and therefore all of the components are effective, $\forall C \in D_{\mathrm{s}}^{\mathrm{P}}(\operatorname{size}(A *$ $C)>0$ ), and there are fewer, larger components, $\left|D_{\mathrm{s}}^{\mathrm{P}}\right|<\left|D^{\mathrm{P}}\right|$. The component cardinalities, $|C|$, tend to be more correlated with the component sizes, size $(A * C)$, and hence the component size cardinality relative entropy is lower in the contingently reduced decomposition, $D_{\mathrm{s}}$. Thus, the history space, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(D_{\mathrm{s}}^{\mathrm{P} V \mathrm{~T}}\right)^{\mathrm{s}}(H)$, may be larger than that of the decomposition, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(D^{\mathrm{P} V \mathrm{~T}}\right)^{\mathrm{s}}(H)$. So the skeletal reduction, $D_{\mathrm{s}}$, is less likely to be a maximum of the minimum space search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$. The skeletal reduction, $D_{\mathrm{s}}$, cannot be a maximum of the summed alignment valencydensity search function, $Z_{D, \mathrm{~F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, because it has zero summed alignment, $\operatorname{algnValDensSum}(U)\left(A, D_{\mathrm{s}}^{\mathrm{D}}\right)=0$.

In the special case of full functional fud decomposition, $D_{\mathrm{f}}$, the component size cardinality relative entropy equals the log volume less the histogram en-
tropy

$$
\text { entropyRelative }\left(A * D_{\mathrm{f}}^{\mathrm{T}}, V^{\mathrm{C}} * D_{\mathrm{f}}^{\mathrm{T}}\right)=\ln v-\operatorname{entropy}(A)
$$

At the other extreme of unary fud decomposition, $D_{\mathrm{u}}$, the component size cardinality relative entropy is zero,

$$
\operatorname{entropyRelative}\left(A * D_{\mathrm{u}}^{\mathrm{T}}, V^{\mathrm{C}} * D_{\mathrm{u}}^{\mathrm{T}}\right)=0
$$

To continue the comparison of the properties of the minimum space search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$, and the summed alignment valency-density search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, consider the correlation between summed alignment valency-density, algnValDensSum $(U)\left(A, D^{\mathrm{D}}\right)$, and expected component entropy, entropyComponent $\left(A, D^{\mathrm{T}}\right)$, where $D \in \operatorname{maxd}\left(Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)\right) \subset \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}$, $H \in \mathcal{H}_{U, X}, A=\operatorname{histogram}(H)$ and $z=\operatorname{size}(A)$.

The minimisation of specialising derived coder space, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(D^{\mathrm{P} V \mathrm{~T}}\right)^{\mathrm{s}}(H)$, also minimises the specialising-canonical space difference, $2 C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(D^{\mathrm{PVT}}\right)^{\mathrm{s}}(H)-$ $C_{\mathrm{H}, V}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, which tends to maximise the entropy of the underlying components.

The limited-models summed alignment valency-density aligned non-overlapping fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)$, is maximised when the fud decomposition $D \in \operatorname{maxd}\left(Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)\right) \subset \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}$, is ideal with respect to the histogram, ideal $\left(A, D^{\mathrm{T}}\right)$, because contingent alignments are successively removed along the decomposition paths. Thus the components of the fully decomposed model are independent,

$$
\operatorname{ideal}\left(A, D^{\mathrm{T}}\right) \Longrightarrow \forall(\cdot, C) \in\left(D^{\mathrm{T}}\right)^{-1}\left(A * C=(A * C)^{\mathrm{x}}\right)
$$

and so

$$
\begin{aligned}
& \text { entropyComponent }\left(A, D^{\mathrm{T}}\right) \\
= & \operatorname{expected}\left(\hat{A} * D^{\mathrm{T}}\right)\left(\left\{(R, \text { entropy }(A * C)):(R, C) \in\left(D^{\mathrm{T}}\right)^{-1}\right\}\right) \\
= & \operatorname{expected}\left(\hat{A} * D^{\mathrm{T}}\right)\left(\left\{\left(R, \operatorname{entropy}\left((A * C)^{\mathrm{X}}\right)\right):(R, C) \in\left(D^{\mathrm{T}}\right)^{-1}\right\}\right)
\end{aligned}
$$

In section 'Minimum alignment', above, it is shown that the entropy of the independent of a histogram tends to be greater than the entropy of the histogram,

$$
\operatorname{entropy}(A * C) \leq \operatorname{entropy}\left((A * C)^{\mathrm{x}}\right)
$$

So the entropies are expected to be higher than would be the case if the decomposition were not ideal. The maximisation of summed alignment valencydensity, algnValDensSum $(U)\left(A, D^{\mathrm{D}}\right)$, tends to maximise the expected component entropy of the nullable transform,

$$
\sum_{(C, F) \in \operatorname{cont}(D)} \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}} \sim \text { entropyComponent }\left(A, D^{\mathrm{T}}\right)
$$

The correlation between the minimum space search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$, and the summed alignment valency-density search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, in this respect however, is not perfect. Maximum entropy is obtained when a component is uniform,

$$
\operatorname{entropy}\left((A * C)^{\mathrm{X}}\right) \leq \operatorname{entropy}\left((A * C)^{\mathrm{XF}}\right)
$$

but an independent component that is not uniform cannot be further decomposed into smaller, more uniform components by the fully decomposed decomposition, $\forall C_{1}, C_{2} \in \operatorname{dom}(\operatorname{cont}(D))\left(\left(A * C_{1}=\left(A * C_{1}\right)^{\mathrm{X}}\right) \wedge\left(C_{2} \neq\right.\right.$ $\left.\left.C_{1}\right) \Longrightarrow C_{2} \nsubseteq C_{1}\right)$.

In the special case of full functional fud decomposition, $D_{\mathrm{f}}$, the expected component entropy is zero,

$$
\text { entropyComponent }\left(A, D_{\mathrm{f}}^{\mathrm{T}}\right)=0
$$

At the other extreme of unary fud decomposition, $D_{\mathrm{u}}$, the expected component entropy equals the histogram entropy,

$$
\operatorname{entropyComponent}\left(A, D_{\mathrm{u}}^{\mathrm{T}}\right)=\operatorname{entropy}(A)
$$

To continue the comparison of the properties of the minimum space search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$, and the summed alignment valency-density search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, consider the correlation between summed alignment valency-density, algnValDensSum $(U)\left(A, D^{\mathrm{D}}\right)$, and possible derived volume, $w^{\prime}=\left|\left(D^{\mathrm{T}}\right)^{-1}\right|$, where $D \in \operatorname{maxd}\left(Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)\right) \subset \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}$ and $H \in \mathcal{H}_{U, X}$. As shown in section 'Decompositions', above, the possible derived volume, $w^{\prime}$, is bounded by the possible derived volumes of the individual fuds,

$$
\begin{aligned}
w^{\prime} & \leq \sum_{F \in G}\left(\left|\left(F^{\mathrm{T}}\right)^{-1}\right|\right)+1-|G| \\
& =\sum_{F \in G} w_{F}^{\prime}+1-|G|
\end{aligned}
$$

where $G=$ fuds $(D)$ and $w_{F}^{\prime}=\left|\left(F^{\mathrm{T}}\right)^{-1}\right|$. In this case all of the fuds are non-overlapping, so

$$
\begin{aligned}
w^{\prime} & \leq \sum_{F \in G}\left(\left|W_{F}^{\mathrm{C}}\right|\right)+1-|G| \\
& =\sum_{F \in G} w_{F}+1-|G|
\end{aligned}
$$

where $W_{F}=\operatorname{der}(F)$ and $w_{F}=\left|W_{F}^{\mathrm{C}}\right|$.
The fud decompositions of the alignment search, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)$, are limitedmodels fud decompositions, $\mathcal{D}_{\mathrm{F}, U, \mathrm{P}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right)$ and hence the fuds are limited-derived, $\mathcal{F}_{\mathrm{d}} \subset \mathcal{F}_{\mathrm{q}} \subset \mathcal{F}$. In the case where there is a maximum derived volume limit wmax $\in \mathbf{N}_{\geq 4}$, then then possible derived volume is also explicitly limited,

$$
w^{\prime} \leq|G| \times \operatorname{wmax}+1-|G|
$$

The maximisation of the midisation, or its tractable counterpart, the alignment valency-density, of a decomposition fud, $(C, F) \in \operatorname{cont}(D)$, tends to decrease the valency-capacity, $w_{F}^{1 / m_{F}}$, shortening the diagonal. Therefore the derived volume, $w_{F}=w_{F}^{\prime}$, also tends to decrease. The possible derived volume of the decomposition, $w^{\prime}$, is bounded by the sum of the fuds' derived volumes, $\sum_{F \in G} w_{F}$, and so it also tends to decrease.

The possible derived volume, $w^{\prime}$, equals the cardinality of the leaf components of the decomposition, $w^{\prime}=\left|\left(D^{\mathrm{T}}\right)^{-1}\right|=\left|D^{\mathrm{P}}\right|$, and so the possible derived volume does not depend on the cardinality of the fuds, $|G|$. For example, (i) a multi-fud decomposition $D_{1}$ such that $\mid$ fuds $\left(D_{1}\right) \mid>1$ and (ii) a singleton decomposition $D_{2}=\{((\emptyset, \cdot), \emptyset)\}$, which are such that the partitions are equal, $D_{1}^{\mathrm{P}}=D_{2}^{\mathrm{P}}$, have the same possible derived volume, $w^{\prime}=\left|D_{1}^{\mathrm{P}}\right|=\left|D_{2}^{\mathrm{P}}\right|$. The possible derived volume of a multi-fud decomposition does not necessarily increase with fud cardinality, $\left|G_{1}\right|$ where $G_{1}=$ fuds $\left(D_{1}\right)$, or decomposition path length, $|L|$ where $L \in \operatorname{paths}\left(D_{1}\right)$.

So the possible derived volume, $w^{\prime}$, can be minimised by choosing a decomposition tree, $D \in \operatorname{trees}(\mathcal{S} \times \mathcal{F})$, that minimises the cardinality of the decomposition partition, $\left|D^{\mathrm{P}}\right|$. This is achieved in the summed alignment valencydensity search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, by removing alignments as quickly as possible along the decomposition paths, resulting in a few large cardinality independent components, $A * C=(A * C)^{\mathrm{x}}$ where $(C, F) \in \operatorname{cont}(D)$
and $C^{\mathrm{S}} \in D^{\mathrm{P}}$. The rate of derived alignment removal per additional component along the decomposition path is the derived alignment per effective non-independent slice,

$$
\frac{\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)}{\left|\left\{C^{\prime}:\left(\cdot, C^{\prime}\right) \in\left(F^{\mathrm{T}}\right)^{-1}, \operatorname{algn}\left(A * C * C^{\prime}\right)>0\right\}\right|} \geq \frac{\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)}{\left|\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{F}}\right|}
$$

where $(C, F) \in \operatorname{cont}(D)$. The alignment effective-density is less than or equal to the alignment valency-density,

$$
\frac{\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)}{\left|\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{F}}\right|} \leq \frac{\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)}{w_{F}^{1 / m_{F}}}
$$

In the case of a regular diagonalised derived histogram, diagonal $\left(A * C * F^{\mathrm{T}}\right)$, of valency $\left\{d_{F}\right\}=\left\{\left|U_{w}\right|: w \in W_{F}\right\}$, which is such that $d_{F}=w_{F}^{1 / m_{F}}$, the alignment effective-density equals the alignment valency-density,

$$
\frac{\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)}{\left|\left(A * C * F^{\mathrm{T}}\right)^{\mathrm{F}}\right|}=\frac{\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)}{d_{F}}
$$

Thus the maximisation of the fud's alignment valency-density tends to maximise the rate of derived alignment removal per additional component. Along the decomposition path the parent fud's alignment, $\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)$, is removed from the children slices, reducing the cardinality of effective children slices that are not independent, $\mid\left\{C^{\prime}:\left(\cdot, C^{\prime}\right) \in\left(F^{\mathrm{T}}\right)^{-1}, \operatorname{algn}\left(A * C * C^{\prime}\right)>\right.$ $0\} \mid$. By balancing the removal of alignment in the numerator with the creation of new non-independent components in the denominator, the maximisation tends to deep, narrow decompositions that minimise the possible derived volume, $w^{\prime}$. The maximisation of summed alignment valency-density, algnValDensSum $(U)\left(A, D^{\mathrm{D}}\right)$, tends to minimise the derived volume of the nullable transform,

$$
\sum_{(C, F) \in \operatorname{cont}(D)} \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}} \sim 1 / w^{\prime}
$$

The effect on the possible derived volume, $w^{\prime}$, of maximising the alignment valency-density, $\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}}$, is similar to the effect on the derived entropy, entropy $\left(A * C * F^{\mathrm{T}}\right)$. However, the tendency to large cardinality leaf components, $|C|$ where $C^{\mathrm{S}} \in D^{\mathrm{P}}$, which also have large size, $\operatorname{size}(A * C)$, may reduce (a) the component size cardinality relative entropy and (b) the underlying component entropies. To optimise these properties both (i) maximisation of midisation, and (ii) maximisation of idealisation by decomposition,
are required.
While viewing the decomposition as constructed from a sequence of subdecompositions in a computational process is a useful way of describing the removal of alignments along the decomposition paths, the search merely optimises the sum of the contingent alignment valency-densities for the whole decomposition. Therefore in some cases children fuds may have higher alignment valency-densities than their parents, $\operatorname{algn}\left(A * C_{1} * F_{1}^{\mathrm{T}}\right) / w_{F_{1}}^{1 / m_{F_{1}}}<\operatorname{algn}(A *$ $\left.C_{2} * F_{2}^{\mathrm{T}}\right) / w_{F_{2}}^{1 / m_{F_{2}}}$, where $\left(C_{1}, F_{1}\right),\left(C_{2}, F_{2}\right) \in \operatorname{cont}(D)$ and $C_{2} \subset C_{1}$, although the sizes necessarily decrease, $\operatorname{size}\left(A * C_{1}\right)>\operatorname{size}\left(A * C_{2}\right)$. However, the maximum alignment, approximately $z \ln v^{(n-1) / n}$, varies with size, and so it is often the case that the highest alignments are near the root of the decomposition tree.

In the special case of full functional fud decomposition, $D_{\mathrm{f}}$, the possible derived volume is the substrate volume, $w^{\prime}=v$, where $v=\left|V^{\mathrm{C}}\right|$. At the other extreme of unary fud decomposition, $D_{\mathrm{u}}$, the possible derived volume is one, $w^{\prime}=1$.

Also, note that each non-root fud adds no more than $w_{F}-1$ to the possible derived volume,

$$
\begin{aligned}
w^{\prime} & \leq \sum_{F \in G} w_{F}+1-|G| \\
& =\sum_{F \in G}\left(w_{F}-1\right)+1
\end{aligned}
$$

so there is a case for optimising the alignment decremented-valency-density,

$$
\frac{\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)}{\left(w_{F}^{1 / m_{F}}-1\right)}
$$

The alignment decremented-valency-density has a slightly weaker capacity than the alignment valency-density, and so its maximisation would tend to longer diagonals and shallower, wider decompositions.

The comparisons above between the properties of the minimum space search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$, and the summed alignment valency-density search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, provide evidence for the conjecture that the search functions are positively correlated for uniform history probability func-
tion,
$\forall U \in \mathcal{U} \forall X \subset \mathcal{X}\left(\left|\mathcal{H}_{U, X}\right|<\infty \Longrightarrow\right.$

$$
\left.\exists \mathcal{F}_{\mathrm{q}} \subset \mathcal{F}\left(\operatorname{covariance}\left(P_{U, X}\right)\left(\operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}, \operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}\right) \geq 0\right)\right)
$$

where $P_{U, X}=\mathcal{H}_{U, X} \times\left\{1 /\left|\mathcal{H}_{U, X}\right|\right\}$.

Although the minimum space search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$, searches for a fud decomposition, the history itself is encoded in a specialising derived substrate history coder parameterised only with the transform of the fud decomposition, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(D^{\mathrm{PVT}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, V, X}\right)$.

In some cases, however, a history may be encoded in less space by means of a specialising fud substrate history coder if $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)<C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(D^{\mathrm{T}}\right)^{\mathrm{s}}(H)$, where $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F) \in \operatorname{coders}\left(\mathcal{H}_{U, V, X}\right)$ and fud $F$ is such that its transform equals that of the fud decomposition, $F^{\mathrm{T}}=D^{\mathrm{T}}$. It is shown in 'Derived history space', above, that in the law-like case where the fud has a top transform, $\exists T \in F\left(W_{T}=\operatorname{der}(F)\right)$, the space difference is just the difference in partitioned events space,

$$
\begin{aligned}
C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}( & H)-C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(F^{\mathrm{T}}\right)^{\mathrm{s}}(H)= \\
& \sum_{T \in F} \operatorname{spaceEventsPartition}\left(A * \operatorname{depends}\left(F, V_{T}\right)^{\mathrm{T}}, T\right) \\
- & \text { spaceEventsPartition }\left(A, F^{\mathrm{T}}\right)
\end{aligned}
$$

which is the size scaled difference in component size cardinality cross entropies,

$$
\begin{aligned}
C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H) & -C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(F^{\mathrm{T}}\right)^{\mathrm{s}}(H)= \\
& z \times \text { entropyCross }\left(A * F^{\mathrm{T}}, V^{\mathrm{C}} * F^{\mathrm{T}}\right) \\
- & z \times \sum_{T \in F} \text { entropyCross }\left(A * \operatorname{depends}\left(F, W_{T}\right)^{\mathrm{T}}, V_{T}^{\mathrm{C}} * T\right)
\end{aligned}
$$

where $V_{T}=\operatorname{und}(T)$ and $W_{T}=\operatorname{der}(T)$.
It was also conjectured that when the specialising fud space, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)$, is minimised, (i) the derived entropy decreases up the layers, (ii) the possible derived volume decreases up the layers, (iii) the expected component entropy increases up the layers, and (iv) the component size cardinality cross entropy increases up the layers. The optimisation of a fud without a layer limit may be made computable by building the fud layer by layer, minimising the specialising space at each step, until the addition of a layer fails to reduce the
specialising space.
In some cases a history may be encoded in yet smaller space by means of a specialising fud decomposition substrate history coder if $C_{\mathrm{G}, V, \mathrm{D}, \mathrm{F}, \mathrm{H}}(D)^{\mathrm{s}}(H)<$ $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(D^{\mathrm{T}}\right)^{\mathrm{s}}(H)$, where $C_{\mathrm{G}, V, \mathrm{D}, \mathrm{F}, \mathrm{H}}(D) \in \operatorname{coders}\left(\mathcal{H}_{U, V, X}\right)$. This is because (i) a specialising fud decomposition substrate history coder allows different slices to have different fuds and (ii) complete coverage of the substrate is only required for whole paths, $\forall L \in \operatorname{paths}\left(D^{*}\right)\left(\bigcup_{(\cdot,(F,)) \in L} V_{F}=V\right)$. Therefore consider the fud decomposition minimum space specialising fud decomposition search function which is defined in terms of the expanded specialising fud decomposition history coder $C_{\mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}(D) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$,

$$
Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}(H)=\left\{\left(D,-C_{\mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}(D)^{\mathrm{s}}(H)\right): D \in \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}\right\}
$$

The limited-models summed alignment valency-density aligned non-overlapping fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, which is derived from the summed alignment valency-density decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is conjectured to be positively correlated with the fud decomposition minimum space specialising fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}$, for uniform history probability function,

```
\(\forall U \in \mathcal{U} \forall X \subset \mathcal{X}\left(\left|\mathcal{H}_{U, X}\right|<\infty \Longrightarrow\right.\)
    \(\exists \mathcal{F}_{\mathrm{q}} \subset \mathcal{F}\) (covariance \(\left(P_{U, X}\right)\)
        \(\left.\left(\operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}, \operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}\right) \geq 0\right)\) )
```

where $P_{U, X}=\mathcal{H}_{U, X} \times\left\{1 /\left|\mathcal{H}_{U, X}\right|\right\}$. However, the correlation is less than or equal to the correlation with the fud decomposition minimum space specialising derived search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$,

$$
\begin{aligned}
& \operatorname{covariance}\left(P_{U, X}\right)\left(\operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}, \operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathbf{n}, \mathrm{q}, \mathrm{Sd}}\right) \\
\leq & \operatorname{covariance}\left(P_{U, X}\right)\left(\operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}, \operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}\right)
\end{aligned}
$$

The reason for this is that the alignment search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, does not depend directly on the transforms of the fuds of the decomposition. The optimisation of the alignment search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, does not necessarily minimise the space difference, $C_{\mathrm{G}, V_{F}, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}\left(H \% V_{F}\right)-C_{\mathrm{G}, V_{F}, \mathrm{~T}, \mathrm{H}}\left(F^{\mathrm{T}}\right)^{\mathrm{s}}\left(H \%_{F}\right)$, whereas the optimisation of the fud decomposition minimum space specialising fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}$, tends to do so. For example, the alignment search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, is independent of the component cardinalities of the transforms, so the optimisation is neutral with respect to the component size cardinality cross entropies,

$$
\operatorname{entropy} \operatorname{Cross}\left(A * \operatorname{depends}\left(F, W_{T}\right)^{\mathrm{T}}, V_{T}^{\mathrm{C}} * T\right)
$$

where $T \in F$ and $F \in$ fuds $(D)$. Neither does the alignment search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, depend directly on the component sizes of the transforms except in the case of a top transform $A * \operatorname{depends}\left(F, W_{T}\right)^{\mathrm{T}}=A * F^{\mathrm{T}}$, where $W_{T}=W_{F}$. Even in this case, there is no dependency on the component cardinalities of the top transform, $\{(R,|C|):(R, C) \in T\}$. The alignment search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, does tend to maximise the component size cardinality cross entropy,

$$
\text { entropy } \operatorname{Cross}\left(A * D^{\mathrm{T}}, V^{\mathrm{C}} * D^{\mathrm{T}}\right)
$$

by decomposing high on-diagonal component sizes, but this is the component size cardinality cross entropy of the transform of the decomposition, $D^{\mathrm{T}}$, rather than the cross entropies of the transforms of the fuds of the decomposition. There is no constraint that the derived entropy and the possible derived volume decreases up the layers, nor any constraint that the expected component entropy increases up the layers. There is no sense that the fuds are built layer by layer in sequence.

The practicable highest-layer summed shuffle content alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}$, however, does impose a sequence on the search and other constraints that do not apply to the tractable summed alignment valency-density decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, corresponding to the limited-models summed alignment valency-density aligned nonoverlapping fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$. The practicable highest-layer summed shuffle content alignment valency-density fud decomposition inducer is implemented in section 'Optimisation', above, as

$$
\begin{aligned}
& I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime *}(A)= \\
& \operatorname{if}\left(Q \neq \emptyset,\left\{\left(D, I_{\operatorname{Scsd}}^{*}((A, D))\right)\right\},\left\{\left(D_{\emptyset}, 0\right)\right\}\right): \\
& \quad Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{~d}}\right)\right),\{D\}=Q
\end{aligned}
$$

Define the practicable highest-layer summed shuffle content alignment valencydensity fud decomposition search function

$$
\begin{aligned}
& Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{q}, \mathrm{~d}, P, \mathrm{Scsd}}(H)= \\
& \quad\left\{\left(D, I_{\mathrm{Scsd}}^{*}\left(\left(A_{H}, D\right)\right)\right): Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A_{H}, \mathrm{D}, \mathrm{~F}, \mathrm{~d}}\right)\right), Q \neq \emptyset,\{D\}=Q\right\} \cup \\
& \quad\left\{\left(D_{\mathrm{u}}, 0\right)\right\}
\end{aligned}
$$

Corresponding to the conjecture that the tractable limited-models summed alignment valency-density aligned non-overlapping fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, and the fud decomposition minimum space specialising
derived search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$, are positively correlated,

```
\(\forall U \in \mathcal{U} \forall X \subset \mathcal{X}\left(\left|\mathcal{H}_{U, X}\right|<\infty \Longrightarrow\right.\)
    \(\exists \mathcal{F}_{\mathrm{q}} \subset \mathcal{F}\) (covariance \(\left(P_{U, X}\right)\)
        \(\left.\left.\left(\operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}, \operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}\right) \geq 0\right)\right)\)
```

conjecture that for all finite systems and finite event identifier sets there exists a tuple of parameters such that the practicable highest-layer summed shuffle content alignment valency-density fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{q}, \mathrm{d}, P, \mathrm{Scsd}}$, is positively correlated with the fud decomposition minimum space specialising fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}$, for uniform history probability function,

$$
\begin{aligned}
& \forall U \in \mathcal{U} \forall X \subset \mathcal{X}\left(\left|\mathcal{H}_{U, X}\right|<\infty \Longrightarrow\right. \\
& \exists P \in \mathcal{L}(\mathcal{X})\left(\operatorname{covariance}\left(P_{U, X}\right)\right. \\
&\left.\left.\quad\left(\operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}, \operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{q}, \mathrm{~d}, P, \mathrm{Scsd}}\right) \geq 0\right)\right)
\end{aligned}
$$

Depending on the parameters, $P$, which imply a set of limited-models, $\mathcal{F}_{\mathrm{q}} \subset$ $\mathcal{F}$, the domain of the application of the practicable highest-layer summed shuffle content alignment valency-density fud decomposition inducer is a subset of domain of the application of the tractable summed alignment valency-density decomposition inducer, $\operatorname{dom}\left(I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime *}(A)\right) \subseteq \operatorname{dom}\left(I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)\right)$, so, in some cases, the maximum decompositions of the practicable search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{q}, \mathrm{d}, P, \mathrm{Scsd}}$, intersect with the maximum decompositions of the tractable search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$,

$$
\left|\operatorname{maxd}\left(Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{q}, \mathrm{~d}, P, \mathrm{Scsd}}(H)\right) \cap \operatorname{maxd}\left(Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)\right)\right| \geq 0
$$

and, in general, there is a high correlation

$$
\operatorname{covariance}\left(P_{U, X}\right)\left(\operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{q}, \mathrm{~d}, P, \mathrm{Scsd}}, \operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}\right)
$$

So the relationships between the properties of the fud decomposition minimum space specialising derived search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$, and the properties of the tractable search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, in the discussion above, also tend to hold for the relationships between the properties of the minimum space search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$, and the properties of the practicable search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{q}, \mathrm{d}, P, \mathrm{Scsd}}$.

In the case of the practicable search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{q}, \mathrm{d}, P, \mathrm{Scsd}}$, however, the fuds of the decomposition are built layer by layer,

$$
\forall(i, G) \in L(\operatorname{layer}(G, \operatorname{der}(G))=i)
$$

where $\{L\}=\operatorname{paths}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{~d}}\right)\right)$ and the highest-layer limited-layer limitedunderlying limited-breadth fud tree searcher is

$$
Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{~d}}=\operatorname{searchTreer}\left(\mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}, P_{P, A, A_{R}, \mathrm{~L}, \mathrm{~d}},\{\emptyset\}\right)
$$

So the properties of the fuds of the decomposition also depend on layer. In particular the highest-layer fud tree searcher, $Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{~d}}$, is constrained such that the shuffle content alignment valency-density of the derived variables set increases in each layer. Let the cumulative fud $F_{\{1 \ldots i\}}=\bigcup_{j \in\{1 \ldots i\}} F_{j}$, where $F_{i}=\{T: T \in F$, layer $(F, \operatorname{der}(T))=i\}$. Then consecutive fuds, $F_{\{1 \ldots i\}}$ and $F_{\{1 \ldots i+1\}}$ are in the path,

$$
\left\{\left(i, F_{\{1 \ldots i\}}\right),\left(i+1, F_{\{1 \ldots i+1\}}\right)\right\} \subseteq L
$$

where $F=L_{l}$ and $l=|L|$. The highest-layer limited-layer limited-underlying limited-breadth fud tree searcher neighbourhood function is defined

$$
\begin{aligned}
& P_{P, A, A_{R}, \mathrm{~L}, \mathrm{~d}}(F)=\{G: \\
& \quad G \in P_{P, A, A A_{R}, \mathrm{~L}}(F) \\
& \left.\quad\left(F \neq \emptyset \Longrightarrow \operatorname{maxr}\left(\mathrm{el}\left(Z_{P, A, A_{R}, F, \mathrm{D}, \mathrm{~d}}\right)\right)<\operatorname{maxr}\left(\mathrm{el}\left(Z_{P, A, A_{R}, G, \mathrm{D}, \mathrm{~d}}\right)\right)\right)\right\}
\end{aligned}
$$

where the highest-layer limited-derived derived variables set list maximiser is $Z_{P, A, A_{R}, F, \mathrm{D}, \mathrm{d}}=\operatorname{maximiseLister}\left(X_{P, A, A_{R}, F, \mathrm{D}}, P_{P, A, A_{R}, F, \mathrm{D}}, \operatorname{top}(\operatorname{omax}), R_{P, A, A_{R}, F, \mathrm{D}, \mathrm{d}}\right)$
so the neighbouring layers are such that

$$
\operatorname{maxr}\left(\operatorname{el}\left(Z_{P, A, A_{R}, F_{\{1 \ldots i\}}, \mathrm{D}, \mathrm{~d}}\right)\right)<\operatorname{maxr}\left(\operatorname{el}\left(Z_{P, A, A_{R}, F_{\{1 \ldots i+1\}}, \mathrm{D}, \mathrm{~d}}\right)\right)
$$

Let the layer derived variables set $J_{i}$ found by the highest-layer derived variables set list maximiser be

$$
J_{i} \in \operatorname{maxd}\left(\operatorname{el}\left(Z_{P, A, A_{R}, F_{\{1 \ldots, i\}}, \mathrm{D}, \mathrm{~d}}\right)\right)
$$

The layer derived variables set is such that $J_{i} \subseteq \operatorname{vars}\left(F_{\{1 \ldots i\}}\right) \backslash V$. The layer derived variables set, $J_{i}$, is not necessarily equal to the derived variables of the whole layer, $\operatorname{der}\left(F_{\{1 \ldots i\}}\right)$, but there must be an intersection, $J_{i} \cap \operatorname{der}\left(F_{\{1 \ldots i\}}\right) \neq$ $\emptyset$. The shuffle content alignment valency-density of the derived variables set of a layer is $X_{P, A, A_{R}, F_{\{1 \ldots i\}}, \mathrm{D}}\left(J_{i}\right)=\operatorname{maxr}\left(\mathrm{el}\left(Z_{P, A, A_{R}, F_{\{1 \ldots i\}}, \mathrm{D}, \mathrm{d}}\right)\right)$ where the limited-derived derived variables set list maximiser optimiser function is

$$
\begin{aligned}
& X_{P, A, A_{R}, F, \mathrm{D}}=\left\{\left(K, I_{\mathrm{csd}}^{*}\left(\left(A, A_{R}, G\right)\right)\right):\right. \\
&K \subseteq \operatorname{vars}(F), K \neq \emptyset, G=\operatorname{depends}(F, K)\}
\end{aligned}
$$

the shuffle content alignment valency-density computer is

$$
I_{\mathrm{csd}}^{*}\left(\left(A, A_{R}, F\right)\right)=\left(I_{\mathrm{a}}^{*}\left(A * F^{\mathrm{T}}\right)-I_{\mathrm{a}}^{*}\left(A_{R} * F^{\mathrm{T}}\right)\right) / I_{\mathrm{cvl}}^{*}(F)
$$

and the valency capacity computer is

$$
I_{\mathrm{cvl}}^{*}(F):=\left(I_{\approx \mathrm{pow}}^{*}((w, 1 / m)): W=\operatorname{der}(F), w=\left|W^{\mathrm{C}}\right|, m=|W|\right)
$$

The layer derived variables set, $J_{i}$, intersects with the derived variables of the whole layer, $\operatorname{der}\left(F_{\{1 \ldots i\}}\right)$, so the shuffle content alignment valency-density varies with the derived entropy

$$
\begin{aligned}
X_{P, A, A_{R}, F_{\{1 \ldots i\}}, \mathrm{D}}\left(J_{i}\right) & \sim \operatorname{algn}\left(A * \operatorname{depends}\left(F_{\{1 \ldots i\}}, J_{i}\right)^{\mathrm{T}}\right) \\
& \sim-z \times \operatorname{entropy}\left(A * \operatorname{depends}\left(F_{\{1 \ldots i\}}, J_{i}\right)^{\mathrm{T}}\right) \\
& \sim-z \times \operatorname{entropy}\left(A * F_{\{1 \ldots i\}}^{\mathrm{T}}\right)
\end{aligned}
$$

The shuffle content alignment valency-density of the derived variables set increases in each layer,

$$
X_{P, A, A_{R}, F_{\{1 \ldots i\}}, \mathrm{D}}\left(J_{i}\right)<X_{P, A, A_{R}, F_{\{1 \ldots i+1\}}, \mathrm{D}}\left(J_{i+1}\right)
$$

so, in general, the derived entropy decreases up the layers,

$$
\forall i \in\{2 \ldots l\}\left(\operatorname{entropy}\left(A * F_{\{1 \ldots i\}}^{\mathrm{T}}\right)<\operatorname{entropy}\left(A * F_{\{1 \ldots i-1\}}^{\mathrm{T}}\right)\right)
$$

which is a property of the specialising fud substrate history coder, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)$, and hence a property of the specialising fud decomposition substrate history coder, $C_{\mathrm{G}, V, \mathrm{D}, \mathrm{F}, \mathrm{H}}\left(D^{V}\right)$.

Note that it is the shuffle content alignment valency-density that is maximised, rather than the shuffle content alignment. The shuffle content alignment valency-density varies against the derived volume,

$$
\begin{aligned}
X_{P, A, A_{R}, F_{\{1 \ldots i\}}, \mathrm{D}}\left(J_{i}\right) & \sim 1 /\left|J_{i}^{\mathrm{C}}\right|^{1 /\left|J_{i}\right|} \\
& \sim 1 /\left|J_{i}^{\mathrm{C}}\right|
\end{aligned}
$$

and so, in general, the derived volume decreases up the layers,

$$
\forall i \in\{2 \ldots l\}\left(\left|W_{i}^{\mathrm{C}}\right|<\left|W_{i-1}^{\mathrm{C}}\right|\right)
$$

where $W_{i}=\operatorname{der}\left(G_{i}\right), G=\operatorname{depends}\left(F_{\mathrm{L}}, K\right), K \in \operatorname{maxd}\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F_{\mathrm{L}}, \mathrm{D}, \mathrm{d}}\right)\right)$ and $\left\{F_{\mathrm{L}}\right\}=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{~d}}\right)\right)$.

That is, the derived entropy and the derived volume tend to decrease up the layers of the fuds of the decompositions in both the practicable highestlayer summed shuffle content alignment valency-density fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{q}, \mathrm{d}, P, \mathrm{Scsd}}$, and the fud decomposition minimum space specialising fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}$.

Another correlation that is a consequence of the layer by layer search in the highest-layer limited-layer limited-underlying limited-breadth fud tree searcher, $Z_{P, A, A_{R}, \mathrm{~L}, \mathrm{~d}}$, arises in the contracted decrementing linear non-overlapping fuds list maximiser,

$$
\begin{aligned}
& Z_{P, A, A_{R}, F, \mathrm{n},-, K}= \\
& \quad \text { maximiseLister }\left(X_{P, A, A_{R}, F, \mathbf{n},-, K}, N_{P, A, A_{R}, F, \mathbf{n},-, K}, \operatorname{top}(\operatorname{pmax}), R_{P, A, A_{R}, F, \mathrm{n},-, K}\right)
\end{aligned}
$$

which value rolls a tuple, $K$, from the limited-underlying tuple set list maximiser, $Z_{P, A, A_{R}, F, \mathrm{~B}}$, in the limited-layer limited-underlying limited-breadth fud tree searcher neighbourhood function,

$$
\begin{aligned}
& P_{P, A, A_{R}, \mathrm{~L}}(F)=\{G: \\
& G=F \cup\left\{T: K \in \operatorname{topd}(\lfloor\operatorname{bmax} / \operatorname{mmax}\rfloor)\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{~B}}\right)\right),\right. \\
& H \in \operatorname{topd}(\operatorname{pmax})\left(\operatorname{elements}\left(Z_{P, A, A_{R}, F, \mathrm{n},-, K}\right)\right), \\
&\left.w \in \operatorname{der}(H), I=\operatorname{depends}(\operatorname{explode}(H),\{w\}), T=I^{\mathrm{TPT}}\right\}, \\
&\operatorname{layer}(G, \operatorname{der}(G)) \leq \operatorname{lmax}\}
\end{aligned}
$$

The contracted decrementing linear non-overlapping fuds list maximiser optimiser function is

$$
\left.\left.\begin{array}{rl}
X_{P, A, A_{R}, F, \mathrm{n},-, K}=\{ & (
\end{array}\right) I_{\text {csd }}^{*}\left(\left(A, A_{R}, G\right)\right)\right): \quad \begin{aligned}
& \\
&\left.H \in \mathcal{F}_{U_{A}, \mathrm{n},-,-K, \overline{\mathrm{~b}}, \mathrm{mmax}, \overline{2}}, G=\operatorname{depends}(F \cup H, \operatorname{der}(H))\right\}
\end{aligned}
$$

The contracted decrementing linear non-overlapping fuds list maximiser initial subset,

$$
\begin{aligned}
& R_{P, A, A_{R}, F, \mathrm{n},-, K}=\left\{\left(\left\{M^{\mathrm{T}}\right\}, X_{P, A, A_{R}, F, \mathrm{n},-, K}\left(\left\{M^{\mathrm{T}}\right\}\right)\right):\right. \\
& \left.\quad Y \in \mathrm{~B}(K), 2 \leq|Y| \leq \operatorname{mmax}, M=\left\{J^{\mathrm{CS}\{ \}}: J \in Y\right\}\right\}
\end{aligned}
$$

partitions the tuple, $Y \in \mathrm{~B}(K)$, maximising the shuffle content alignment valency-density, $X_{P, A, A_{R}, F, \mathrm{n},-, K}\left(G_{Y}\right)$, of the fud of self transforms on the components of the tuple partition, $G_{Y}=\left\{J^{\mathrm{CS}\{ \} \mathrm{T}}: J \in Y\right\}$. The maximisation of the derived alignment between the derived variables of the components, $\operatorname{algn}\left(A_{F} * G_{Y}^{\mathrm{T}}\right)$, where $A_{F}=A * \prod_{(X, \cdot) \in F} X$, tends to minimise the underlying
alignments within the components, $\sum_{J \in Y} \operatorname{algn}\left(A_{F} \% J\right)$. So in some cases the intra-component alignments are less than the inter-component alignments, $\operatorname{algn}\left(A_{F} \%\left\{v_{1}, v_{2}\right\}\right)<\operatorname{algn}\left(A_{F} \%\left\{v_{1}, v_{3}\right\}\right)$, where $v_{1}, v_{2} \in J$ and $v_{3} \in K \backslash J$.

The fud, $H$, resulting from the contracted decrementing linear non-overlapping fuds list maximiser, $Z_{P, A, A_{R}, F, \mathrm{n},-, K}$, is value rolled from the fud, $G_{Y}$, of self transforms, partitioning the underlying histogram, $A_{F} \% K$. Conjecture that alignments of the components of this partition vary against the derived alignment,

$$
\sum_{(\cdot, C) \in\left(H^{\mathrm{T}}\right)^{-1}} \operatorname{algn}\left(A_{F} \% K * C\right) \sim-\operatorname{algn}\left(A_{F} * H^{\mathrm{T}}\right)
$$

Then the fud, $H$, is exploded into a fud of transforms each corresponding to a component of the tuple partition. Let $w \in \operatorname{der}(H)$ correspond to the component $J$. Then $\operatorname{der}(T)=\{w\}$ and $\operatorname{und}(T)=J$, where $T=$ depends(explode $(H),\{w\})^{\mathrm{TPT}}$. The layer, $F_{i}$, is the set of these transforms, $F_{\{1 \ldots i\}}=P_{P, A, A_{R}, \mathrm{~L}}\left(F_{\{1 \ldots i-1\}}\right)$. The differential between the intra-component alignments and the inter-component alignments in each layer implies that the layer derived entropy varies against the layer expected component entropy,

$$
\begin{aligned}
z & \times \operatorname{entropy}\left(A * F_{\{1 \ldots i\}}^{\mathrm{T}}\right) \\
& \sim-\operatorname{algn}\left(A * F_{\{1 \ldots i\}}^{\mathrm{T}}\right) \\
& \sim \sum_{T \in F_{i}} \sum_{(\cdot, C) \in T^{-1}} \operatorname{algn}\left(A * F_{\{1 . . .-1\}}^{\mathrm{T}} \% V_{T} * C\right) \\
& \sim-\sum_{T \in F_{i}} \sum_{(R, C) \in T^{-1}}\left(A * F_{\{1 \ldots i-1\}}^{\mathrm{T}} * T\right)_{R} \times \operatorname{entropy}\left(A * F_{\{1 \ldots i-1\}}^{\mathrm{T}} \% V_{T} * C\right) \\
& \sim-\sum_{(R, C) \in\left(F_{i}^{\mathrm{T}}\right)^{-1}}\left(A * F_{\{1 \ldots i\}}^{\mathrm{T}}\right)_{R} \times \operatorname{entropy}\left(A * F_{\{1 \ldots i-1\}}^{\mathrm{T}} * C\right) \\
& =-\operatorname{entropyComponent}\left(A * F_{\{1 \ldots i-1\}}^{\mathrm{T}}, F_{i}^{\mathrm{T}}\right)
\end{aligned}
$$

It has already been shown that, in general, the derived entropy decreases up the layers,

$$
\forall i \in\{2 \ldots l\}\left(\operatorname{entropy}\left(A * F_{\{1 . . i\}}^{\mathrm{T}}\right)<\operatorname{entropy}\left(A * F_{\{1 \ldots i-1\}}^{\mathrm{T}}\right)\right)
$$

so, in general, the expected component entropy increases up the layers,

$$
\begin{aligned}
& \forall i \in\{2 \ldots l\} \\
& \quad\left(\operatorname{entropyComponent}\left(A, F_{\{1 \ldots i\}}^{\mathrm{T}}\right)>\operatorname{entropyComponent}\left(A, F_{\{1 \ldots i-1\}}^{\mathrm{T}}\right)\right)
\end{aligned}
$$

because the layer derived entropy varies against the layer expected component entropy. Again, this is a property of the specialising fud substrate history coder, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)$, and hence a property of the specialising fud decomposition substrate history coder, $C_{\mathrm{G}, V, \mathrm{D}, \mathrm{F}, \mathrm{H}}\left(D^{V}\right)$. That is, the expected component entropy tends to increase up the layers of the fuds of the decompositions in both the practicable highest-layer summed shuffle content alignment valencydensity fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{q}, \mathrm{d}, P, \mathrm{Scsd}}$, and the fud decomposition minimum space specialising fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}$.

Although the alignments within the tuple components tend to be less than the alignments between components, $\operatorname{algn}\left(A_{F} \%\left\{v_{1}, v_{2}\right\}\right)<\operatorname{algn}\left(A_{F} \%\left\{v_{1}, v_{3}\right\}\right)$, the tuple is found in the limited-underlying tuple set list maximiser, $Z_{P, A, A_{R}, F, \mathrm{~B}}$, by maximising the shuffle content alignment of the whole tuple, $X_{P, A, A_{R}, F, \mathrm{~B}}(K) \sim$ $\operatorname{algn}\left(A_{F} \% K\right)$. So the intra-component alignments are only small relative to the inter-component alignments and are not necessarily small absolutely, $\operatorname{algn}\left(A_{F} \% J\right) \geq 0$.

The last property of the specialising fud substrate history coder, $C_{G, V, F, H}(F)$, to be considered is the increase of the component size cardinality cross entropy up the layers. This also arises in the contracted decrementing linear nonoverlapping fuds list maximiser, $Z_{P, A, A_{R}, F, \mathrm{n},-, K}$. If the component histogram, $A_{F} \% J$, where $J \in Y$ and $Y \in \mathrm{~B}(K)$, is not uniform, $\left|\operatorname{ran}\left(A_{F} \% J\right)\right| \neq 1$, which is the case if component histogram is not independent, $\operatorname{algn}\left(A_{F} \% J\right)>0$, then the initial self transform, $J^{\mathrm{CS}\{ \} \mathrm{T}}$, of the component histogram has non-zero component size cardinality cross entropy,

$$
\begin{aligned}
\operatorname{entropyCross}\left(A_{F} * J^{\mathrm{CS}\{ \} \mathrm{T}}, J^{\mathrm{C}} * J^{\mathrm{CS}\{ \} \mathrm{T}}\right) & =-\sum_{S \in\left(A_{F} \% J\right)^{\mathrm{FS}}}\left(\hat{A}_{F} \% J\right)_{s} \ln \frac{1}{\left|J^{\mathrm{C}}\right|} \\
& >0
\end{aligned}
$$

This is because the component cardinalities within the layer, $\{|C|:(\cdot, C) \in$ $\left.\left(J^{\mathrm{CS}\{ \} \mathrm{T}}\right)^{-1}\right\}=\{1\}$, are uniform, but the component sizes are not, $\mid\left\{\operatorname{size}\left(A_{F} *\right.\right.$ $\left.C):(\cdot, C) \in\left(J^{\mathrm{CS}\{ \} \mathrm{T}}\right)^{-1}\right\} \mid>1$.

The decrementing fuds maximiser, $Z_{P, A, A_{R}, F, \mathbf{n},-, K}$, value rolls one value in each step, so the largest counts of the component histogram, $A_{F} \% J$, tend to roll together at the beginning of the derived diagonal. The diagonal is constructed approximately in a sequence tending to minimise component cardinalities at the beginning of the diagonal and maximise component cardinalities at the end of the diagonal and off-diagonal. Maximisation of the derived
alignment tends to uniform counts along the diagonal. Thus the component size cardinality cross entropy increases as the diagonal shortens below the volume of a component histogram, $\left|W^{\mathrm{C}}\right|^{1 /|W|}<\left|J^{\mathrm{C}}\right|$, where $W=\operatorname{der}(H)$. Conjecture that component size cardinality cross entropy varies with the derived alignment valency-density,

$$
\begin{aligned}
z \times \operatorname{entropyCross}\left(A_{F} * H^{\mathrm{T}}, K^{\mathrm{C}} * H^{\mathrm{T}}\right) & =-\sum_{(R, C) \in\left(H^{\mathrm{T}}\right)^{-1}}\left(A_{F} * H^{\mathrm{T}}\right)_{R} \ln \frac{|C|}{\left|K^{\mathrm{C}}\right|} \\
& \sim \operatorname{algn}\left(A_{F} * H^{\mathrm{T}}\right) /\left|W^{\mathrm{C}}\right|^{1 /|W|}
\end{aligned}
$$

So the layer derived entropy varies against the layer component size cardinality cross entropy,

$$
\begin{aligned}
z & \times \operatorname{entropy}\left(A * F_{\{1 \ldots i\}}^{\mathrm{T}}\right) \\
& \sim-\operatorname{algn}\left(A * F_{\{1 \ldots i\}}^{\mathrm{T}}\right) \\
& \sim-\left(-\frac{1}{\left|F_{i}\right|} \sum_{T \in F_{i}} \sum_{(R, C) \in T^{-1}}\left(A * F_{\{1 \ldots i-1\}}^{\mathrm{T}} * T\right)_{R} \ln \frac{|C|}{\left|V_{T}^{\mathrm{C}}\right|}\right) \\
& \sim-\left(-\sum_{(R, C) \in\left(F_{i}^{\mathrm{T}}\right)^{-1}}\left(A * F_{\{1 \ldots i\}}^{\mathrm{T}}\right)_{R} \ln \frac{|C|}{\left|V_{i}^{\mathrm{C}}\right|}\right) \\
& \sim-z \times \operatorname{entropyCross}\left(A * F_{\{1 \ldots i\}}^{\mathrm{T}}, V_{i}^{\mathrm{C}} * F_{i}^{\mathrm{T}}\right)
\end{aligned}
$$

It has already been shown that, in general, the derived entropy decreases up the layers,

$$
\forall i \in\{2 \ldots l\}\left(\operatorname{entropy}\left(A * F_{\{1 \ldots i\}}^{\mathrm{T}}\right)<\operatorname{entropy}\left(A * F_{\{1 \ldots i-1\}}^{\mathrm{T}}\right)\right)
$$

so, in general, the component size cardinality cross entropy increases up the layers,

$$
\begin{aligned}
& \forall i \in\{2 \ldots l\} \\
& \quad\left(\text { entropy } \operatorname{Cross}\left(A * F_{\{1 \ldots i\}}^{\mathrm{T}}, V^{\mathrm{C}} * F_{\{1 \ldots i\}}^{\mathrm{T}}\right)>\right. \\
& \left.\quad \quad \text { entropyCross }\left(A * F_{\{1 \ldots i-1\}}^{\mathrm{T}}, V^{\mathrm{C}} * F_{\{1 \ldots i-1\}}^{\mathrm{T}}\right)\right)
\end{aligned}
$$

because the layer derived entropy varies against the layer component size cardinality cross entropy. Again, this is a property of the specialising fud substrate history coder, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)$, and hence a property of the specialising fud decomposition substrate history coder, $C_{\mathrm{G}, V, \mathrm{D}, \mathrm{F}, \mathrm{H}}\left(D^{V}\right)$. That is, the component size cardinality cross entropy tends to increase up the layers of
the fuds of the decompositions in both the practicable highest-layer summed shuffle content alignment valency-density fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{q}, \mathrm{d}, P, \mathrm{Scsd}}$, and the fud decomposition minimum space specialising fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}$.

As well as retaining much of the correlation with the fud decomposition minimum space specialising derived search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$, via the tractable search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, the practicable highest-layer summed shuffle content alignment valency-density fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{q}, \mathrm{d}, P, \mathrm{Scs}}$, is additionally correlated with the fud decomposition minimum space specialising fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}$. This is the case even though the additional constraints implemented in the practicable highest-layer summed shuffle content alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Scs}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}$, were imposed purely for practicable reasons.

The comparisons above between the properties of the fud decomposition minimum space specialising fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}$, and the practicable highest-layer summed shuffle content alignment valencydensity fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{q}, \mathrm{d}, P, \mathrm{Scsd}}$, provide evidence for the conjecture that the search functions are positively correlated for uniform history probability function,

$$
\begin{aligned}
& \forall U \in \mathcal{U} \forall X \subset \mathcal{X}\left(\left|\mathcal{H}_{U, X}\right|<\infty \Longrightarrow\right. \\
& \quad \exists P \in \mathcal{L}(\mathcal{X})\left(\operatorname{covariance}\left(P_{U, X}\right)\right. \\
& \left.\left.\quad\left(\operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}, \operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{q}, \mathrm{~d}, P, \mathrm{Scsd}}\right) \geq 0\right)\right)
\end{aligned}
$$

### 5.2 Artificial neural networks and Compression

The discussion above compares (i) the properties of the tractable and practicable alignment inducers to (ii) the properties of the specialising derived history coder and the specialising fud decomposition history coder. Now consider how artificial neural networks relate to the specialising fud history coder.

The fud minimum space specialising fud search function for history $H \in \mathcal{H}_{U, X}$ is defined in terms of the expanded specialising fud history coder, $C_{\mathrm{G}, \mathrm{F}, \mathrm{H}}(F) \in$ $\operatorname{coders}\left(\mathcal{H}_{U, X}\right)$, as

$$
Z_{\mathrm{F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{~F}, \mathrm{H}}(H)=\left\{\left(F,-C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)\right): F \in \mathcal{F}_{U, \mathrm{P}}\right\}
$$

To construct a search function for a neural network, first consider how a neuron may be represented in a transform. Section 'Transforms', above, has
an example of a transform defined by a real valued function that represents a perceptron, $T=\left(V, w, f_{\sigma}(Q)\right)$, where the dimension is $n=|V|$ and the function $f_{\sigma}(Q) \in \mathbf{R}^{n}: \rightarrow \mathbf{R}$ is parameterised by (i) some differentiable function $\sigma \in \mathbf{R}: \rightarrow \mathbf{R}$, called the activation function, and (ii) a vector of weights, $Q \in \mathbf{R}^{n+1}$, and is defined

$$
f_{\sigma}(Q)(S):=\sigma\left(\sum_{i \in\{1 \ldots n\}} Q_{i} S_{i}+Q_{n+1}\right)
$$

Usually the activation function is such that it has a positive gradient everywhere, $\forall x \in \mathbf{R}(\mathrm{~d}(\sigma)(x) \geq 0)$, where $\mathrm{d} \in(\mathbf{R} \rightarrow \mathbf{R}) \rightarrow(\mathbf{R} \rightarrow \mathbf{R})$ is defined $\mathrm{d}(F):=\{(x, d F(x) / d x): x \in \operatorname{dom}(F)\}$.

The function composition of artificial neural networks may be represented by fuds of these transforms. Define nets as a subset of the set of lists of tuples of the graph and real weights,

$$
\text { nets }:=\{G: G \in \mathcal{L}(\mathrm{P}(\mathcal{V}) \times \mathcal{V} \times \mathcal{L}(\mathbf{R})), \forall(\cdot,(V, \cdot, Q)) \in G(|Q|=|V|+1)\}
$$

Define the graph, graph $\in$ nets $\rightarrow \mathcal{L}(\mathrm{P}(\mathcal{V}) \times \mathcal{V})$ as

$$
\operatorname{graph}(G):=\{(i,(V, w)):(i,(V, w, \cdot)) \in G\}
$$

Define the real weights, weights $\in$ nets $\rightarrow \mathcal{L}(\mathbf{R})$ as

$$
\operatorname{weights}(G):=\operatorname{concat}(\{(i, Q):(i,(\cdot, \cdot, Q)) \in G\})
$$

Define the set of transforms, $\operatorname{fud}(\sigma) \in$ nets $\rightarrow \mathrm{P}\left(\mathcal{T}_{f}\right)$ as

$$
\begin{aligned}
& \text { fud }(\sigma)(G):= \\
& \qquad \begin{array}{l}
\left\{\left(\left\{S^{V} \cup\left\{\left(w, \sigma\left(\sum_{i \in\{1 \ldots n\}} Q_{i} S_{i}+Q_{n+1}\right)\right)\right\}: S \in \mathbf{R}^{n}\right\} \times\{1\},\{w\}\right):\right. \\
\\
\quad(\cdot,(V, w, Q)) \in G, n=|V|\}
\end{array}
\end{aligned}
$$

The construction of a coordinate from a state is defined ()$^{[]} \in \mathcal{S} \rightarrow \mathcal{L}(\mathcal{W})$ as

$$
S^{\square}:=\left\{(i, u):((v, u), i) \in \operatorname{order}\left(D_{\mathcal{V} \times \mathcal{W}}, S\right)\right\}
$$

where $D_{\mathcal{V} \times \mathcal{W}}$ is an order on the variables and values. The converse function to construct a state from a coordinate ()$^{V} \in \mathcal{L}(\mathcal{W}) \rightarrow \mathcal{S}$ is

$$
S^{V}:=\left\{\left(v, S_{i}\right):(v, i) \in \operatorname{order}\left(D_{\mathcal{V}}, V\right)\right\}
$$

Let the neural net substrate fud set $\mathcal{F}_{\infty, U, V, \sigma}$ be a subset of the infinite-layer substrate fud set, $\mathcal{F}_{\infty, U, V, \sigma}=\mathcal{F}_{\infty, U, V} \cap(\operatorname{fud}(\sigma) \circ$ nets $)$.

An example of a neural net substrate fud $F \in \mathcal{F}_{\infty, U, V, \sigma}$ has $l=\operatorname{layer}(F, \operatorname{der}(F))$ layers of fixed breadth equal to the underlying dimension, $\forall i \in\{1 \ldots l\}\left(\left|F_{i}\right|=\right.$ $n$ ) where $n=|V|$ and $F_{i}=\{T: T \in F, \operatorname{layer}(F, \operatorname{der}(T))=i\}$, such that the underlying of each transform is the derived of the layer below, $\forall T \in F_{1}(\operatorname{und}(T)=V)$ and $\forall i \in\{2 \ldots l\} \forall T \in F_{i}\left(\operatorname{und}(T)=\operatorname{der}\left(F_{i-1}\right)\right)$.

The optimisation of artificial neural networks can be divided into unsupervised and supervised types. In the supervised case there is additional knowledge. First, there exists an unknown distribution histogram $E$ from which the known sample histogram, $A$, is drawn, $A<E$. Secondly, the substrate can be partitioned into query variables $K \subset V$ and label variables, $V \backslash K$, such that the distribution histogram, $E$, is causal between the query variables and the label variables,

$$
\operatorname{split}\left(K, E^{\mathrm{FS}}\right) \in K^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}
$$

and so the sample histogram, $A$, is also causal,

$$
\operatorname{split}\left(K, A^{\mathrm{FS}}\right) \in K^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}
$$

That is, in the supervised case, there is a functional relation such that there is exactly one label state for every effective query state. In an optimisation, a fud $F \in \mathcal{F}_{\infty, U, K, \sigma}$ has its underlying variables restricted to the query variables, und $(F) \subseteq K$. The optimisation maximises the causality between the derived variables and the label variables by minimising some cost or loss function. At the optimum there is no error and the relation is functional,

$$
\operatorname{split}\left(W_{F},\left(A * X_{F} \%\left(W_{F} \cup V \backslash K\right)\right)^{\mathrm{FS}}\right) \in W_{F}^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}
$$

where $X_{F}=\operatorname{histogram}\left(F^{\mathrm{T}}\right)$ and $W_{F}=\operatorname{der}(F)$. In some cases the choice of optimisation parameters, such as the graph or the definition of the loss function, is such that, when optimal, (i) the model is causal from the derived variables to the label variables, and (ii) a query application via model is equal to a query application on the unknown distribution histogram,

$$
\forall Q \in(E \% K)^{\mathrm{F}\{ \}}\left(\left(Q * F^{\mathrm{T}} * X_{F} * A\right)^{\wedge} \%(V \backslash K)=Q * E^{\mathrm{F}} \%(V \backslash K)\right)
$$

That is, even in the case where the sample is ineffective with respect to the query, $Q^{\mathrm{F}} \not \leq A^{\mathrm{F}}$, if the model is not over-fitted, $\left(Q * F^{\mathrm{T}}\right)^{\mathrm{F}} \leq\left(A * F^{\mathrm{T}}\right)^{\mathrm{F}}$, then an estimate of the query application, $Q * E^{\mathrm{F}} \%(V \backslash K)$, may sometimes be made.

Note that there are some cases where no set of optimisation parameters can
avoid an over-fitted model. For example, if the sample reduced to the query variables is independent, $A \% K=(A \% K)^{\mathrm{X}}$, but the distribution histogram is not, $E \% K \neq(E \% K)^{\mathrm{X}}$, then the self-transform obtained from the optimisation will be over-fitted, $Q^{\mathrm{F}} \not \leq A^{\mathrm{F}} \Longrightarrow\left(Q * K^{\mathrm{CS}\{ \} \mathrm{T}}\right)^{\mathrm{F}} \not \leq\left(A * K^{\mathrm{CS}\{ \} \mathrm{T}}\right)^{\mathrm{F}}$.

There are various candidates for the loss function. Given a sample histogram $A$, a functional definition set $F$, and a set of query variables $K$, the label entropy loss function lent $\in \mathcal{A} \times \mathcal{F} \times \mathrm{P}(\mathcal{V}) \rightarrow \mathbf{R}$ is

$$
\operatorname{lent}(A, F, K):=\sum_{(R, C) \in\left(F^{\mathrm{T}}\right)^{-1}}\left(A * F^{\mathrm{T}}\right)_{R} \times \operatorname{entropy}(A * C \%(V \backslash K))
$$

where $V=\operatorname{vars}(A)$. It is not obvious, however, if the derivative of the label entropy function with respect to an underlying neural net weight has an analytic solution. Given $D \subset \mathbf{R}$, a numeric approximation to a discretised fud transform, $\left(V, w, \operatorname{discrete}(D, n)\left(f_{\sigma}(Q)\right)\right)$ where $\left(V, w, f_{\sigma}(Q)\right)=F^{\mathrm{T}}$, can be defined, but its computation may be intractable.

In the case where the derived variables of the fud is a literal frame of the label variables, $W_{F}: \leftrightarrow:(V \backslash K)$ and $\forall v \in(V \backslash K)\left(U_{v} \subseteq \mathbf{R}\right)$, the least squares loss function lsq $\in \mathcal{A} \times \mathcal{F} \times \mathrm{P}(\mathcal{V}) \rightarrow \mathbf{R}$ is

$$
\operatorname{lsq}(A, F, K):=\sum_{(S, c) \in A * X_{F}}\left(c \times \sum_{i \in\{1 \ldots m\}}\left(\left(S \% W_{F}\right)_{i}^{\square}-(S \%(V \backslash K))_{i}^{\square}\right)^{2}\right)
$$

where $m=\left|W_{F}\right|=|(V \backslash K)|$. Let $\operatorname{lsq}(\sigma) \in \mathcal{A} \times$ nets $\times \mathrm{P}(\mathcal{V}) \rightarrow \mathbf{R}$ be

$$
\operatorname{lsq}(\sigma)(A, G, K):=\operatorname{lsq}(A, \operatorname{fud}(\sigma)(G), K)
$$

and its derivative with respect to the $i$-th weight $\operatorname{dlsq}(\sigma)(i) \in \mathcal{A} \times$ nets $\times$ $\mathrm{P}(\mathcal{V}) \rightarrow(\mathcal{L}(\mathbf{R}) \rightarrow \mathbf{R})$ be

$$
\begin{aligned}
& \operatorname{dlsq}(\sigma)(i)(A, G, K):= \\
& \quad \partial_{i}\left(\left\{\left(\operatorname{weights}\left(G^{\prime}\right), \operatorname{lsq}(\sigma)\left(A, G^{\prime}, K\right)\right): G^{\prime} \in \operatorname{nets}, \operatorname{graph}\left(G^{\prime}\right)=\operatorname{graph}(G)\right\}\right)
\end{aligned}
$$

where $\partial_{j} \in(\mathcal{L}(\mathbf{R}) \rightarrow \mathbf{R}) \rightarrow(\mathcal{L}(\mathbf{R}) \rightarrow \mathbf{R})$ is defined $\partial_{j}(F):=\left\{\left(Z, \partial F(Z) / \partial Z_{j}\right):\right.$ $Z \in \operatorname{dom}(F)\}$.

Typically the label variables form a bivalent crown, $\operatorname{crown}(A \%(V \backslash K))$ where $\forall v \in(V \backslash K)\left(U_{v}=\{0,1\}\right)$, with each label variable corresponding to a label value. When the loss is zero, a query via the model need not compute the component,

$$
\forall Q \in(E \% K)^{\mathrm{F}\{ \}}\left(\operatorname{reframe}\left(Y, Q * F^{\mathrm{T}}\right)=Q * E^{\mathrm{F}} \%(V \backslash K)\right)
$$

where the frame mapping is $Y=\left\{\left(L_{W_{F}}(i), L_{V \backslash K}(i)\right): i \in\{1 \ldots m\}\right\} \in$ $W_{F}: \leftrightarrow:(V \backslash K)$ and $L_{W}=\operatorname{flip}\left(\operatorname{order}\left(D_{\mathcal{V}}, W\right)\right)$.

Define the substrate net set as nets $(U, V, \sigma)=\{G: G \in \operatorname{nets}, \operatorname{fud}(\sigma)(G) \in$ $\left.\mathcal{F}_{\infty, U, V}\right\}$, which is such that $\mathcal{F}_{\infty, U, V, \sigma}=\operatorname{fud}(\sigma) \circ \operatorname{nets}(U, V, \sigma)$.

Given a loss function, a search function for a neural network can be defined using the method of gradient descent. Let $P \in \mathcal{L}(\mathcal{X})$ be a list of search parameters. Let the activation function, system and query variables be defined in the search parameters, $\sigma, U, K \in \operatorname{set}(P)$. Let initial substrate net $G_{R} \in \operatorname{nets}(U, K, \sigma)$ have (a) graph $\operatorname{graph}\left(G_{R}\right) \in \operatorname{set}(P)$ and (b) arbitrary weights $R \in \mathcal{L}(\mathbf{R})$ where $R=$ weights $\left(G_{R}\right) \in \operatorname{set}(P)$. Given a histogram A of variables $V$ in system $U$ such that (i) the variables are real valued, $\forall v \in V\left(U_{v} \subseteq \mathbf{R}\right)$, (ii) $A$ is causal, $\operatorname{split}\left(K, A^{\mathrm{FS}}\right) \in K^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}$, and (iii) the set of derived variables, $\operatorname{der}\left(\operatorname{fud}(\sigma)\left(G_{R}\right)\right)$, is a literal frame of the set of label variables, $V \backslash K$, define the least squares gradient descent substrate net tree searcher as

$$
Z_{P, A, \mathrm{gr}, \mathrm{lsq}}=\operatorname{search} \operatorname{Treer}\left(\operatorname{nets}(U, K, \sigma), P_{P, A, \mathrm{gr}, \mathrm{lsq}},\left\{G_{R}\right\}\right)
$$

where the neighbourhood function is

$$
\begin{aligned}
& P_{P, A, \mathrm{gr}, \mathrm{lsq}}(G)=\left\{G^{\prime}: \operatorname{lsq}(\sigma)(A, G, K)>t,\right. \\
& \quad G^{\prime} \in \operatorname{nets}(U, K, \sigma), \operatorname{graph}\left(G^{\prime}\right)=\operatorname{graph}(G), \\
& \quad Q=\operatorname{weights}(G), Q^{\prime}=\operatorname{weights}\left(G^{\prime}\right), \\
& \left.Q^{\prime}=\left\{\left(i, Q_{i}-r \times \operatorname{dlsq}(\sigma)(i)(A, G, K)(Q)\right): i \in\{1 \ldots|Q|\}\right\}\right\}
\end{aligned}
$$

and loss threshold $t \in \operatorname{set}(P)$ and rate of descent $r \in \operatorname{set}(P)$.
Note that a practicable implementation of the net searcher would usually (i) perform an optimise step for each event rather than the whole history, and (ii) compute the deltas to be applied to the net weights, $Q$, one layer at a time in sequence from the top to the bottom (which is called backpropagation).

Let history $H \in \mathcal{H}_{U, X}$ be such that its histogram $A=\operatorname{histogram}(H)$ satisfies the constraints, of (i) real valued variables, (ii) causal histogram, and (iii) a literal frame, imposed by the search parameters $P$ of the least squares gradient descent substrate net tree searcher, $Z_{P, A, g r, \mathrm{lsq}}$. Define the least squares gradient descent fud search function as

$$
\begin{aligned}
& Z_{\mathrm{F}, \mathrm{P}, P, \mathrm{gr}, \mathrm{lsq}}(H)= \\
& \quad\left\{(\operatorname{fud}(\sigma)(G),-\operatorname{lsq}(\sigma)(A, G, K)): Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, \mathrm{gr}, \mathrm{lsq}}\right)\right),\{G\}=Q\right\}
\end{aligned}
$$

It is conjectured above that for all finite systems and finite event identifier sets there exists a tuple of parameters such that the practicable highest-layer summed shuffle content alignment valency-density fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{q}, \mathrm{d}, P, \mathrm{Scsd}}$, is positively correlated with the fud decomposition minimum space specialising fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}$, for uniform history probability function,

$$
\begin{aligned}
& \forall U \in \mathcal{U} \forall X \subset \mathcal{X}\left(\left|\mathcal{H}_{U, X}\right|<\infty \Longrightarrow\right. \\
& \quad \exists P \in \mathcal{L}(\mathcal{X})\left(\operatorname{covariance}\left(P_{U, X}\right)\right. \\
& \left.\left.\quad\left(\operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}, \operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{q}, \mathrm{~d}, P, \mathrm{Scss}}\right) \geq 0\right)\right)
\end{aligned}
$$

A similar generalisation of a correlation between the least squares gradient descent fud search function, $Z_{\mathrm{F}, \mathrm{P}, P, \mathrm{gr}, \mathrm{lsq}}$, and the fud minimum space specialising fud search function, $Z_{\mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{F}, \mathrm{H}}$, cannot be made because the history, $H$, is not independent of the search parameters, $P$. That is, least squares gradient descent supervised neural net optimisation requires specific configuration. Conjecture, however, that in some cases the properties of the net search function and the minimum space search function are similar.

First consider the simpler relation to the minimum space search function for the specialising derived history coder. The fud minimum space specialising derived search function for history $H \in \mathcal{H}_{U, X}$ is defined in terms of the expanded specialising derived history coder, $C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}\left(F^{\mathrm{T}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$, as

$$
Z_{\mathrm{F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}(H)=\left\{\left(F,-C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(F^{\mathrm{T}}\right)^{\mathrm{s}}(H)\right): F \in \mathcal{F}_{U, \mathrm{P}}\right\}
$$

The minimisation of the specialising derived substrate history coder space, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(F^{\mathrm{T} V}\right)^{\mathrm{s}}(H)$, occurs where (i) the derived entropy is low, (ii) the possible derived volume is small, (iii) the underlying components have high entropy and (iv) high counts are in low cardinality components and high cardinality components have low counts.

Note that, in some cases, particularly where there is a residual loss, the derived histogram may be unit, $A * F^{\mathrm{T}}=\left(A * F^{\mathrm{T}}\right)^{\mathrm{F}}$, because the derived values are continuous. The infinite derived volume of the real valued derived variables, $\left|W^{\mathrm{C}}\right|=\left|\mathbf{R}^{m}\right|=\infty$ where $m=|W|=|V \backslash K|$, may be made finite by discretising with the values of the label variables, $\{(i$, nearest $(D, r))$ : $\left.(i, r) \in R^{\rrbracket}\right\} \in D^{m}$ where $D=\cup\left\{U_{v}: v \in(V \backslash K)\right\} \subset \mathbf{R}$ and $R \in W^{\mathrm{CS}}$. If the label variables form a bivalent crown, crown $(A \%(V \backslash K))$ where $\forall v \in(V \backslash K)\left(U_{v}=\{0,1\}\right)$, then the discretised derived volume reduces to a finite $\left|W_{\{0,1\}}^{\mathrm{C}}\right|=\left|(V \backslash K)^{\mathrm{C}}\right|=2^{m}$. In the computations of alignment and
entropy that follow, the derived variables are discretised to the values of the label variables.

The initial substrate net, $G_{R}$, has arbitrary weights, $R=$ weights $\left(G_{R}\right) \in$ $\mathcal{L}(\mathbf{R})$, and so the corresponding initial fud, $F_{R}=\operatorname{fud}(\sigma)\left(G_{R}\right)$, is likely to have a high least squares loss. That is, far from the derived variables and the label variables being causally related, $W_{D}^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}$, they are likely to be independent,

$$
\begin{aligned}
& A * X_{F_{R}} *\left\{W_{D}^{\mathrm{CS}\{ \} \mathrm{T}},(V \backslash K)^{\mathrm{CS}\{ \} \mathrm{T}}\right\}^{\mathrm{T}} \approx \\
&\left(A * X_{F_{R}} *\left\{W_{D}^{\mathrm{CS}\{ \} \mathrm{T}},(V \backslash K)^{\mathrm{CS}\{ \} \mathrm{T}}\right\}^{\mathrm{T}}\right)^{\mathrm{X}}
\end{aligned}
$$

or

$$
\operatorname{algn}\left(A * X_{F_{R}} *\left\{W_{D}^{\mathrm{CS}\{ \} \mathrm{T}},(V \backslash K)^{\mathrm{CS}\{ \} \mathrm{T}}\right\}^{\mathrm{T}}\right) \approx 0
$$

where $\left\{W_{D}^{\mathrm{CS}\{ \} \mathrm{T}},(V \backslash K)^{\mathrm{CS}\{ \} \mathrm{T}}\right\}$ is the fud of the self transforms of the (i) discretised derived variables and (ii) label variables.

As the optimisation proceeds from the initial fud, $F_{R}$, to the optimal fud, $F \in \operatorname{maxd}\left(Z_{\mathrm{F}, \mathrm{P}, P, \mathrm{gr}, \mathrm{lsq}}(H)\right)$, the loss decreases and the relation between the top layer and the label becomes more causal,

$$
\operatorname{algn}\left(A * X_{F} *\left\{W_{D}^{\mathrm{CS}\{ \} \mathrm{T}},(V \backslash K)^{\mathrm{CS}\{ \} \mathrm{T}}\right\}^{\mathrm{T}}\right)>0
$$

If the loss is zero, after discretising, then the relation between the derived variables and the label variables is not only causal but bijective, $W_{D}^{\mathrm{CS}} \leftrightarrow$ $(V \backslash K)^{\mathrm{CS}}$. So the self partition transforms are highly aligned because diagonalised,

$$
\operatorname{diagonal}\left(A * X_{F} *\left\{W_{D}^{\mathrm{CS}\{ \} \mathrm{T}},(V \backslash K)^{\mathrm{CS}\{ \} \mathrm{T}}\right\}^{\mathrm{T}}\right)
$$

The negative least squares loss (i) varies with the alignment of the self partition transforms, (ii) varies with the alignment of the reduction to the union of the derived variables and label variables, (iii) varies against the size scaled entropy of the reduction to the union of the derived variables and label variables, and so (iv) varies against the derived entropy of the fud transform,

$$
\begin{aligned}
-\operatorname{lsq}\left(A, F_{D}, K\right) & \sim \operatorname{algn}\left(A * X_{F} *\left\{W_{D}^{\mathrm{CS}\{ \} \mathrm{T}},(V \backslash K)^{\mathrm{CS}\{ \} \mathrm{T}}\right\}^{\mathrm{T}}\right) \\
& \sim \operatorname{algn}\left(A * X_{F} \%\left(W_{D} \cup V \backslash K\right)\right) \\
& \sim-z \times \operatorname{entropy}\left(A * X_{F} \%\left(W_{D} \cup V \backslash K\right)\right) \\
& \sim-z \times \operatorname{entropy}\left(A * X_{F} \% W_{D}\right) \\
& =-z \times \operatorname{entropy}\left(A * F_{D}^{\mathrm{T}}\right)
\end{aligned}
$$

That is, as the loss, $\operatorname{lsq}\left(A, F_{D}, K\right)$, is minimised the derived entropy, entropy $(A *$ $F_{D}^{\mathrm{T}}$ ), tends to be minimised, which is a property of the specialising coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(F_{D}^{\mathrm{TV}}\right)$.

The discretised derived volume is fixed, $\left|W_{D}^{\mathrm{C}}\right|=|D|^{m}$, because the graph is fixed in the parameters, $\operatorname{graph}(G) \in \operatorname{set}(P)$ where $F=\operatorname{fud}(\sigma)(G)$ and $F \in \operatorname{maxd}\left(Z_{\mathrm{F}, \mathrm{P}, P, \mathrm{gr}, \mathrm{lsq}}(H)\right)$. So the derived volume is not minimised during the optimisation. The optimisation does not share the property of low derived volume with the specialising coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(F_{D}^{\mathrm{TV}}\right)$. However, as the derived alignment, $\operatorname{algn}\left(A * F_{D}^{\mathrm{T}}\right)$, increases during least squares optimisation, the causal relation between the discretised derived variables and the label variables tends to bijective, $W_{D}^{\mathrm{CS}} \leftrightarrow(V \backslash K)^{\mathrm{CS}}$. So if the label is diagonalised then the derived tends to be diagonalised, diagonal $(A \%(V \backslash K)) \Longrightarrow$ $\operatorname{diagonal}\left(A * F_{D}^{\mathrm{T}}\right)$, and if the label is a crown then the derived tends to be a crown, $\operatorname{crown}(A \%(V \backslash K)) \Longrightarrow \operatorname{crown}\left(A * F_{D}^{\mathrm{T}}\right)$. In both cases the effective derived volume is less than the derived volume, $\left|\left(A * F_{D}^{\mathrm{T}}\right)^{\mathrm{F}}\right|<\left|W_{D}^{\mathrm{C}}\right|$, if the label is multi-variate, $m \geq 2$, and multi-valent, $|D| \geq 2$.

The minimisation of the least squares loss function, $\operatorname{lsq}\left(A, F_{D}, K\right)$, tends to minimise the label entropy loss function, lent $\left(A, F_{D}, K\right)$, as the relation between the discretised derived variables and the label variables tends to functional or causal, $W_{D}^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}$. The corollary of the label entropy loss function,

$$
\operatorname{lent}(A, F, K):=\sum_{(R, C) \in\left(F^{\mathrm{T}}\right)^{-1}}\left(A * F^{\mathrm{T}}\right)_{R} \times \operatorname{entropy}(A * C \%(V \backslash K))
$$

is the query entropy loss function qent $\in \mathcal{A} \times \mathcal{F} \times \mathrm{P}(\mathcal{V}) \rightarrow \mathbf{R}$,

$$
\operatorname{qent}(A, F, K):=\sum_{(R, C) \in\left(F^{\mathrm{T}}\right)^{-1}}\left(A * F^{\mathrm{T}}\right)_{R} \times \operatorname{entropy}(A * C \% K)
$$

The fud, $F \in \mathcal{F}_{\infty, U, K}$, is in substrate $K$, so the query entropy is just the size scaled expected component entropy of the reduced histogram,

$$
\operatorname{qent}(A, F, K)=z \times \operatorname{entropyComponent}\left(A \% K, F^{\mathrm{T}}\right)
$$

The histogram entropy, entropy $(A)$, is a constant, so the query entropy, qent $(A, F, K)$, varies against the label entropy, $\operatorname{lent}(A, F, K)$. The negative least squares loss (i) varies with the negative label entropy loss, (ii) varies with the query entropy, (iii) varies with the size scaled expected component
entropy of the reduction to the query variables, and so (iv) varies with the size scaled expected component entropy,

$$
\begin{aligned}
-\operatorname{lsq}\left(A, F_{D}, K\right) & \sim-\operatorname{lent}\left(A, F_{D}, K\right) \\
& \sim \operatorname{qent}\left(A, F_{D}, K\right) \\
& \sim z \times \operatorname{entropyComponent}\left(A \% K, F_{D}^{\mathrm{T}}\right) \\
& \sim z \times \operatorname{entropyComponent}\left(A, F_{D}^{\mathrm{T}}\right)
\end{aligned}
$$

That is, as the loss, $\operatorname{lsq}\left(A, F_{D}, K\right)$, is minimised the expected component entropy, entropyComponent $\left(A, F_{D}^{\mathrm{T}}\right)$, tends to be maximised, which is a property of the specialising coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(F_{D}^{\mathrm{TV}}\right)$.

Consider the case of a multi-variate set of real valued query variables $K$, where $k=|K| \geq 2$ and $\forall x \in K\left(U_{x} \subseteq \mathbf{R}\right)$, and a neural net fud $F \in \mathcal{F}_{\infty, U, K, \sigma}$ consisting of two transforms, $F=\left\{T_{1}, T_{2}\right\}$, each having the query variables as the underlying, $\operatorname{und}\left(T_{1}\right)=\operatorname{und}\left(T_{2}\right)=K$. Given a coordinate $S \in \mathbf{R}^{k}$ the weights of the transforms form a pair of hyperplanes,

$$
\sum_{i \in\{1 \ldots k\}} Q_{1, i} S_{i}+Q_{1, k+1}=0
$$

and

$$
\sum_{i \in\{1 \ldots k\}} Q_{2, i} S_{i}+Q_{2, k+1}=0
$$

where $Q_{1}, Q_{2} \in \mathbf{R}^{k+1}$ are the weights correspondng to $T_{1}, T_{2}$. If the hyperplanes of the arbitrarily weighted initial fud, $F_{R}$, intersect, the acute angle between them is expected to be $45^{\circ}$. That is, given an activation function, $\sigma$, which is a step function, or a binary set of discrete values, $D=\{0,1\}$, the probability distribution of the component cardinalities of the initial fud is bi-modal. If $\left(\cdot, C_{1}\right),\left(\cdot, C_{2}\right) \in\left(F_{R,\{0,1\}}^{\mathrm{T}}\right)^{-1}$ are such that $\left|C_{1}\right|<\left|C_{2}\right|$, then it is expected that $3\left|C_{1}\right|=\left|C_{2}\right|$. So the component cardinality entropy of the initial $f u d$ is expected to be less than maximal,

$$
\operatorname{entropy}\left(K^{\mathrm{C}} * F_{R, D}^{\mathrm{T}}\right)<\operatorname{entropy}\left(W_{D}^{\mathrm{C}}\right)
$$

The derived entropy of the initial fud is expected to be approximately equal to the component cardinality entropy,

$$
\operatorname{entropy}\left(A * F_{R, D}^{\mathrm{T}}\right) \approx \operatorname{entropy}\left(K^{\mathrm{C}} * F_{R, D}^{\mathrm{T}}\right)
$$

and so the component size cardinality relative entropy of the initial fud is expected to be small,

$$
\operatorname{entropyRelative}\left(A * F_{R, D}^{\mathrm{T}}, K^{\mathrm{C}} * F_{R, D}^{\mathrm{T}}\right) \approx 0
$$

If the histogram, $A$, is approximately uniformly distributed over the volume, then the component size cardinality relative entropy remains small during the optimisation,

$$
\text { entropyRelative }\left(A * F_{D}^{\mathrm{T}}, K^{\mathrm{C}} * F_{D}^{\mathrm{T}}\right) \approx 0
$$

In contrast, consider the case where the histogram, $A$, is not uniformly distributed, but clustered by label state. Let $Y_{L} \subset K^{\mathrm{CS}}$ be the set of the centres of the clusters for effective label state $L \in(A \%(V \backslash K))^{\mathrm{FS}}$. The maximum radius $r_{L} \in \mathbf{R}_{>0}$ is such that

$$
\forall S \in A^{\mathrm{FS}} \diamond L=S \%(V \backslash K) \exists Q \in Y_{L}\left(\sum_{i \in\{1 \ldots k\}}\left(Q_{i}^{\square}-S_{i}^{\rrbracket}\right)^{2} \leq r_{L}^{2}\right)
$$

Let $r_{C}$ be the radius of component $C$. In the case where the histogram is clustered such that the cluster radius of a label state is much smaller than the least initial component radius, $\forall(\cdot, C) \in\left(F_{R,\{0,1\}}^{\mathrm{T}}\right)^{-1}\left(r_{L} \ll r_{C}\right)$, then optimised rotations of the hyperplanes, that sweep up nearby clusters in the same label state, tend to be such that the magnitude of the change in the fractional component size, $\left|\left(A * F_{2, D}^{\mathrm{T}}\right)(R)-\left(A * F_{1, D}^{\mathrm{T}}\right)(R)\right| / z$, is greater than magnitude of the change in the fractional component cardinality, $\mid\left(K^{\mathrm{C}} *\right.$ $\left.F_{2, D}^{\mathrm{T}}\right)(R)-\left(K^{\mathrm{C}} * F_{1, D}^{\mathrm{T}}\right)(R)\left|/\left|K^{\mathrm{C}}\right|\right.$. So, in the clustered case, as the optimisation decreases the derived entropy, entropy $\left(A * F_{D}^{\mathrm{T}}\right)$, the component sizes and component cardinalities become less synchronised and the component size cardinality relative entropy increases,

$$
\begin{aligned}
-\operatorname{lsq}\left(A, F_{D}, K\right) & \sim-z \times \operatorname{entropy}\left(A * F_{D}^{\mathrm{T}}\right) \\
& \sim z \times \operatorname{entropyRelative}\left(A * F_{D}^{\mathrm{T}}, K^{\mathrm{C}} * F_{D}^{\mathrm{T}}\right) \\
& =z \times \operatorname{entropyRelative}\left(A * F_{D}^{\mathrm{T}}, V^{\mathrm{C}} * F_{D}^{\mathrm{T}}\right)
\end{aligned}
$$

The same reasoning applies to fuds consisting of more than two transforms, $|F|>2$, but note that at higher fud cardinalities the initial component cardinality entropy, entropy $\left(K^{\mathrm{C}} * F_{R, D}^{\mathrm{T}}\right)$, tends to be multi-modal and so approximates more closely to the uniform cartesian derived entropy, entropy $\left(W_{D}^{\mathrm{C}}\right)$. So there is less freedom for the relative entropy of the fud to increase during optimisation. In the case of multi-layer fuds, however, the breadth can be constrained and so the relative entropy of taller, narrrower fuds may be
higher than in shorter, wider fuds of the same cardinality.
In general, in the clustered case, the optimised fud is such that high counts are in low cardinality components and high cardinality components have low counts, which, again, is a property of the specialising coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(F_{D}^{\mathrm{TV}}\right)$.

Overall, the comparisons above suggest that, given search parameters $P$, there sometimes exists a subset of histories $\mathcal{H}_{U, X, P} \subset \mathcal{H}_{U, X}$ satisfying the constraints of (i) real valued variables, (ii) causal histogram, (iii) a literal frame, and (iv) clustered histogram such that there is a positive correlation between the least squares gradient descent fud search function, $Z_{\mathrm{F}, \mathrm{P}, P, \mathrm{gr}, \mathrm{lsq}}$, and the fud minimum space specialising derived search function, $Z_{\mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$,

$$
\operatorname{covariance}\left(P_{U, X, P}\right)\left(\operatorname{maxr} \circ Z_{\mathrm{F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}, \operatorname{maxr} \circ Z_{\mathrm{F}, \mathrm{P}, P, \mathrm{gr}, \mathrm{lsq}}\right) \geq 0
$$

where $P_{U, X, P}=\mathcal{H}_{U, X, P} \times\left\{1 /\left|\mathcal{H}_{U, X, P}\right|\right\}$.

Now consider the relation to the minimum space search function for the specialising fud history coder. It is conjectured that when the specialising fud space, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)$, is minimised in the fud minimum space specialising fud search function, $Z_{\mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{F}, \mathrm{H}}$, (i) the derived entropy decreases up the layers, (ii) the possible derived volume decreases up the layers, (iii) the expected component entropy increases up the layers, and (iv) the component size cardinality cross entropy increases up the layers. The optimisation of a fud without a layer limit may be made computable by building the fud layer by layer, minimising the specialising space at each step, until the addition of a layer fails to reduce the specialising space.

In the case of the net search function, $Z_{\mathrm{F}, \mathrm{P}, P, \mathrm{gr}, \mathrm{lsq}}$, the substrate nets are not built layer by layer during the optimisation because the graph, $\operatorname{graph}(G)$ where $F=\operatorname{fud}(\sigma)(G)$ and $F \in \operatorname{maxd}\left(Z_{\mathrm{F}, \mathrm{P}, P, \mathrm{gr}, \mathrm{lsq}}(H)\right)$, is fixed in the parameters, $\operatorname{graph}(G)=\operatorname{graph}\left(G_{R}\right) \in \operatorname{set}(P)$. The properties of the nets do vary layer by layer, however, because the optimisation of the least squares loss function minimises the square of the distance between the top layer, $W=\operatorname{der}(F)$, and the label variables, $V \backslash K$. So the top layer is more closely aligned to the label variables than the other layers.

The loss function with respect to the neuron weights is composed of layers. The second order sensitivity of the loss function generally increases with the layer,

$$
\operatorname{ddlsq}(\sigma)(i)(A, G, K)(Q)<\operatorname{ddlsq}(\sigma)(j)(A, G, K)(Q)
$$

where $Q=$ weights $(G)$, weights $i, j \in\{1 \ldots|Q|\}$ parameterise corresponding transforms $T_{i}, T_{j} \in F$ such that layer $\left(F, \operatorname{der}\left(T_{i}\right)\right)<\operatorname{layer}\left(F, \operatorname{der}\left(T_{j}\right)\right)$, and the second order derivative of the least squares loss function is defined

$$
\begin{aligned}
& \operatorname{ddlsq}(\sigma)(i)(A, G, K):= \\
& \quad \partial_{i}^{2}\left(\left\{\left(\operatorname{weights}\left(G^{\prime}\right), \operatorname{lsq}(\sigma)\left(A, G^{\prime}, K\right)\right): G^{\prime} \in \operatorname{nets}, \operatorname{graph}\left(G^{\prime}\right)=\operatorname{graph}(G)\right\}\right)
\end{aligned}
$$

So gradient descent optimisation resolves more quickly for higher layers than lower layers.

Let $F_{i}$ be the $i$-th layer of the fud, $F$, where $i \in\{1 \ldots l\}$ and $l=\operatorname{layer}(F, W)$. The second order sensitivity of the loss function generally increases with the layer because, although the relation between a lower layer and a higher layer is always causal, $W_{i-1, D}^{\mathrm{CS}} \rightarrow W_{i, D}^{\mathrm{CS}}$, it is not usually bijective, $W_{i-1, D}^{\mathrm{CS}} \leftrightarrow W_{i, D}^{\mathrm{CS}}$. For example, the relation between layers is sometimes only partially bijective, $J_{i-1, D}^{\mathrm{CS}} \leftrightarrow J_{i, D}^{\mathrm{CS}}$ where $J_{i-1} \subset W_{i-1}$ and $J_{i} \subset W_{i}$. The relation is always functional so the degree of multijectivity is the query entropy, qent $\left(A * F_{\{1 \ldots i-1\}, D}^{\mathrm{T}}, F_{i, D}, W_{i-1, D}\right)$. When the query entropy is zero, the relation is effectively bijective, corresponding to a self transform, $W_{i-1, D}^{\mathrm{CS}\{ \} \mathrm{T}}$. When the query entropy is maximised, the relation is multijective, corresponding to a unary transform, $\left\{W_{i-1, D}^{\mathrm{CS}}\right\}^{\mathrm{T}}$.

For the same reason it is less likely for the lower layer to be causal to the label variables, $W_{i-1, D}^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}$, than for the higher layer to be causal to the label variables, $W_{i, D}^{\mathrm{CS}} \rightarrow(V \backslash K)^{\mathrm{CS}}$. So, in general, the alignment between the layer variables and the label variables increases up the layers. For $i \in\{2 \ldots l\}$,

$$
\begin{aligned}
\operatorname{algn}\left(A * X *\left\{W_{i, D}^{\mathrm{CS}\{ \} \mathrm{T}},(V \backslash K)^{\mathrm{CS}\{ \} \mathrm{T}}\right\}^{\mathrm{T}}\right) & > \\
& \operatorname{algn}\left(A * X *\left\{W_{i-1, D}^{\mathrm{CS}\{ \} \mathrm{T}},(V \backslash K)^{\mathrm{CS}\{ \} \mathrm{T}}\right\}^{\mathrm{T}}\right)
\end{aligned}
$$

and

$$
\operatorname{algn}\left(A * X \%\left(W_{i, D} \cup V \backslash K\right)\right)>\operatorname{algn}\left(A * X \%\left(W_{i-1, D} \cup V \backslash K\right)\right)
$$

where $X=\prod_{T \in F} \operatorname{his}(T)$. So the entropy between the layer variables and the label variables tends to decrease up the layers,

```
entropy}(A*X % (\mp@subsup{W}{i,D}{}\cupV\K)) < entropy(A*X % (W Wi-1,D \cup V\K))
```

Therefore conjecture that, in general, the derived entropy also decreases up the layers, regardless of the label variables,

$$
\forall i \in\{2 \ldots l\}\left(\operatorname{entropy}\left(A * F_{\{1 \ldots i\}, D}^{\mathrm{T}}\right)<\operatorname{entropy}\left(A * F_{\{1 \ldots i-1\}, D}^{\mathrm{T}}\right)\right)
$$

which is a property of the specialising fud substrate history coder, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}\left(F_{D}\right)$.
In the comparison above between the least squares gradient descent fud search function, $Z_{\mathrm{F}, \mathrm{P}, P, \mathrm{gr}, \mathrm{lsq}}$, and the fud minimum space specialising derived search function, $Z_{\mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$ it is shown that the derived entropy, entropy $\left(A * F_{D}^{\mathrm{T}}\right)$, (i) varies with the effective derived volume, $\left|\left(A * F_{D}^{\mathrm{T}}\right)^{\mathrm{F}}\right|$, (ii) varies against the expected component entropy, entropyComponent $\left(A, F_{D}^{\mathrm{T}}\right)$, and (iii) varies against the component size cardinality relative entropy, entropyRelative $(A$ * $F_{D}^{\mathrm{T}}, V^{\mathrm{C}} * F_{D}^{\mathrm{T}}$ ). So conjecture that, in general, (i) the effective derived volume decreases up the layers,

$$
\forall i \in\{2 \ldots l\}\left(\left|\left(A * F_{\{1 . . . i\}, D}^{\mathrm{T}}\right)^{\mathrm{F}}\right|<\left|\left(A * F_{\{1 \ldots i-1\}, D}^{\mathrm{T}}\right)^{\mathrm{F}}\right|\right)
$$

(ii) the expected component entropy increases up the layers,

```
\(\forall i \in\{2 \ldots l\}\)
    (entropyComponent \(\left.\left(A, F_{\{1 \ldots . .1\}, D}^{\mathrm{T}}\right)>\operatorname{entropyComponent}\left(A, F_{\{1 \ldots i-1\}, D}^{\mathrm{T}}\right)\right)\)
```

and (iii) the component size cardinality relative entropy increases up the layers,

```
\(\forall i \in\{2 \ldots l\}\)
    (entropyRelative \(\left(A * F_{\{1 \ldots i\}, D}^{\mathrm{T}}, V_{D}^{\mathrm{C}} * F_{\{1 \ldots i\}, D}^{\mathrm{T}}\right)>\)
    entropyRelative \(\left.\left(A * F_{\{1 . . i-1\}, D}^{\mathrm{T}}, V_{D}^{\mathrm{C}} * F_{\{1 \ldots i-1\}, D}^{\mathrm{T}}\right)\right)\)
```

Again, these properties are also properties of the specialising fud substrate history coder, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}\left(F_{D}\right)$.

To conclude, the comparisons above suggest that, given search parameters $P$, there sometimes exists a subset of histories $\mathcal{H}_{U, X, P} \subset \mathcal{H}_{U, X}$ satisfying the constraints of (i) real valued variables, (ii) causal histogram, (iii) a literal frame, and (iv) clustered histogram such that there is a positive correlation between the least squares gradient descent fud search function, $Z_{\mathrm{F}, \mathrm{P}, P, \mathrm{gr}, \mathrm{lsq}}$, and the fud minimum space specialising fud search function, $Z_{\mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{F}, \mathrm{H}}$,

$$
\operatorname{covariance}\left(P_{U, X, P}\right)\left(\operatorname{maxr} \circ Z_{\mathrm{F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{~F}, \mathrm{H}}, \operatorname{maxr} \circ Z_{\mathrm{F}, \mathrm{P}, P, \mathrm{gr}, \mathrm{lsq}}\right) \geq 0
$$

where $P_{U, X, P}=\mathcal{H}_{U, X, P} \times\left\{1 /\left|\mathcal{H}_{U, X, P}\right|\right\}$.
An example of additional supervised knowledge is where it is known that the substrate exhibits some symmetry. The supervised models can be constrained to exhibit these symmetries by copying common submodels amongst
them. For example, in the case where the substrate represents a visual or auditory field with translational symmetry, the common submodel can consist of a relative model on a frame subset of the substrate which is copied across the whole substrate by adding translation offsets to the frame variables.

If the optimisation of artificial neural networks is of the unsupervised type, there is no knowledge of a causal label. An example of an unsupervised optimisation is the auto-encoder [2]. Here the method of least squares gradient descent is used but the label is simply the substrate itself. Let $Y \in V: \leftrightarrow: V_{Y}$ be a mapping from the sample variables, $V$, to a disjoint reframed set, $V_{Y}$, such that the reframe is literal, $\forall(v, w) \in Y\left(U_{w}=U_{v}\right)$. The histogram may be extended by dotting with the reframe,

$$
A_{Y}=\{(S \cup \operatorname{reframe}(Y, S), c):(S, c) \in A\}
$$

Then the query variables are the substrate, $K=V \in \operatorname{set}(P)$, the label variables are the reframed substrate, $V_{Y}$, and the search is performed on the dotted histogram, $Z_{P, A_{Y}, \mathrm{gr}, \mathrm{lsq}}$.

If the auto-encoder's graph is such that all layers have the same breadth, $\forall i \in\{1 \ldots l\}\left(\left|F_{i}\right|=n\right)$, then the likely model is the over-fitted effective self transform, $F^{\mathrm{T}}=\left(A^{\mathrm{FS}\{ \}} \cup\left\{V^{\mathrm{CS}} \backslash A^{\mathrm{FS}}\right\}\right)^{\mathrm{T}}$ or the full functional transform, $F^{\mathrm{T}}=\left\{\{w\}^{\mathrm{CS}\{ \} \mathrm{T}}: w \in V\right\}^{\mathrm{T}}$. However, if the fud has an hourglass shape such that there is an intermediate layer $F_{a}$ which has a breadth less than all other layers, $\forall i \in\{1 \ldots l\}\left(i \neq a \Longrightarrow\left|F_{i}\right|>\left|F_{a}\right|\right)$, then it may be expected that (i) the derived entropy decreases up to this layer,

$$
\forall i \in\{2 \ldots a\}\left(\operatorname{entropy}\left(A * F_{\{1 \ldots i\}, D}^{\mathrm{T}}\right)<\operatorname{entropy}\left(A * F_{\{1 \ldots i-1\}, D}^{\mathrm{T}}\right)\right)
$$

(ii) the effective derived volume decreases up to this layer,

$$
\forall i \in\{2 \ldots a\}\left(\left|\left(A * F_{\{1 \ldots i\}, D}^{\mathrm{T}}\right)^{\mathrm{F}}\right|<\left|\left(A * F_{\{1 \ldots i-1\}, D}^{\mathrm{T}}\right)^{\mathrm{F}}\right|\right)
$$

(iii) the expected component entropy increases up to this layer,

```
\(\forall i \in\{2 \ldots a\}\)
    (entropyComponent \(\left.\left(A, F_{\{1 \ldots i\}, D}^{\mathrm{T}}\right)>\operatorname{entropyComponent}\left(A, F_{\{1 \ldots i-1\}, D}^{\mathrm{T}}\right)\right)\)
```

and (iv) the component size cardinality relative entropy increases up to this layer,

```
\(\forall i \in\{2 \ldots a\}\)
    (entropyRelative \(\left(A * F_{\{1 \ldots i\}, D}^{\mathrm{T}}, V_{D}^{\mathrm{C}} * F_{\{1 \ldots i\}, D}^{\mathrm{T}}\right)>\)
        entropyRelative \(\left.\left(A * F_{\{1 . . . i-1\}, D}^{\mathrm{T}}, V_{D}^{\mathrm{C}} * F_{\{1 \ldots i-1\}, D}^{\mathrm{T}}\right)\right)\)
```

Above the intermediate layer, $a$, it is expected that there is little change in these properties. For example, entropy $\left(A * F_{\{1 \ldots l\}, D}^{\mathrm{T}}\right) \approx \operatorname{entropy}\left(A * F_{\{1 \ldots a\}, D}^{\mathrm{T}}\right)$.

### 5.3 Classical induction

The following sections consider how induction is related to likelihood and sensitivity. First consider classical induction.

As defined at the beginning of this section $P \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}$ is an unknown history probability function in the non-empty histories $\mathcal{H}_{U, X}$, where $U$ is a non-empty finite system and $X \subset \mathcal{X}$ is a non-empty unknown finite set of event identifiers.

Now, similarly to section 'Derived history space', above, let $H_{\mathrm{h}} \in \mathcal{H}_{U, X}$ be a distribution history with substrate $V_{\mathrm{h}}$ equal to the system variables, $V_{\mathrm{h}}=\operatorname{vars}\left(H_{\mathrm{h}}\right)=\operatorname{vars}(U)$. Its volume is $v_{\mathrm{h}}=\left|V_{\mathrm{h}}^{\mathrm{C}}\right|$. Its domain is the entire set of event identifiers, ids $\left(H_{\mathrm{h}}\right)=X$, so that the size $z_{\mathrm{h}}=\left|H_{\mathrm{h}}\right|$ equals the cardinality of the event identifiers, $z_{\mathrm{h}}=|X|$. Thus the distribution history is a left total state-valued function of the event identifiers, $H_{\mathrm{h}} \in X: \rightarrow V_{\mathrm{h}}^{\mathrm{CS}}$. The historically distributed history probability function $P_{U, X, H_{\mathrm{h}}} \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}$ is defined

$$
\begin{aligned}
P_{U, X, H_{\mathrm{h}}}:= & \left(\bigcup \left\{\left\{(H, 1): H \subseteq H_{\mathrm{h}} \% V_{H},|H|=z_{H}\right\}^{\wedge}:\right.\right. \\
& \left.\left.V_{H} \subseteq V_{\mathrm{h}}, z_{H} \in\left\{1 \ldots z_{\mathrm{h}}\right\}\right\}\right)^{\wedge} \cup \\
& \left\{(H, 0): H \in \mathcal{H}_{U, X}, H \nsubseteq H_{\mathrm{h}} \% V_{H}\right\} \cup\{(\emptyset, 0)\} \\
= & \left\{\left(H, 1 /\left(z_{\mathrm{h}} 2^{v_{\mathrm{h}}}\binom{z_{\mathrm{h}}}{z_{H}}\right): H \in \mathcal{H}_{U, X}, H \subseteq H_{\mathrm{h}} \% V_{H}, H \neq \emptyset\right\} \cup\right. \\
& \left\{(H, 0): H \in \mathcal{H}_{U, X}, H \nsubseteq H_{\mathrm{h}} \% V_{H}\right\} \cup\{(\emptyset, 0)\}
\end{aligned}
$$

where $V_{H}=\operatorname{vars}(H), z_{H}=|H|, \hat{X}=\operatorname{normalise}(X)$ and normalise $(\emptyset)=\emptyset$.
The historically distributed history probability, $P_{U, X, H_{h}}(H)$, is the probability of drawing the history $H \subseteq H_{\mathrm{h}} \% V_{H}$ of arbitrary variables $V_{H} \subseteq V_{\mathrm{h}}$ and size $z_{H} \in\left\{1 \ldots z_{\mathrm{h}}\right\}$ from distribution history $H_{\mathrm{h}} \in \mathcal{H}_{U, X}$. All subsets of the distribution history for a given set of variables and size are defined as equally probable,

$$
\forall V \subseteq V_{\mathrm{h}} \forall H, G \subseteq H_{\mathrm{h}} \% V\left(|G|=|H| \Longrightarrow P_{U, X, H_{\mathrm{h}}}(G)=P_{U, X, H_{\mathrm{h}}}(H)\right)
$$

Note that this definition does not assume that the subsets of the distribution history, $\mathrm{P}\left(H_{\mathrm{h}} \% V_{H}\right)$, are equally probable, $P_{U, X, H_{\mathrm{h}}} \neq\left\{(H, 1): V_{H} \subseteq\right.$
$\left.V_{\mathrm{h}}, H \subseteq H_{\mathrm{h}} \% V_{H}\right\}^{\wedge}$. Equi-probable subsets would imply that there is a modal sample size at $z_{\mathrm{h}} / 2$. Here it is assumed that there is no constraint on the sample size other than it is non-zero and less than or equal to the distribution size, $1 \leq z_{H} \leq z_{\mathrm{h}}$. So sizes are defined as equi-probable, $\forall z \in\left\{1 \ldots z_{\mathrm{h}}\right\}\left(\sum\left(P_{U, X, H_{\mathrm{h}}}(H): H \in \mathcal{H}_{U, X},|H|=z\right)=1 / z_{\mathrm{h}}\right)$.

Now for arbitrary non-empty drawn history $H \subseteq H_{\mathrm{h}} \% V_{H}$, the historical probability of drawing without replacement its histogram $A_{H}=\operatorname{histogram}(H)$ from the distribution histogram $E_{\mathrm{h}}=$ histogram $\left(H_{\mathrm{h}}\right)$, is the expected historically distributed history probability of the histogram, $A_{H}$, times the normalising factor,

$$
\hat{Q}_{\mathrm{h}}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right)=z_{\mathrm{h}} 2^{v_{\mathrm{h}}} \sum\left(P_{U, X, H_{\mathrm{h}}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}\right)
$$

where the historical distribution is

$$
Q_{\mathrm{h}}(E, z)(A)=\prod_{S \in A^{\mathrm{S}}}\binom{E_{S}}{A_{S}}=\prod_{S \in A^{\mathrm{S}}} \frac{E_{S}!}{A_{S}!\left(E_{S}-A_{S}\right)!} \in \mathbf{N}_{>0}
$$

and the historical probability distribution is normalised,

$$
\hat{Q}_{\mathrm{h}}(E, z)(A)=Q_{\mathrm{h}}(E, z)(A) /\binom{z_{E}}{z}
$$

The stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, U}$, can equally well be expressed in terms of the historically distributed history probability function, $P_{U, X, H_{\mathrm{h}}}$,

$$
\hat{Q}_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right)=z_{\mathrm{h}} 2^{v_{\mathrm{h}}} \sum\left(P_{U, X, H_{\mathrm{h}}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}\right)
$$

where the distribution histogram is complete, $E_{\mathrm{h}}=\operatorname{histogram}\left(H_{\mathrm{h}}\right)+V_{\mathrm{h}}^{\mathrm{CZ}} \in$ $\mathcal{A}_{U, \mathrm{i}, V_{\mathrm{h}}, z_{\mathrm{h}}}$, the histograms are complete, $A_{H}=\operatorname{histogram}(H)+V_{H}^{\mathrm{CZ}} \in \mathcal{A}_{U, \mathrm{i}, V_{H}, z_{H}}$, the stuffed historical distribution, $Q_{\mathrm{h}, U}$, is defined

$$
\begin{aligned}
Q_{\mathrm{h}, U}(E, z)= & \left\{\left(A+A^{\mathrm{CZ}}, f\right):(A, f) \in Q_{\mathrm{h}}(E, z)\right\} \cup \\
& \left(\mathcal{A}_{U, \mathrm{i}, V, z} \backslash\left\{A+A^{\mathrm{CZ}}: A \in \operatorname{dom}\left(Q_{\mathrm{h}}(E, z)\right)\right\}\right) \times\{0\}
\end{aligned}
$$

and the stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, U}$, is defined $\hat{Q}_{\mathrm{h}, U}(E, z):=$ normalise $\left(Q_{\mathrm{h}, U}(E, z)\right)$.

In classical induction it is assumed that the history probability function, $P$, is historically distributed,

$$
P=P_{U, X, H_{\mathrm{h}}}
$$

where the distribution history, $H_{\mathrm{h}}$, is unknown, but there exists a non-empty observation or sample history $H_{\mathrm{o}} \subseteq H_{\mathrm{h}} \% V_{\mathrm{o}}$ of known size $z_{\mathrm{o}}=\left|H_{\mathrm{o}}\right|>0$ in known variables $V_{\mathrm{o}} \subseteq V_{\mathrm{h}}$ that has a known complete histogram $A_{\mathrm{o}}=$ $\operatorname{histogram}\left(H_{\mathrm{o}}\right)+V_{\mathrm{o}}^{\mathrm{CZ}}$. The system, $U$, is known at least for the observation variables, $V_{\mathrm{o}}$. The distribution history, $H_{\mathrm{h}}$, is unknown, so the historically distributed history probability of the sample history, $P_{U, X, H_{\mathrm{h}}}\left(H_{\mathrm{o}}\right)$, is also unknown, except that it is non-zero,

$$
P_{U, X, H_{\mathrm{h}}}\left(H_{\mathrm{o}}\right)>0
$$

because the sample history exists. The complete distribution histogram, $E_{\mathrm{h}}=\operatorname{histogram}\left(H_{\mathrm{h}}\right)+V_{\mathrm{h}}^{\mathrm{CZ}}$, is unknown, so the stuffed historical probability of the sample histogram, $\hat{Q}_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$, is also unknown, except that is non-zero, $\hat{Q}_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)>0$. In order to estimate the distribution histogram, $E_{\mathrm{h}}$, and hence the stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)$, and the historically distributed history probability function, $P_{U, X, H_{\mathrm{h}}}$, the likelihood function for the probability distribution must be defined. See appendix 'Likelihood functions and Fisher information', below.

First make the further induction assumption that the distribution history size, $z_{\mathrm{h}}$, is large with respect to the sample size $z_{\mathrm{o}}=\operatorname{size}\left(A_{\mathrm{o}}\right)$, so that, in the limit, the stuffed historical probability, $\hat{Q}_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$, approximates to the generalised multinomial probability, $\hat{Q}_{\mathrm{m}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$. That is, if $z_{\mathrm{o}} \ll z_{\mathrm{h}}$ then

$$
\hat{Q}_{\mathrm{h}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \approx \hat{Q}_{\mathrm{m}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

where $E_{\mathrm{o}}=E_{\mathrm{h}} \% V_{\mathrm{o}}$ and the generalised multinomial probability is

$$
\hat{Q}_{\mathrm{m}, U}(E, z)(A)=\frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}} \hat{E}_{S}^{A_{S}}
$$

where integral substrate histogram $A \in \mathcal{A}_{U, \mathrm{i}, V, z}$ is drawn with replacement from $E \in \mathcal{A}_{U, V, z_{E}}$.

The maximum likelihood estimate and the Fisher information of the generalised multinomial probability distribution, $\hat{Q}_{\mathrm{m}, U}$, are well defined, but may also be considered by noting that this distribution approximates to the generalised multiple binomial probability distribution, $\hat{Q}_{\mathrm{b}, U}$,

$$
\hat{Q}_{\mathrm{m}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \approx \hat{Q}_{\mathrm{b}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

where the generalised multiple binomial probability distribution is defined

$$
\hat{Q}_{\mathrm{b}, U}(E, z)(A)=\prod_{S \in V \mathrm{CS}}\binom{z}{A_{S}} \hat{E}_{S}^{A_{S}}\left(1-\hat{E}_{S}\right)^{z-A_{S}}
$$

where multiple support histogram $A \in \mathcal{A}_{U, \mathrm{i}, V,\{0 \ldots z\}}$ is drawn with replacement from $E \in \mathcal{A}_{U, V, z_{E}}$. The approximation is best when the entropy of the distribution histogram, entropy $(E)$, is high.

Likelihood functions are parameterised by a real tuple or coordinate, $\mathbf{R}^{n}$. In order to construct a coordinate from a histogram define ()$^{\mathbb{d}} \in \mathcal{A} \rightarrow \mathcal{L}\left(\mathbf{Q}_{\geq 0}\right)$ as

$$
A^{\square}:=\left\{(i, c):((S, c), i) \in \operatorname{order}\left(D_{\mathcal{S} \times \mathbf{Q}}, A\right)\right\}
$$

where $D_{\mathcal{S}}$ is an order on the states. If $A$ is complete, $A^{\mathrm{U}}=A^{\mathrm{C}}$, then $A^{[]} \in \mathbf{R}^{v}$, where $v=\left|A^{\mathrm{C}}\right|$.

The multiple binomial parameterised probability density function $\operatorname{mbppdf}(z) \in$ $\operatorname{ppdfs}(v, v)$, where $v=\left|V^{\mathrm{C}}\right|$, is defined

$$
\begin{aligned}
& \operatorname{mbppdf}(z)(E):= \\
& \qquad\left\{\left(A, \prod_{i \in\{1 \ldots v\}} \frac{z!}{\Gamma_{!}\left(A_{i}\right) \Gamma_{!}\left(z-A_{i}\right)} E_{i}^{A_{i}}\left(1-E_{i}\right)^{z-A_{i}}\right): A \in \mathbf{R}_{[0, z]}^{v}\right\} \cup \\
& \quad\left(\mathbf{R}^{v} \backslash \mathbf{R}_{[0, z]}^{v}\right) \times\{0\}
\end{aligned}
$$

where $z \in \mathbf{N}_{>0}, E \in \mathbf{R}_{(0,1)}^{v}$ and $\Gamma_{!}$is the unit-translated gamma function. The multiple binomial likelihood function $\operatorname{mblf}(z) \in \operatorname{lfs}(v, v)$ is defined

$$
\operatorname{mblf}(z)(A):=\left\{(E, \operatorname{mbppdf}(z)(E)(A)): E \in \mathbf{R}_{(0,1)}^{v}\right\}
$$

where $A \in \mathbf{R}^{v}$.
These definitions only require that each parameter is in the open set between zero and one, $E \in \mathbf{R}_{(0,1)}^{v}=\{r: r \in \mathbf{R}, 0<r<1\}^{v}$, so $E$ is not necessarily a probability function. That is, in some cases $E \neq \hat{E} \in \mathcal{P}$. This is to allow well defined partial derivatives in free parameters. So $\partial_{i}(\operatorname{mblf}(z)(A))(E)$ is the sensitivity of the likelihood to the $i$-th parameter at $E$, where $\partial_{j} \in(\mathcal{L}(\mathbf{R}) \rightarrow$ $\mathbf{R}) \rightarrow(\mathcal{L}(\mathbf{R}) \rightarrow \mathbf{R})$ is defined $\partial_{j}(F):=\left\{\left(Z, \partial F(Z) / \partial Z_{j}\right): Z \in \operatorname{dom}(F)\right\}$ and $F$ is a continuous function.

In the case where the volume is at least two, $v>1$, and the distribution histogram is completely effective, $E^{\mathrm{F}}=V^{\mathrm{C}} \Longrightarrow \hat{E}^{\square} \in \mathbf{R}_{(0,1)}^{v}$, the multiple binomial parameterised probability density and the multiple binomial likelihood equals the generalised multiple binomial probability,

$$
\operatorname{mbppdf}(z)\left(\hat{E}^{\square}\right)\left(A^{\square}\right)=\operatorname{mblf}(z)\left(A^{\square}\right)\left(\hat{E}^{\rrbracket}\right)=\hat{Q}_{\mathrm{b}, U}(E, z)(A)
$$

As shown in the appendix, the binomial parameterised probability density function, $\operatorname{bppdf}(n)(p)$, is defined

$$
\operatorname{bppdf}(n)(p)(k):=\frac{n!}{\Gamma_{!} \Gamma_{!}(n-k)} p^{k}(1-p)^{n-k} \in \mathbf{R}_{(0,1)}
$$

and the corresponding likelihood function is $\operatorname{blf}(n)(k)(p):=\operatorname{bppdf}(n)(p)(k)$, where $n>0$ and $0<p<1$. Given observation coordinate $k_{\circ} \in \mathbf{R}_{(0, n)}$ the maximum likelihood estimate for the parameter of the probability density function is the modal likelihood, $\{\tilde{p}\}=\operatorname{maxd}\left(\operatorname{blf}(n)\left(k_{\mathrm{o}}\right)\right)$, which is $\tilde{p}=$ $k_{\mathrm{o}} / n$. Here the gradient of the likelihood function is zero, $\mathrm{d}\left(\operatorname{blf}(n)\left(k_{\mathrm{o}}\right)\right)(\tilde{p})=$ $\mathrm{d}\left(\operatorname{blf}(n)\left(k_{\mathrm{o}}\right)\right)\left(k_{\mathrm{o}} / n\right)=0$, where $\mathrm{d} \in(\mathbf{R} \rightarrow \mathbf{R}) \rightarrow(\mathbf{R} \rightarrow \mathbf{R})$ is defined $\mathrm{d}(F):=\{(x, d F(x) / d x): x \in \operatorname{dom}(F)\}$.

The multiple binomial parameterised probability density function, $\operatorname{mbppdf}(z)$, is the product of a set of independent binomial parameterised probability density functions, $\operatorname{bppdf}(z)$,

$$
\operatorname{mbppdf}(z)(E)(A)=\prod_{i \in\{1 \ldots v\}} \operatorname{bppdf}(z)\left(E_{i}\right)\left(A_{i}\right)
$$

and so, given non-singleton volume, $v_{\mathrm{o}}=\left|V_{\mathrm{o}}^{\mathrm{C}}\right|>1$, and a completely effective sample histogram, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}} \Longrightarrow \hat{A}_{\mathrm{o}}^{\rrbracket} \in \mathbf{R}_{(0,1)}^{v_{o}}$, the maximum likelihood estimate is $\tilde{E}_{0}^{\square}=\hat{A}_{0}^{\rrbracket}$, where $\left\{\tilde{E}_{o}^{\rrbracket}\right\}=\operatorname{maxd}\left(\operatorname{mblf}\left(z_{0}\right)\left(A_{0}^{\square}\right)\right)$. Thus, in classical induction, in the case of completely effective sample histogram, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}} \Longrightarrow$ $E_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$, the maximum likelihood estimate $\tilde{E}_{\mathrm{o}} \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}$ of the unknown distribution probability histogram, $\hat{E}_{0}$, in the generalised multiple binomial probability distribution, $\hat{Q}_{\mathrm{b}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is

$$
\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

The maximum likelihood estimate in this case is a rational-valued function, $\tilde{E}_{o}^{\rrbracket}=\hat{A}_{0}^{\rrbracket} \in \mathbf{N} \rightarrow \mathbf{Q}_{\geq 0}$, so the maximum likelihood estimate can also be written as the maximisation of the complete congruent histograms of unit size,

$$
\left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E, \hat{Q}_{\mathrm{b}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}\right\}\right)
$$

The maximum likelihood estimate is not computable as a maximisation. Although the substrate histograms are countably infinite, $\mathcal{A}_{U, V_{o}, 1} \leftrightarrow \mathbf{N}$, the maximisation never terminates. An approximation to the continuous case may be made by using a scaling factor. The scaled complete integral congruent histograms equals the complete congruent histograms in the limit

$$
\lim _{k \rightarrow \infty}\left\{A / Z_{k}: A \in \mathcal{A}_{U, \mathrm{i}, V, k z}\right\}=\mathcal{A}_{U, V, z}
$$

where $k \in \mathbf{N}_{>0}$ and $Z_{k}=\operatorname{scalar}(k)$. The finite approximation to the maximum likelihood estimate is

$$
\left\{\tilde{E}_{0}\right\} \approx \operatorname{maxd}\left(\left\{\left(E / Z_{k}, \hat{Q}_{\mathrm{b}, U}\left(E / Z_{k}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, \mathrm{i}, V_{o}, k}\right\}\right)
$$

The approximation improves as the scaling factor, $k$, increases.
The normalised mean of the generalised multiple binomial probability distribution at the maximum likelihood estimate equals the maximum likelihood estimate of the distribution histogram,

$$
\operatorname{normalise}\left(\operatorname{mean}\left(\hat{Q}_{\mathrm{b}, U}\left(\tilde{E}_{\mathrm{o}}, z_{\mathrm{o}}\right)\right)\right)=\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

The multinomial parameterised probability density function $\operatorname{mppdf}(z) \in \operatorname{ppdfs}(v, v)$, where $v \in \mathbf{N}_{>0}$, is defined

$$
\begin{aligned}
& \operatorname{mppdf}(z)(E):= \\
& \quad\left\{\left(A, \frac{n!}{\prod_{i \in\{1 \ldots v\}} \Gamma_{!} A_{i}} \prod_{i \in\{1 . . v\}} E_{i}^{A_{i}}\right): A \in \mathbf{R}_{[0, z]}^{v}, \sum_{i \in\{1 \ldots v\}} A_{i}=z\right\} \cup \\
& \quad\left\{(A, 0): A \in \mathbf{R}_{[0, z]}^{v}, \sum_{i \in\{1 \ldots v\}} A_{i} \neq z\right\} \cup \\
& \quad\left(\mathbf{R}^{v} \backslash \mathbf{R}_{[0, z]}^{v}\right) \times\{0\}
\end{aligned}
$$

where $z \in \mathbf{N}_{>0}, E \in \mathbf{R}_{(0,1)}^{v}$ and $\sum_{i \in\{1 \ldots v\}} E_{i}=1$, otherwise $\operatorname{mppdf}(z)(E)$ is undefined.

The multinomial likelihood function $\operatorname{mlf}(z) \in \operatorname{lfs}(v, v)$ is defined

$$
\operatorname{mlf}(n)(A):=\left\{(E, \operatorname{mppdf}(z)(E)(A)): E \in \mathbf{R}_{(0,1)}^{v}\right\}
$$

where $A \in \mathbf{R}^{v}$. Note that the multinomial likelihood function only requires that each parameter is in the open set between zero and one, $E \in \mathbf{R}_{(0,1)}^{v}=$ $\{r: r \in \mathbf{R}, 0<r<1\}^{v}$, so $E$ is not necessarily a probability function. That is, in some cases $E \neq \hat{E} \notin \mathcal{P}$.

In the case where the volume is at least two, $v>1$, and the distribution histogram is completely effective, $E^{\mathrm{F}}=V^{\mathrm{C}} \Longrightarrow \hat{E}^{\square} \in \mathbf{R}_{(0,1)}^{v}$, the multinomial parameterised probability density and the multinomial likelihood equals the generalised multinomial probability,

$$
\operatorname{mppdf}(z)\left(\hat{E}^{\square}\right)\left(A^{\square}\right)=\operatorname{mlf}(z)\left(A^{\square}\right)\left(\hat{E}^{\square}\right)=\hat{Q}_{\mathrm{m}, U}(E, z)(A)
$$

The maximum likelihood estimate for the parameter of the multinomial parameterised probability density function, $\left\{\tilde{E}_{o}^{\square}\right\}=\operatorname{maxd}\left(\operatorname{mlf}\left(z_{o}\right)\left(A_{o}^{\square}\right)\right)$, is equal to the maximum likelihood estimate for the parameter of the multiple binomial parameterised probability density function,

$$
\left\{\tilde{E}_{\mathrm{o}}^{\square}\right\}=\operatorname{maxd}\left(\operatorname{mlf}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}^{\square}\right)\right)=\operatorname{maxd}\left(\operatorname{mblf}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}^{\square}\right)\right)
$$

That is, the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the generalised multinomial probability distribution, $\hat{Q}_{\mathrm{m}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$.

Again, the maximum likelihood estimate can also be written as the maximisation of the complete congruent histograms of unit size,

$$
\left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E, \hat{Q}_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}\right\}\right)
$$

and the normalised mean of the generalised multinomial probability distribution at the maximum likelihood estimate equals the maximum likelihood estimate of the distribution histogram,

$$
\operatorname{normalise}\left(\operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}\left(\tilde{E}_{\mathrm{o}}, z_{\mathrm{o}}\right)\right)\right)=\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

In the multinomial distribution one of the states is not free, because $\operatorname{sum}\left(\hat{A}_{o}\right)=$ $z_{0}$, but the maximum likelihood estimate remains constrained to completely effective sample histogram, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$. This would be the case even if the distribution history size, $z_{\mathrm{h}}$, were known.

Finally, the maximum likelihood estimate for the parameter of the historical parameterised probability density function corresponding to the stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, U}$, is conjectured to be the same as the maximum likelihood estimate for the parameter of the multinomial parameterised probability density function, $\operatorname{maxd}\left(\operatorname{mlf}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}^{\square}\right)\right)$. That is, the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$.

To conclude, in classical induction where (i) the history probability function is historically distributed, $P=P_{U, X, H_{\mathrm{h}}}$, (ii) the volume is non-singleton, $v_{\mathrm{o}}>1$, and (iii) the sample histogram is completely effective, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$, the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, is simply estimated to be equal to the sample probability histogram, $\hat{A}_{\mathrm{o}}$,

$$
\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

Consider the maximum likelihood estimate of the generalised multinomial probability distribution, $\hat{Q}_{\mathrm{m}, U}(E, z)$, in the case where the distribution is the maximum likelihood estimate, $\tilde{E}=\hat{A}$. The logarithm of the generalised multinomial probability is

$$
\ln \hat{Q}_{\mathrm{m}, U}(A, z)(A)=\ln z!-z \ln z-\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!+\sum_{S \in A^{\mathrm{FS}}} A_{S} \ln A_{S}
$$

Applying Stirling's approximation, $\ln n!=n \ln n-n+\mathrm{O}(\ln n)$, the log likelihood varies against the sum of the logarithm of the histogram

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{m}, U}(A, z)(A) & \sim-\sum_{S \in A^{\mathrm{FS}}} \ln A_{S} \\
& =-\operatorname{sum}(\ln (A))
\end{aligned}
$$

where $\ln \in(\mathcal{X} \rightarrow \mathbf{Q}) \rightarrow\left(\mathcal{X} \rightarrow \ln \mathbf{Q}_{>0}\right)$ is defined as $\ln (X):=\{(x, \ln q):$ $(x, q) \in X, q>0\}$. This is to say that the likelihood varies against the product of the counts of the histogram,

$$
\hat{Q}_{\mathrm{m}, U}(A, z)(A) \sim 1 / \prod_{S \in A^{\mathrm{FS}}} A_{S}
$$

The sum of the logarithm of the histogram varies with the entropy of the histogram,

$$
\operatorname{sum}(\ln (A)) \sim \operatorname{entropy}(A)
$$

The so the log-likelihood varies against the histogram entropy,

$$
\ln \hat{Q}_{\mathrm{m}, U}(A, z)(A) \sim-\operatorname{entropy}(A)
$$

Note that the entropy is not scaled by the size.
In classical induction where (i) the history probability function is historically distributed, $P=P_{U, X, H_{\mathrm{h}}}$, (ii) the volume is non-singleton, $v_{\mathrm{o}}>1$, and (iii) the sample histogram is completely effective, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$, the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, so, if it is also the case that (iv) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{\mathrm{o}}$, and such that (v) the scaled probability sample histogram is integral, $A_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$ where $A_{\mathrm{o}, z_{\mathrm{h}}}=\operatorname{scalar}\left(z_{\mathrm{h}}\right) * \hat{A}_{\mathrm{o}}$, then the log likelihood of the stuffed historical probability distribution at the maximum likelihood estimate (a) varies against the sum of the logarithm of the sample histogram

$$
\ln \hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\operatorname{sum}\left(\ln \left(A_{\mathrm{o}}\right)\right)
$$

and (b) varies against the sample entropy

$$
\ln \hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\operatorname{entropy}\left(A_{\mathrm{o}}\right)
$$

The Fisher information of the parameter $p$ of the binomial parameterised probability density function, $\operatorname{bppdf}(n)(p)$, is the second moment of the loglikelihood sensitivity,

$$
\begin{aligned}
I_{\operatorname{bppdf}(n)}(p) & :=\int_{0}^{n}(\mathrm{~d}(\ln \circ \operatorname{blf}(n)(k))(p))^{2} \times \operatorname{bppdf}(n)(p)(k) d k \\
& =\frac{n}{p(1-p)}
\end{aligned}
$$

where $n>0$ and $0<p<1$. The Fisher information of the parameter, $I_{\mathrm{bppdf}(n)}(p)$, is minimised where $p=0.5$. In this case the Fisher information is $I_{\mathrm{bppdf}(n)}(0.5)=4 n$. If an observation coordinate is $k_{\mathrm{o}}=n / 2$, then the maximum likelihood estimate, $\tilde{p}=k_{\circ} / n=0.5$, minimises the Fisher information. The Fisher information is maximised at the extremes of the parameter. As the parameter, $p$, tends to zero or one, the Fisher information tends to infinity. The Fisher information is proportional to the size, $n$.

The multiple binomial parameterised probability density function, $\operatorname{mbppdf}(z)$, is the product of a set of independent binomial parameterised probability density functions, $\operatorname{bppdf}(z)$, so the Fisher information of the multiple binomial parameterised probability density function is the sum,

$$
\begin{aligned}
I_{\operatorname{mbppdf}(z)}(E) & =\sum_{i \in\{1 \ldots v\}} I_{\mathrm{bppdf}(z)}\left(E_{i}\right) \\
& =\sum_{i \in\{1 \ldots v\}} \frac{z}{E_{i}\left(1-E_{i}\right)}
\end{aligned}
$$

where $z \in \mathbf{N}_{>0}$ and $E \in \mathbf{R}_{(0,1)}^{v}$.
The sum sensitivity of the generalised multiple binomial probability distribution, $\hat{Q}_{\mathrm{b}, U}(E, z)$, to the distribution histogram, $E$, is defined as the Fisher information of the multiple binomial parameterised probability density function, $\operatorname{mbppdf}(z)$. Define the sensitivity of a state for a complete distribution as sensitivity $(U) \in \mathcal{Q}_{U} \rightarrow\left(\mathcal{S}_{U} \rightarrow \mathbf{R}_{\geq 0}\right)$, and for the generalised multiple binomial probability distribution as

$$
\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{b}, U}(E, z)\right)(S):=\frac{z}{\hat{E}_{S}\left(1-\hat{E}_{S}\right)}
$$

where $\hat{E}_{S} \notin\{0,1\}$. The sum sensitivity is

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{b}, U}(E, z)\right)\right):=\sum_{S \in E^{\mathrm{FS}}} \frac{z}{\hat{E}_{S}\left(1-\hat{E}_{S}\right)}
$$

where $\left|E^{\mathrm{F}}\right|>1$.
In the case of non-singleton volume, $v>1$, and completely effective distribution histogram, $E^{\mathrm{F}}=V^{\mathrm{C}}$, the sensitivity is equal to the Fisher information,

$$
\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{b}, U}(E, z)\right)(S):=I_{\mathrm{bppdf}(z)}\left(\hat{E}_{i}^{\mathrm{]}}\right)=\frac{z}{\hat{E}_{S}\left(1-\hat{E}_{S}\right)}
$$

where $S \in V^{\mathrm{CS}}$ and $i \in\{1 \ldots v\}$ corresponds to $S$. The sum sensitivity is

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{b}, U}(E, z)\right)\right):=I_{\operatorname{mbppdf}(z)}\left(\hat{E}^{\mathbb{d}}\right)=\sum_{S \in V^{\mathrm{CS}}} \frac{z}{\hat{E}_{S}\left(1-\hat{E}_{S}\right)}
$$

The sensitivity of the generalised multinomial probability distribution, $\hat{Q}_{\mathrm{m}, U}(E, z)$, is conjectured to be equal to sensitivity of the generalised multiple binomial probability distribution, $\hat{Q}_{\mathrm{b}, U}(E, z)$,
$\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)(S)=\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{b}, U}(E, z)\right)(S)=\frac{z}{\hat{E}_{S}\left(1-\hat{E}_{S}\right)}$
and hence the sum sensitivities are equal

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right) & =\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{b}, U}(E, z)\right)\right) \\
& =\sum_{S \in V^{\mathrm{CS}}} \frac{z}{\hat{E}_{S}\left(1-\hat{E}_{S}\right)}
\end{aligned}
$$

The sum sensitivity varies with size,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right) \sim z
$$

The variance of state $S$ in the generalised multinomial probability distribution is

$$
\operatorname{var}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)(S)=z \hat{E}_{S}\left(1-\hat{E}_{S}\right)
$$

The sum variance is shown in 'Multinomial distributions', above, to vary with the scaled entropy,

$$
\operatorname{sum}\left(\operatorname{var}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right) \sim z \times \operatorname{entropy}(E)
$$

The sensitivity varies against the variance,

$$
\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)(S) \sim-\operatorname{var}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)(S)
$$

so the sum sensitivity varies against the scaled entropy,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right) \sim-z \times \operatorname{entropy}(E)
$$

The entropy is maximised, and the sum sensitivity minimised, when the distribution histogram is uniform, $E=V^{\mathrm{C}}$,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}}, z\right)\right)\right)=\frac{v^{2} z}{(v-1)}
$$

where $v=\left|V^{\mathrm{C}}\right|>1$. For large volume, $v \gg 1$, the uniform sum sensitivity is asymptotically proportionate to the volume, $v$. That is, sample histograms that have large volumes and sizes tend to be more sensitive to the distribution histogram, $E$, than smaller sample histograms.

The sensitivity of the stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, U}(E, z)$, is conjectured to vary with the sensitivity of the generalised multinomial probability distribution, $\hat{Q}_{\mathrm{m}, U}(E, z)$, and hence the sum sensitivities also vary together

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}(E, z)\right)\right) & \sim \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right) \\
& =\sum_{S \in V^{\mathrm{CS}}} \frac{z}{\hat{E}_{S}\left(1-\hat{E}_{S}\right)}
\end{aligned}
$$

As the distribution history size exceeds the sample size, $z_{E} \gg z$, in the limit the sum sensitivity of the stuffed historical probability distribution tends to equal the sum sensitivity of the generalised multinomial probability distribution,

$$
\lim _{z_{E} \rightarrow \infty} \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}(E, z)\right)\right)=\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right)
$$

In classical induction where (i) the history probability function is historically distributed, $P=P_{U, X, H_{\mathrm{h}}}$, (ii) the volume is non-singleton, $v_{\mathrm{o}}>1$, and (iii) the sample histogram is completely effective, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$, the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, so, if it is also the case that (iv) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{\mathrm{o}}$, and such that (v) the scaled probability sample histogram is integral, $A_{0, z_{\mathrm{h}}} \in \mathcal{A}_{\mathfrak{i}}$, then (a) the sum sensitivity of the
stuffed historical probability distribution at the maximum likelihood estimate is approximately

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \approx \sum_{S \in V_{\mathrm{o}}^{\mathrm{CS}}} \frac{z_{\mathrm{o}}}{\hat{A}_{\mathrm{o}}(S)\left(1-\hat{A}_{\mathrm{o}}(S)\right)}
$$

(b) the sum sensitivity varies against the size scaled entropy,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}}\right)
$$

The sum sensitivity varies against the size scaled entropy, and the loglikelihood also varies against the entropy, albeit not size scaled, so conjecture that the sum sensitivity varies weakly with the log-likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim \ln \hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

This is consistent with the discussion in appendix 'Likelihood functions and Fisher information' where it is conjectured that, in some cases, the sensitivity of the probability density function to parameter at the maximum likelihood estimate varies with the log-likelihood.

In the discussion above of the maximum likelihood estimate and sum sensitivity in classical induction, the sample histogram is constrained to be completely effective, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$. This allows the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, to be made by deriving the likelihood function of the historical parameterised probability density function from the binomial likelihood function,

$$
\operatorname{blf}(n)(k)(p):=\frac{n!}{\Gamma_{!} k \Gamma_{!}(n-k)} p^{k}(1-p)^{n-k}
$$

which is only defined for non-zero, non-unit parameter, $0<p<1$.
Similarly, the sum sensitivity is derived from the Fisher information of the binomial likelihood function. The Fisher information tends to infinity in the limit,

$$
\lim _{p \rightarrow 0} I_{\operatorname{bppdf}(n)}(p)=\lim _{p \rightarrow 0} \frac{n}{p(1-p)}=\infty
$$

If it is the case that the sample histogram is neither singleton nor completely effective, $1<\left|A_{\mathrm{o}}^{\mathrm{F}}\right|<v_{\mathrm{o}}$, then the coordinate has smaller, but not unit, dimension, $\left(\hat{A}_{\mathrm{o}} * A_{\mathrm{o}}^{\mathrm{F}}\right)^{\rrbracket} \in \mathcal{R}_{(0,1)}^{\left|A_{\mathrm{o}}^{\mathrm{F}}\right|} \notin\left\{\{1\}, \mathcal{R}_{(0,1)}^{v_{\mathrm{o}}}\right\}$, and so the maximum likelihood estimate and sum sensitivity must be restricted to a subset of the cartesian
states, $A_{\mathrm{o}}^{\mathrm{FS}} \subset V_{\mathrm{o}}^{\mathrm{CS}}$. The maximum likelihood estimate for an incompletely effective non-singleton sample histogram is then

$$
\left(\tilde{E}_{\mathrm{o}} * A_{\mathrm{o}}^{\mathrm{F}}\right)^{\wedge}=\hat{A}_{\mathrm{o}}
$$

The maximum likelihood estimate for the ineffective states, $\tilde{E}_{\mathrm{o}} \backslash\left(\tilde{E}_{\mathrm{o}} * A_{\mathrm{o}}^{\mathrm{F}}\right)$, remains unknown. In addition, the effective normalising factor, $1 / \operatorname{size}\left(\tilde{E}_{\mathrm{o}} * A_{\mathrm{o}}^{\mathrm{F}}\right)$, is unknown.

Similarly, the approximation of the sum sensitivity is restricted to the effective states,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}} * A_{\mathrm{o}}^{\mathrm{F}}, z_{\mathrm{o}}\right)\right)\right) \approx \sum_{S \in A_{\mathrm{o}}^{\mathrm{FS}}} \frac{z_{\mathrm{o}}}{\hat{A}_{\mathrm{o}}(S)\left(1-\hat{A}_{\mathrm{o}}(S)\right)}
$$

This may be an underestimate, however, because of the unknown effective normalisation. The sum sensitivity of the ineffective states is unknown because there is no draw from $\tilde{E}_{\mathrm{o}} \backslash\left(\tilde{E}_{\mathrm{o}} * A_{\mathrm{o}}^{\mathrm{F}}\right)$.

The sum sensitivity of the stuffed historical probability distribution at the maximum likelihood estimate, $\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)$, can be related to queries on the maximum likelihood estimate of the distribution histogram, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$. Let non-zero histogram $Q \in \mathcal{A}_{U}$, be a query histogram in the variables $K=\operatorname{vars}(Q)$ that are a subset of the sample variables, $K \subseteq V_{0}$. The normalisation of the query histogram is a probability histogram, $\hat{Q} \in \mathcal{A} \cap \mathcal{P}$. The estimated transform induced from the maximum likelihood estimate, $\hat{A}_{\mathrm{o}}$, for the query variables, $K$, is $T_{\hat{A}_{\circ}, K}=\left(\hat{A}_{\mathrm{o}},\left(V_{\mathrm{o}} \backslash K\right)\right) \in \mathcal{T}$. The estimated transformed product is $\hat{Q} * T_{\hat{A}_{\mathrm{o}}, K}=\hat{Q} *\left(\hat{A}_{\mathrm{o}},\left(V_{\mathrm{o}} \backslash K\right)\right) \in \mathcal{A} \cap \mathcal{P}^{\prime}$. The estimated conditional transform induced from $\hat{A}_{o}$ and $K$ is $T_{\hat{A}_{o}, K}^{\prime}=$ $\left(\hat{A}_{\mathrm{o}} /\left(\hat{A}_{\mathrm{o}} \% K\right),\left(V_{\mathrm{o}} \backslash K\right)\right) \in \mathcal{T}$. In the case where the sample histogram is completely effective, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}} \Longrightarrow Q^{\mathrm{F}} \leq\left(A_{\mathrm{o}} \% K\right)^{\mathrm{F}}$, the estimated transformed conditional product is a probability histogram,

$$
\hat{Q} * T_{\hat{A}_{\mathrm{o}}, K}^{\prime}=\hat{Q} *\left(\frac{\hat{A}_{\mathrm{o}}}{\hat{A}_{\mathrm{o}} \% K},\left(V_{\mathrm{o}} \backslash K\right)\right) \in \mathcal{A} \cap \mathcal{P}
$$

The sum sensitivity is a property of the distribution, so, in the case where the query histogram consists of one effective state, $\left|Q^{\mathrm{F}}\right|=1 \Longrightarrow Q+K^{\mathrm{CZ}} \in$ $\mathcal{A}_{U, \mathrm{i}, K, 1}$, (i) expand the query histogram to the sample variables, $V_{o}$, and (ii) scale the expanded query histogram to the sample size, $z_{0}$. Now the estimated
transformed conditional product can be rewritten in terms of a draw of the sample size, $z_{0}$, from the distribution histogram

$$
\begin{aligned}
\hat{Q} * T_{\hat{A}_{\mathrm{o}}, K}^{\prime}= & \left.\left\{\left(N, \hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, 1\right)\left(\hat{Q} *\{N\}^{\mathrm{U}}+V_{\mathrm{o}}^{\mathrm{CZ}}\right)\right): N \in\left(V_{\mathrm{o}} \backslash K\right)\right)^{\mathrm{CS}}\right\}^{\wedge} \\
= & \left\{\left(N,\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(Z_{\mathrm{o}} * \hat{Q} *\{N\}^{\mathrm{U}}+V_{\mathrm{o}}^{\mathrm{CZ}}\right)\right)^{1 / z_{\mathrm{o}}}\right)\right. \\
& \left.\left.: N \in\left(V_{\mathrm{o}} \backslash K\right)\right)^{\mathrm{CS}}\right\}^{\wedge}
\end{aligned}
$$

where $Z_{\mathrm{o}}=\operatorname{scalar}\left(z_{\mathrm{o}}\right)$.
The application of the model induced from the maximum likelihood estimate to the query histogram, $\hat{Q}_{*} T_{\hat{A}_{o}, K}^{\prime}$, can be viewed as a probability function of label, $T^{\prime}\left(\hat{A}_{\mathrm{o}}, \hat{Q}\right) \in\left(\left(V_{\mathrm{o}} \backslash K\right)^{\mathrm{CS}} \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}$, parameterised by (i) the maximum likelihood estimate, $\hat{A}_{\mathrm{o}}$, and (ii) the query histogram, $Q$. The model application is relatively independent of the query state, $S_{Q}$ where $\left\{S_{Q}\right\}=Q^{\mathrm{FS}}$, and query variables, $K$. The model application depends on the geometric scaling of the historical distribution, $\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)$, so the query sensitivity to the distribution histogram varies with the sum sensitivity of the historical distribution at the maximum likelihood estimate divided by the sample size,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}} & \approx \sum_{S \in V_{\mathrm{o}}^{\mathrm{CS}}} \frac{1}{\hat{A}_{\mathrm{o}}(S)\left(1-\hat{A}_{\mathrm{o}}(S)\right)} \\
& \sim-\operatorname{entropy}\left(A_{\mathrm{o}}\right)
\end{aligned}
$$

That is, as the sample entropy increases, the sum sensitivity of the query to the model implied by the sample decreases.

If it is known that the label variables are a function of the query variables,

$$
\operatorname{split}\left(K, E_{\mathrm{o}}^{\mathrm{FS}}\right) \in K^{\mathrm{CS}} \rightarrow\left(V_{\mathrm{o}} \backslash K\right)^{\mathrm{CS}}
$$

then the distribution histogram, $E_{\mathrm{o}}$, is known to be ineffective, $E_{\mathrm{o}}^{\mathrm{F}}<V_{\mathrm{o}}^{\mathrm{C}}$, and so the sample histogram cannot be completely effective, $A_{\mathrm{o}}^{\mathrm{F}} \neq V_{\mathrm{o}}^{\mathrm{C}}$. However, the effectiveness of the distribution histogram in the query variables is not known, $\left(E_{0} \% K\right)^{\mathrm{F}} \leq K^{\mathrm{C}}$, unless the sample histogram is completely effective in the query variables, $\left(A_{0} \% K\right)^{\mathrm{F}}=K^{\mathrm{C}} \Longrightarrow\left(E_{0} \% K\right)^{\mathrm{F}}=K^{\mathrm{C}}$. So if the sample histogram is ineffective in the query variables, $\left(A_{0} \% K\right)^{\mathrm{F}}<K^{\mathrm{C}}$, then there still exists an unknown normalising factor,

$$
1 / \operatorname{size}\left(\tilde{E}_{\mathrm{o}} * A_{\mathrm{o}}^{\mathrm{F}} \% K\right)=1 / \operatorname{size}\left(\tilde{E}_{\mathrm{o}} * A_{\mathrm{o}}^{\mathrm{F}}\right)
$$

In this case the maximum likelihood estimate remains restricted,

$$
\begin{aligned}
\left(\tilde{E}_{\mathrm{o}} * A_{\mathrm{o}}^{\mathrm{F}} \% K\right)^{\wedge} & =\hat{A}_{\mathrm{o}} \% K \\
\left(\tilde{E}_{\mathrm{o}} * A_{\mathrm{o}}^{\mathrm{F}}\right)^{\wedge} & =\hat{A}_{\mathrm{o}}
\end{aligned}
$$

and the sum sensitivity may be an underestimate.

### 5.4 Classical independent induction

In classical induction it is assumed that the history probability function is historically distributed, $P=P_{U, X, H_{\mathrm{h}}}$. Consider the related case of classical independent induction where all drawn histories are known to be independent, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{x}}$, where the independent historically distributed history probability function $P_{U, X, H_{\mathrm{h}}, \mathrm{x}} \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}$, is

$$
\begin{aligned}
P_{U, X, H_{\mathrm{h}}, \mathrm{x}}:= & \left(\bigcup \left\{\left\{(H, 1): H \subseteq H_{\mathrm{h}} \% V_{H},|H|=z_{H}, A_{H}=A_{H}^{\mathrm{X}}\right\}^{\wedge}:\right.\right. \\
& \left.\left.V_{H} \subseteq V_{\mathrm{h}}, z_{H} \in\left\{1 \ldots z_{\mathrm{h}}\right\}\right\}\right)^{\wedge} \cup \\
& \left\{(H, 0): H \in \mathcal{H}_{U, X}, A_{H} \neq A_{H}^{\mathrm{X}}\right\} \cup \\
& \left\{(H, 0): H \in \mathcal{H}_{U, X}, H \nsubseteq H_{\mathrm{h}} \% V_{H}\right\} \cup\{(\emptyset, 0)\}
\end{aligned}
$$

That is, drawn histories are necessarily independent, $\forall H \in \mathcal{H}_{U, X}\left(P_{U, X, H_{\mathrm{h}}, \mathrm{x}}(H)>\right.$ $\left.0 \Longrightarrow A_{H}=A_{H}^{\mathrm{X}}\right)$.

Now, since drawing the distribution history, $H_{\mathrm{h}}$, itself is always possible, $P_{U, X, H_{\mathrm{h}}, \mathrm{X}}\left(H_{\mathrm{h}}\right)>0$, the distribution histogram is known to be independent, $E_{\mathrm{h}}=E_{\mathrm{h}}^{\mathrm{X}}$, as well as the sample histogram, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{X}}$. Given a drawn history $H \in \mathcal{H}_{U, X}$, where $P_{U, X, H_{\mathrm{h}}, \mathrm{X}}(H)>0$, the independent historical probability of histogram $A_{H}=\operatorname{histogram}(H)+V_{H}^{\mathrm{CZ}} \in \mathcal{A}_{U, \mathrm{i}, V_{H}, z_{H}}$ is now conditional,

$$
\hat{Q}_{\mathrm{h}, \mathrm{x}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right) \propto \sum\left(P_{U, X, H_{\mathrm{h}}, \mathrm{x}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}\right)
$$

where the independent conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{x}, U}$, is defined

$$
\begin{aligned}
\hat{Q}_{\mathrm{h}, \mathrm{x}, U}(E, z)= & \left\{\left(A, \frac{\hat{Q}_{\mathrm{h}, U}(E, z)(A)}{\sum\left(\hat{Q}_{\mathrm{h}, U}(E, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B=B^{\mathrm{X}}\right)}\right)\right. \\
& \left.: A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A=A^{\mathrm{x}}\right\} \cup \\
& \left\{(A, 0): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \neq A^{\mathrm{X}}\right\}
\end{aligned}
$$

The denominator, $\sum\left(\hat{Q}_{\mathrm{h}, U}(E, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B=B^{\mathrm{X}}\right)$, is a constant and so the independent conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{x}, U}$, is just the normalisation of the stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, U}$, where the histogram is independent,

$$
\begin{aligned}
\hat{Q}_{\mathrm{h}, \mathrm{x}, U}(E, z)= & \left\{\left(A, \hat{Q}_{\mathrm{h}, U}(E, z)(A)\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A=A^{\mathrm{x}}\right\}^{\wedge} \cup \\
& \left\{(A, 0): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \neq A^{\mathrm{x}}\right\}
\end{aligned}
$$

The maximum likelihood estimate now corresponds to

$$
\left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E^{\mathrm{X}}, \hat{Q}_{\mathrm{h}, \mathrm{x}, U}\left(E^{\mathrm{X}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}\right\}\right)
$$

Conjecture that, though the sample histogram, $A_{\mathrm{o}}=\tilde{\sim}_{\mathrm{o}}^{\mathrm{X}}$, is in the denominator, the maximum likelihood estimate is as before, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, because the distribution histogram, $E^{\mathrm{X}}$, is also independent. The sum sensitivity, however, is lower now. In section 'Alignment and independent histograms', above, it is shown that the multinomial probability density of an independent histogram $A^{\mathrm{X}}$ of size $z$ and variables $V$ drawn from an independent distribution $E^{\mathrm{X}}$ is approximately equal to the product of the multinomial probability densities of the reduced independent histogram $A^{\mathrm{X}} \%\{w\}$, where $w \in V$, drawn from the reduced independent distribution $E^{\mathrm{X}} \%\{w\}$

$$
\operatorname{mpdf}(U)\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right) \approx \prod_{w \in V} \operatorname{mpdf}(U)\left(E^{\mathrm{X}} \%\{w\}, z\right)\left(A^{\mathrm{X}} \%\{w\}\right)
$$

where the multinomial probability density function is defined

$$
\operatorname{mpdf}(U)(E, z):=\left\{\left(A, \frac{\Gamma_{!} z}{\prod_{S \in A^{S}} \Gamma_{!} A_{S}} \prod_{S \in A^{\mathrm{S}}} \hat{E}_{S}^{A_{S}}\right): A \in \mathcal{A}_{U, V, z}\right\}
$$

In this case where the sample histogram is integral, $A=A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, the generalised multinomial probability distribution approximates

$$
\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right) \approx \prod_{w \in V} \hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}} \%\{w\}, z\right)\left(A^{\mathrm{X}} \%\{w\}\right)
$$

and therefore the sum sensitivity of the numerator is the sum of the sum sensitivities of the perimeter, which is less than the sum sensitivity of the volume,

$$
\begin{aligned}
\sum_{w \in V} \operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{m}, U}\right.\right. & \left.\left.\left(E^{\mathrm{X}} \%\{w\}, z\right)\right)\right) \\
& =\sum_{w \in V} \sum_{S \in\{w\} \mathrm{CS}} \frac{z}{\hat{E}^{\mathrm{x}} \%\{w\}(S)\left(1-\hat{E}^{\mathrm{X}} \%\{w\}(S)\right)} \\
& \leq \sum_{S \in V^{\mathrm{CS}}} \frac{z}{\hat{E}_{S}\left(1-\hat{E}_{S}\right)} \\
& =\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}\left(E^{\mathrm{X}}, z\right)\right)\right)
\end{aligned}
$$

The sum sensitivity of independent conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{x}, U}$, is conjectured to be less than the sum sensitivity of the
numerator because the denominator has sum sensitivity

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{h}, \mathrm{x}, U}\right.\right. & \left.\left.\left(E^{\mathrm{X}}, z\right)\right)\right) \\
& \leq \sum_{w \in V} \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(E^{\mathrm{X}} \%\{w\}, z\right)\right)\right)
\end{aligned}
$$

The perimeter sum sensitivities are minimised when the distribution histogram is uniform, $E=V^{\mathrm{C}}$, and so the perimeters are uniform, $\forall w \in$ $V\left((E \%\{w\})^{\wedge}=\left(\{w\}^{\mathrm{C}}\right)^{\wedge}\right)$. In the case of regular distribution histogram of dimension $n=|V|$ and valency $\{d\}=\left\{\left|U_{w}\right|: w \in V\right\}$, the minimum sum sensitivity is
$\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{x}, U}\left(V^{\mathrm{C}}, z\right)\right)\right) \leq \frac{n d z}{(d-1)} \leq d^{n} z \leq \frac{d^{2 n} z}{\left(d^{n}-1\right)}=\frac{v^{2} z}{(v-1)}$
where $v=\left|V^{\mathrm{C}}\right|>1$. That is, in the independent case, sum sensitivity varies with dimension, $n$, rather than volume, $v$.

In classical independent induction where (i) the history probability function is independent historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{X}}$, (ii) the volume is non-singleton, $v_{0}>1$, and (iii) the sample histogram is completely effective, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$, the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the independent conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{x}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, so, if it is also the case that (iv) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{\mathrm{o}}$, and such that ( v ) the scaled probability sample histogram is integral, $A_{o, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the sum sensitivity of the independent conditional stuffed historical probability distribution at the maximum likelihood estimate varies as the sum of the perimeter sum sensitivities,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{x}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim \sum_{w \in V_{\mathrm{o}},} \sum_{S \in\{w\} \mathrm{CS}} \frac{z_{\mathrm{o}}}{\hat{A}_{\mathrm{o}}^{\mathrm{X}} \%\{w\}(S)\left(1-\hat{A}_{\mathrm{o}}^{\mathrm{X}} \%\{w\}(S)\right)}
$$

Given a mono-effective query histogram $Q=\left\{S_{Q}\right\}^{\mathrm{U}}$, where $S_{Q} \in K^{\mathrm{CS}}$ and $K \subset V_{\mathrm{o}}$, the estimated transformed conditional product is $\hat{Q} * T_{\hat{A}_{o}, K}^{\prime}$, where the estimated conditional transform induced from the sample histogram, $\hat{A}_{\mathrm{o}}$, and the query variables, $K$, is $T_{\hat{A}_{o}, K}^{\prime}=\left(\hat{A}_{\mathrm{o}} /\left(\hat{A}_{\mathrm{o}} \% K\right),\left(V_{\mathrm{o}} \backslash K\right)\right)$. The query sensitivity varies as the sum sensitivity of the independent conditional historical distribution at the maximum likelihood estimate divided by the sample
size,

$$
\begin{aligned}
& \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{x}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}} \sim \\
& \qquad \sum_{w \in V_{\mathrm{o}}} \sum_{S \in\{w\} \mathrm{CS}} \frac{1}{\hat{A}_{\mathrm{o}}^{\mathrm{X}} \%\{w\}(S)\left(1-\hat{A}_{\mathrm{o}}^{\mathrm{X}} \%\{w\}(S)\right)}
\end{aligned}
$$

Of course, in the case of independent sample histogram, $\hat{A}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{X}}$, the label variables, $V_{\mathrm{o}} \backslash K$, are independent of the query variables, $K$, and so the estimated transformed conditional product is trivial,

$$
\hat{Q} * T_{\hat{A}_{\mathrm{o}}^{\mathrm{x}}, K}^{\prime}=\hat{A}_{\mathrm{o}}^{\mathrm{x}} \%\left(V_{\mathrm{o}} \backslash K\right)
$$

That is, in spite of lower query sensitivity to the estimate of the unknown distribution histogram, $E_{\mathrm{o}}^{\mathrm{X}}$, there is no functional or causal relation between the query variables and the label variables,

$$
\operatorname{split}\left(K, \hat{A}_{\mathrm{o}}^{\mathrm{XFS}}\right) \notin K^{\mathrm{CS}} \rightarrow\left(V_{\mathrm{o}} \backslash K\right)^{\mathrm{CS}}
$$

This is true for any query in the contrived case of independent historically distributed history probability function, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{x}}$.

### 5.5 Classical modelled induction

Having considered (i) the case of classical induction, where the history probability function is historically distributed, $P=P_{U, X, H_{\mathrm{h}}}$, and (ii) the special case of classical independent induction where the history probability function is independent historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{x}}$, now consider (iii) the special case of classical modelled induction.

### 5.5.1 Necessary derived

Given some known substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, the derived histogram of the distribution probability histogram is $\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}$. In classical modelled induction, while the distribution probability histogram, $\hat{E}_{\mathrm{h}}$, remains unknown, the derived distribution probability histogram, $\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}$, is known and necessary. That is, the history probability function, $P$, is historically distributed but constrained such that all drawn histories have a derived probability histogram equal to the known derived distribution probability histogram, $\hat{A}_{H} * T_{\mathrm{o}}=\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}$. Define the iso-derived historically distributed
history probability function $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{o}} \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}$,

$$
\begin{aligned}
& P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, T_{\mathrm{o}}}:= \\
& \qquad \begin{array}{l}
\left(\bigcup \left\{\left\{(H, 1): H \subseteq H_{\mathrm{h}} \% V_{H},|H|=z_{H}, \hat{A}_{H} * T_{\mathrm{o}}=\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right\}^{\wedge}:\right.\right. \\
\left.\left.\quad V_{H} \subseteq V_{\mathrm{h}}, z_{H} \in\left\{1 \ldots z_{\mathrm{h}}\right\}\right\}\right)^{\wedge} \cup \\
\quad\left\{(H, 0): H \in \mathcal{H}_{U, X}, \hat{A}_{H} * T_{\mathrm{o}} \neq \hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right\} \cup \\
\left\{(H, 0): H \in \mathcal{H}_{U, X}, H \nsubseteq H_{\mathrm{h}} \% V_{H}\right\} \cup\{(\emptyset, 0)\}
\end{array}
\end{aligned}
$$

For drawn histories the derived probability histogram is necessary, $\forall H \in$ $\mathcal{H}_{U, X}\left(P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{\mathrm{o}}}(H)>0 \Longrightarrow \hat{A}_{H} * T_{\mathrm{o}}=\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)$. Not all sizes and sets of variables are necessarily drawable. That is, in some cases, $\exists z \in$ $\left\{1 \ldots z_{\mathrm{h}}\right\} \exists V \subseteq V_{\mathrm{h}} \forall H \in \mathcal{H}_{U, X}\left(\left(z_{H}=z\right) \wedge\left(V_{H}=V\right) \Longrightarrow P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{\mathrm{o}}}(H)=\right.$ 0 ). A size $z \in\left\{1 \ldots z_{\mathrm{h}}\right\}$ can be drawn if (i) the variables $V \subseteq V_{\mathrm{h}}$ are a superset of the transform underlying, und $\left(T_{\mathrm{o}}\right)$, and (ii) the scaled derived distribution histogram, $\operatorname{scalar}(z) * \hat{E}_{\mathrm{h}} * T_{\mathrm{o}}$, is integral,

$$
\begin{aligned}
& \left(\operatorname{und}\left(T_{\mathrm{o}}\right) \subseteq V\right) \wedge\left(\operatorname{scalar}(z) * \hat{E}_{\mathrm{h}} * T_{\mathrm{o}} \in \mathcal{A}_{\mathrm{i}}\right) \Longrightarrow \\
& \quad \exists H \in \mathcal{H}_{U, X}\left(\left(z_{H}=z\right) \wedge\left(V_{H}=V\right) \wedge\left(P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, T_{\mathrm{o}}}(H)>0\right)\right)
\end{aligned}
$$

The distribution history can always be drawn, so the probability function is not a weak probability function, $\sum_{H \in \mathcal{H}_{U, X}} P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{\mathrm{o}}}(H)=1$.

All iso-derived subsets of the distribution history for a given set of variables and size are defined as equally probable,

$$
\begin{aligned}
& \forall V \subseteq V_{\mathrm{h}} \forall H, G \subseteq H_{\mathrm{h}} \% V \\
& \quad\left(A_{G} * T_{\mathrm{o}}=A_{H} * T_{\mathrm{o}} \Longrightarrow P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, T_{\mathrm{o}}}(G)=P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, T_{\mathrm{o}}}(H)\right)
\end{aligned}
$$

In classical modelled induction the history probability function is iso-derived historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{\mathrm{o}}}$.

Given a drawn history $H \in \mathcal{H}_{U, X}$, where $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{\mathrm{o}}}(H)>0$, the iso-derived historical probability of histogram $A_{H}=\operatorname{histogram}(H)+V_{H}^{\mathrm{CZ}} \in \mathcal{A}_{U, \mathrm{i}, V_{H}, z_{H}}$ is now conditional,

$$
\begin{aligned}
& \frac{Q_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right)}{\sum_{B \in D_{U,,, T_{\mathrm{o}}, z_{H}}^{-1}\left(A_{H} * T_{\mathrm{o}}\right)} Q_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)(B)}= \\
& \frac{\sum P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, T_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}}{\sum P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, T_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, V_{G}=V_{H},|G|=z_{H}}
\end{aligned}
$$

The iso-derived historical probability may be expressed in terms of a histogram distribution which is not explicitly conditional on the necessary derived, $\hat{E}_{\mathrm{h}}$ * $T_{\mathrm{o}}$,

$$
\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right) \propto \sum\left(P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, T_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}\right)
$$

where the iso-derived conditional stuffed historical probability distribution is defined

$$
\left.\left.\left.\begin{array}{rl}
\hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U} & (E, z) \\
:= & \left\{\left(A, \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum_{B \in D_{U, i}^{-1}, T, z}^{-1}(A * T)} Q_{\mathrm{h}, U}(E, z)(B)\right.\right.
\end{array}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \leq E\right\}^{\wedge} \cup\right\}
$$

which is defined if $z \leq \operatorname{size}(E)$. The derived histogram valued integral histogram function $D_{U, \mathbf{i}, T, z}$ is defined

$$
D_{U, \mathbf{i}, T, z}=\left\{(A, A * T): A \in \mathcal{A}_{U, \mathbf{i}, V, z}\right\}
$$

The finite set of iso-deriveds of derived histogram $A * T$ is

$$
D_{U, \mathbf{i}, T, z}^{-1}(A * T)=\left\{B: B \in \mathcal{A}_{U, i, V, z}, B * T=A * T\right\}
$$

which is such that the lifted iso-deriveds is a singleton, $\{B * T: B \in$ $\left.\mathcal{A}_{U, \mathrm{i}, V, z}, B * T=A * T\right\}=\{A * T\}$.

In the case where all the derived are possible,

$$
\forall A^{\prime} \in \operatorname{ran}\left(D_{U, \mathbf{i}, T, z}\right) \exists A \in \mathcal{A}_{U, \mathbf{i}, V, z}\left(\left(A * T=A^{\prime}\right) \wedge(A \leq E)\right)
$$

the normalisation of the iso-derived conditional stuffed historical probability distribution is a fraction $1 /\left|\operatorname{ran}\left(D_{U, i, T, z}\right)\right|$,

$$
\begin{aligned}
& \hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U}(E, z) \\
& \quad=\left\{\left(A, \frac{1}{\left|\operatorname{ran}\left(D_{U, \mathrm{i}, T, z}\right)\right|} \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum_{B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)} Q_{\mathrm{h}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
\end{aligned}
$$

The case of possible derived is equivalent to possible iso-derived, $\forall A^{\prime} \in$ $\operatorname{ran}\left(D_{U, \mathrm{i}, T, z}\right)\left(\sum_{B \in D_{U, i, T, z}^{-1}\left(A^{\prime}\right)} Q_{\mathrm{h}, U}(E, z)(B)>0\right)$. All derived are possible in the case where the least count of the distribution histogram is greater than or equal to the sample size, $z \leq \operatorname{mind}\left(E_{\mathrm{h}}\right)$.

In the case of possible derived the iso-derived historical probability is

$$
\begin{aligned}
& \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right)= \\
& \quad \frac{1}{\left|\operatorname{ran}\left(D_{U, \mathrm{i}, T_{\mathrm{o}}, z_{H}}\right)\right|} \frac{\sum P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, T_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}}{\sum P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, T_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, V_{G}=V_{H},|G|=z_{H}}
\end{aligned}
$$

In the case of a full functional transform, $T_{\mathrm{s}}=\left\{\{w\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: w \in V\right\}^{\mathrm{T}}$, the iso-derived is a singleton of the sample histogram, $D_{U, i, T_{\mathrm{s}}, z}^{-1}\left(A * T_{\mathrm{s}}\right)=\{A\}$, and so the denominator equals the numerator, $\sum_{B \in D_{U, i, T, T_{s}, z}^{-1}\left(A * T_{\mathrm{s}}\right)} Q_{\mathrm{h}, U}(E, z)(B)=$ $Q_{\mathrm{h}, U}(E, z)(A)$. Thus the scaled iso-derived historically distributed history probability is certain, $\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right| \times \hat{Q}_{\mathrm{h}, \mathrm{d}, T_{s}, U}(E, z)(Z * \hat{E})=1$, where $Z=$ $\operatorname{scalar}(z)$. In this case, the distribution probability histogram, $\hat{E}$, is known, because $\hat{E} * T_{\text {s }}$ is known, and so everything is known.

At the other extreme of a unary transform, $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$, the iso-derived includes all substrate histograms, $D_{U,, 1, T_{\mathrm{u}}, z}^{-1}\left(A * T_{\mathrm{u}}\right)=\mathcal{A}_{U, \mathrm{i}, V, z}$, and the normalised denominator is one, $\sum_{B \in D_{U, i, T, z}^{-1}\left(A * T_{\mathrm{u}}\right)} \hat{Q}_{\mathrm{h}, U}(E, z)(B)=1$. Thus the isoderived conditional stuffed historical probability distribution equals the underlying stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{\mathrm{u}}, U}(E, z)=\hat{Q}_{\mathrm{h}, U}(E, z)$. In this case, nothing is known, because $\hat{E} * T_{\mathrm{u}}=\left\{\left(\left\{\left(\left\{V^{\mathrm{CS}}\right\}, V^{\mathrm{CS}}\right)\right\}, 1\right)\right\}$ is trivially known. In this case classical modelled induction reduces to classical induction.

The iso-derived conditional generalised multinomial probability distribution is defined

$$
\begin{aligned}
& \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(E, z) \\
&:=\left\{\left(A, \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in D_{U, i, T, z}^{-1}(A * T)} Q_{\mathrm{m}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A^{\mathrm{F}} \leq E^{\mathrm{F}}\right\}^{\wedge} \cup \\
&\left\{(A, 0): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A^{\mathrm{F}} \neq E^{\mathrm{F}}\right\}
\end{aligned}
$$

which is defined if $\operatorname{size}(E)>0$.
The case where all the derived are possible is weaker than for historical,

$$
\forall A^{\prime} \in \operatorname{ran}\left(D_{U, \mathbf{i}, T, z}\right) \exists A \in \mathcal{A}_{U, \mathrm{i}, V, z}\left(\left(A * T=A^{\prime}\right) \wedge\left(A^{\mathrm{F}} \leq E^{\mathrm{F}}\right)\right)
$$

In this case the iso-derived conditional generalised multinomial probability distribution is

$$
\begin{aligned}
& \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(E, z) \\
& \quad=\left\{\left(A, \frac{1}{\left|\operatorname{ran}\left(D_{U, i, T, z}\right)\right|} \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in D_{U, i, T, z}^{-1}(A * T)} Q_{\mathrm{m}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
\end{aligned}
$$

Let $A_{\mathrm{o}} \in \mathcal{A}_{U, \mathrm{i}, V_{0}, z_{\mathrm{o}}}$ be a known sample integral histogram of size $z_{\mathrm{o}}$ in the underlying variables of the transform $V_{\mathrm{o}}=\operatorname{und}\left(T_{\mathrm{o}}\right)$. It is assumed that the distribution history size, $z_{\mathrm{h}}$, is large with respect to the sample size $z_{0}=\operatorname{size}\left(A_{0}\right)$, so that, in the limit, the iso-derived historical probability, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$, approximates to the iso-derived multinomial probability, $\hat{Q}_{\mathrm{m}, \mathrm{d}, T_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$. That is, if $z_{\mathrm{o}} \ll z_{\mathrm{h}}$ then

$$
\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \approx \hat{Q}_{\mathrm{m}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

where $E_{\mathrm{o}}=E_{\mathrm{h}} \% V_{\mathrm{o}}$.
The iso-derived conditional generalised multinomial parameterised probability density function, $\operatorname{mdtppdf}(T, z) \in \operatorname{ppdfs}(v, v)$, and iso-derived conditional generalised multinomial likelihood function, $\operatorname{mdtlf}(T, z) \in \operatorname{lfs}(v, v)$, corresponding to the iso-derived conditional generalised multinomial probability distribution, $\hat{Q}_{\mathrm{m}, \mathrm{d}, T, U}$, are not given explicitly here, but are such that

$$
\operatorname{mdtppdf}(T, z)\left(\hat{E}^{\mathbb{\square}}\right)\left(A^{\mathbb{\square}}\right)=\operatorname{mdtlf}(T, z)\left(A^{\rrbracket}\right)\left(\hat{E}^{\mathbb{\square}}\right)=\hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(E, z)(A)
$$

Now in the case of classical modelled induction where the transform, $T_{\mathrm{o}}$, is known, the real maximum likelihood estimate $\tilde{E}_{o}^{\prime} \in \mathbf{R}_{(0,1)}^{v_{o}}$ for the parameter of the iso-derived multinomial parameterised probability density function is

$$
\left\{\tilde{E}_{\mathrm{o}}^{\prime}\right\}=\operatorname{maxd}\left(\operatorname{mdtlf}\left(T_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}^{\square}\right)\right)
$$

which is such that $\forall i \in\left\{1 \ldots v_{\mathrm{o}}\right\}\left(\partial_{i}\left(\operatorname{mdtlf}\left(T_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}^{\square}\right)\right)\left(\tilde{E}_{\mathrm{o}}^{\prime}\right)=0\right)$. The maximum likelihood estimate $\tilde{E}_{\mathrm{o}}^{\prime}$ is only defined in the case where the sample histogram is completely effective, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}} \Longrightarrow \hat{A}_{\mathrm{o}}^{\square} \in \mathbf{R}_{(0,1)}^{v_{\mathrm{o}}}$, because the binomial likelihood function is only defined for the open set. That is, $\mathrm{d}\left(\operatorname{blf}\left(z_{0}\right)(0)\right)$ is undefined and so the derivative of the iso-derived multinomial parameterised probability density function is undefined where there are ineffective states.

In the case of completely effective sample histogram, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$, the maximisation for known transform, $T_{\mathrm{o}}$, of the iso-derived conditional generalised
multinomial probability parameterised by the complete congruent histograms of unit size is a singleton of the rational maximum likelihood estimate

$$
\left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}\right\}\right)
$$

The real maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}^{\prime}$, is not necessarily a rational coordinate, $\mathbf{R}_{(0,1)}^{v_{0}} \supset \mathbf{Q}_{(0,1)}^{v_{o}}$, and so the rational maximum likelihood estimate is not necessarily equal to the real maximum likelihood estimate. However, it is conjectured that the maximisation of the distribution approximates to the maximisation of the likelihood function,

$$
\tilde{E}_{\mathrm{o}}^{\square} \approx \tilde{E}_{\mathrm{o}}^{\prime}
$$

In the case where the sample histogram is not completely effective, $A_{\mathrm{o}}^{\mathrm{F}}<V_{\mathrm{o}}^{\mathrm{C}}$, the maximisation of the iso-derived conditional generalised multinomial probability distribution for known transform is well defined, unlike the parameterised probability density function, but is not necessarily a singleton

$$
\left|\max \left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}\right\}\right)\right| \geq 1
$$

In the case where the maximisation of the iso-derived conditional generalised multinomial probability distribution is a singleton, it is equal to the normalised derived-dependent, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{D}\left(T_{0}\right)}$, where the derived-dependent $A^{\mathrm{D}(T)} \in \mathcal{A}_{U, V, z}$ is defined in 'Likely histograms', above, as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, $A$, conditional that it is an iso-derived,

$$
\left\{A^{\mathrm{D}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

The derived-dependent, $A^{\mathrm{D}(T)}$, is sometimes not computable. The finite approximation to the derived-dependent is

$$
\begin{aligned}
& \left\{A_{k}^{\mathrm{D}(T)}\right\}= \\
& \quad \quad \operatorname{maxd}\left(\left\{\left(D / Z_{k}, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)}\right): D \in \mathcal{A}_{U, \mathrm{i}, V, k z}\right\}\right)
\end{aligned}
$$

The approximation, $A_{k}^{\mathrm{D}(T)} \approx A^{\mathrm{D}(T)}$, improves as the scaling factor, $k$, increases.

Unlike in classical non-modelled induction where the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, is equal to the sample probability histogram, $\hat{A}_{\mathrm{o}}$, in classical
modelled induction the maximum likelihood estimate is not necessarily equal to the sample probability histogram. It is only in the case where the sample histogram is natural that the maximum likelihood estimate is necessarily equal to the sample probability histogram,

$$
A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger} \Longrightarrow A_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)}=A_{\mathrm{o}} \Longrightarrow \tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

Otherwise, the overall maximum likelihood estimate, which is the deriveddependent, is near the histogram, $\tilde{E}_{\mathrm{o}} \sim \hat{A}_{\mathrm{o}}$, only in as much as it is far from the naturalisation, $\tilde{E}_{\mathrm{o}} \nsim \hat{A}_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$.

The requirement that the distribution history itself be drawable, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{\mathrm{o}}}\left(H_{\mathrm{h}}\right)>$ 0 , has been ignored so far. This requirement modifies the maximisation to add the constraint that the maximum likelihood estimate be iso-derived, $\tilde{E}_{\mathrm{o}} * T_{\mathrm{o}}=\hat{A}_{\mathrm{o}} * T_{\mathrm{o}}$,

$$
\left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}, E * T_{\mathrm{o}}=\hat{A}_{\mathrm{o}} * T_{\mathrm{o}}\right\}\right)
$$

So, strictly speaking, the maximum likelihood estimate is only approximately equal to the normalised derived-dependent, $\tilde{E}_{\mathrm{o}} \approx \hat{A}_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)}$, if the deriveddependent is not iso-derived, $A_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)} * T_{\mathrm{o}} \neq A_{\mathrm{o}} * T_{\mathrm{o}}$. In the special case, however, where the sample histogram is natural, the maximum likelihood estimate is exactly equal to the normalised derived-dependent, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger} \Longrightarrow$ $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)}=\hat{A}_{\mathrm{o}}$, because $A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger} * T_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}}$.

In classical modelled induction, where (i) the history probability function is iso-derived historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{o}}$, given some substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, if it is the case that (ii) the sample histogram is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the isoderived conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is

$$
\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

In section 'Iso-sets', above, the degree to which an integral iso-set $I \subseteq$ $\mathcal{A}_{U, \mathrm{i}, V, z}$, where $A \in I$, is said to be law-like, or the iso-derivedence, is defined as

$$
\frac{\left|I \cap D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}{\left|I \cup D_{U, i, T, z}^{-1}(A * T)\right|}
$$

In the case of classical modelled induction the integral iso-set is the integral iso-derived, $I=D_{U, \mathbf{i}, T, z}^{-1}(A * T)$, and so classical modelled induction is maximally law-like.

The iso-abstractence of the iso-deriveds equals the iso-derivedence of the iso-abstracts,

$$
\frac{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
$$

So classical modelled induction is not maximally entity-like if the iso-deriveds is a proper subset of the iso-abstracts, $D_{U, T, z}^{-1}(A * T) \subset Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$. This is the case if the derived is not independent, $A * T \neq(A * T)^{\mathrm{x}}$.

Given the known substrate transform, $T_{\mathrm{o}}$, consider the log likelihood of the iso-derived conditional generalised multinomial probability distribution, $\hat{Q}_{\mathrm{m}, \mathrm{d}, T_{o}, U}$, at the maximum likelihood estimate.

In section 'Likely histograms', above, the logarithm of the maximum conditional probability with respect to the dependent-analogue is conjectured to vary with the relative space with respect to the independent-analogue. In the case of iso-derived conditional,
$\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{D}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{D}(T)}, z\right)(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)} \sim$ spaceRelative $\left(A * T * T^{\dagger}\right)(A)$
where the distribution-relative multinomial space is defined, in section 'Likely histograms', above, as

$$
\text { spaceRelative }(E)(A):=-\ln \frac{\operatorname{mpdf}(U)(E, z)(A)}{\operatorname{mpdf}(U)(E, z)(E)}
$$

In section 'Transform alignment', above, because the set of iso-deriveds is law-like, it is shown that, in the case where the dependent analogue is in the iso-set, the difference in relative space between the histogram and the dependent must be in the differences between the relative spaces of the components,

$$
\begin{aligned}
A^{\mathrm{D}(T)} & \in D_{U, T, z}^{-1}(A * T) \Longrightarrow \\
& \sum_{(\cdot, C) \in T^{-1}} \text { spaceRelative }\left(A * T * T^{\dagger} * C\right)(A * C) \\
\leq & \sum_{(\cdot, C) \in T^{-1}} \text { spaceRelative }\left(A * T * T^{\dagger} * C\right)\left(A^{\mathrm{D}(T)} * C\right)
\end{aligned}
$$

So, in the case of the derived-dependent, the difference in relative space between the histogram and the dependent must be in the difference between
the non-independent terms of the alignments,

$$
A^{\mathrm{D}(T)} \in D_{U, T, z}^{-1}(A * T) \quad \Longrightarrow \quad \sum_{S \in V^{\mathrm{CS}}} \ln \Gamma_{!} A_{S} \leq \sum_{S \in V^{\mathrm{CS}}} \ln \Gamma_{!} A_{S}^{\mathrm{D}(T)}
$$

The sum of the relative spaces of the components approximates to

$$
\begin{aligned}
& \sum_{(\cdot, C) \in T^{-1}} \text { spaceRelative }\left(A * T * T^{\dagger} * C\right)(A * C) \approx \\
& z+\sum_{S \in V^{\mathrm{CS}}} \ln \Gamma_{!} A_{S}-\sum_{(R, C) \in T^{-1}}(A * T)_{R} \ln \left((A * T)_{R} /|C|\right)
\end{aligned}
$$

So the sum of the relative spaces of the components varies with the nonindependent term of the histogram alignment,

$$
\sum_{(\cdot, C) \in T^{-1}} \operatorname{spaceRelative}\left(A * T * T^{\dagger} * C\right)(A * C) \sim \sum_{S \in V^{\mathrm{CS}}} \ln \Gamma_{!} A_{S}
$$

which is independent of the transform, $T$. The sum of the relative spaces of the components varies against the size scaled component size cardinality relative entropy,

$$
\begin{aligned}
\sum_{(\cdot, C) \in T^{-1}} \operatorname{spaceRelative}\left(A * T * T^{\dagger} * C\right)(A * C) & \sim \\
& -z \times \operatorname{entropyRelative}\left(A * T, V^{\mathrm{C}} * T\right)
\end{aligned}
$$

The derived-dependent varies with the histogram, $\tilde{E}_{\mathrm{o}} \sim \hat{A}_{\mathrm{o}}$, so conjecture that in the case where the sample is not natural, $A \neq A * T * T^{\dagger} \Longrightarrow$ spaceRelative $\left(A * T * T^{\dagger}\right)(A)>0$, the log-likelihood varies with the nonindependent term of the histogram alignment,

$$
\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{D}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{D}(T)}, z\right)(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)} \sim \sum_{S \in V^{\mathrm{CS}}} \ln \Gamma_{!} A_{S}
$$

and varies against the size scaled component size cardinality relative entropy,

$$
\begin{aligned}
\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{D}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{D}(T)}, z\right)(B): B \in D_{U, i, T, z}^{-1}(A * T)} & \sim \\
& -z \times \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)
\end{aligned}
$$

In classical modelled induction, where (i) the history probability function is iso-derived historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{o}}$, given some substrate
transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, if it is the case that (ii) the sample histogram is not natural, $A_{\mathrm{o}} \neq A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, (iii) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{0}$, and such that (iv) the scaled estimate distribution histogram is integral, $\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$ where $\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}=\operatorname{scalar}\left(z_{\mathrm{h}}\right) * \tilde{E}_{\mathrm{o}}$, then the log likelihood of the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the relative space of the sample with respect to the naturalisation,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{spaceRelative}\left(A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}\right)\left(A_{\mathrm{o}}\right)
$$

varies with the non-independent term of the sample alignment,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \sum_{S \in V_{\mathrm{o}}^{\mathrm{CS}}} \ln \Gamma_{!} A_{\mathrm{o}}(S)
$$

and varies against the size scaled component size cardinality relative entropy,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, \tilde{z}_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-z_{\mathrm{o}} \times \text { entropyRelative }\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)
$$

Given the known substrate transform, $T_{\mathrm{o}}$, consider the log likelihood of the iso-derived conditional generalised multinomial probability distribution, $\hat{Q}_{\mathrm{m}, \mathrm{d}, T_{\mathrm{o}}, U}$, at the maximum likelihood estimate, in the special case where the histogram is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger} \Longrightarrow \tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)}=\hat{A}_{\mathrm{o}}$.

First consider the cardinality of the integral iso-deriveds. Let a pair of substrate transforms $T_{1}, T_{2} \in \mathcal{T}_{U, V}$ be such that (i) both are natural, $A * T_{1} * T_{1}^{\dagger}=$ $A * T_{2} * T_{2}^{\dagger}=A$, (ii) the first derived is independent, $A * T_{1}=\left(A * T_{1}\right)^{\mathrm{X}}$, (iii) the second derived is not independent, $A * T_{2} \neq\left(A * T_{2}\right)^{\mathrm{X}}$, but (iv) the second abstract equals the first derived, $\left(A * T_{2}\right)^{\mathrm{X}}=A * T_{1}=\left(A * T_{1}\right)^{\mathrm{X}}$. In section 'Iso-sets', above, it is shown that if and only if the derived is independent then the iso-deriveds equals the iso-abstracts,

$$
A * T=(A * T)^{\mathrm{x}} \Longleftrightarrow D_{U, T, z}^{-1}(A * T)=Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)
$$

So the second integral iso-deriveds is a proper subset of the first integral iso-deriveds,

$$
D_{U,, T_{2}, z}^{-1}\left(A * T_{2}\right) \subset Y_{U, i, T_{1}, \mathrm{~W}, z}^{-1}\left(\left(A * T_{1}\right)^{\mathrm{X}}\right)=D_{U, \mathrm{i}, T_{1}, z}^{-1}\left(A * T_{1}\right)
$$

and the denominator of the second iso-derived conditional multinomial probability is necessarily less than the denominator of the first iso-derived conditional multinomial probability,

$$
\sum_{B \in D_{U, i, T}^{-1}, T_{2}, z}\left(A * T_{2}\right) \quad \hat{Q}_{\mathrm{m}, U}(A, z)(B)<\sum_{B \in D_{U, i, T_{1}, z}^{-1}\left(A * T_{1}\right)} \hat{Q}_{\mathrm{m}, U}(A, z)(B)
$$

So the second iso-derived conditional multinomial probability at the maximum likelihood estimate is necessarily greater than the first iso-derived conditional multinomial probability at the maximum likelihood estimate,

$$
\frac{\hat{Q}_{\mathrm{m}, U}(A, z)(A)}{\sum_{B \in D_{U, i}^{1}, T_{2}, z}\left(A * T_{2}\right)} \hat{Q}_{\mathrm{m}, U}(A, z)(B) \quad>\frac{\hat{Q}_{\mathrm{m}, U}(A, z)(A)}{\sum_{B \in D_{U, i}^{1}, T_{1}, z}\left(A * T_{1}\right)} \hat{Q}_{\mathrm{m}, U}(A, z)(B)
$$

or

$$
\hat{Q}_{\mathrm{m}, \mathrm{~d}, T_{2}, U}(A, z)(A)>\hat{Q}_{\mathrm{m}, \mathrm{~d}, T_{1}, U}(A, z)(A)
$$

That is, in this case the second transform is more likely than the first transform. As shown in 'Minimum alignment', above, the independent entropy is always at least the histogram entropy, $\forall A \in \mathcal{A}\left(\right.$ entropy $\left.\left(A^{\mathrm{X}}\right) \geq \operatorname{entropy}(A)\right)$. The second derived is not independent so its entropy is necessarily less than the entropy of the first derived, entropy $\left(A * T_{2}\right)<\operatorname{entropy}\left(A * T_{1}\right)$. It is conjectured in 'Transform alignment', above, that the log iso-abstractence of the second transform varies with the size scaled derived entropy and against the size scaled independent derived entropy,

$$
\begin{aligned}
\ln \frac{\left|D_{U, i, T, z}^{-1}(A * T)\right|}{\left|Y_{U, \mathbf{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|} & \sim z \times \operatorname{entropy}(A * T)-z \times \operatorname{entropy}\left((A * T)^{\mathrm{X}}\right) \\
& \approx-\operatorname{algn}(A * T)
\end{aligned}
$$

hence conjecture that the log likelihood at the maximum likelihood estimate varies against the derived entropy,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \sim-z \times \operatorname{entropy}(A * T)
$$

This can be refined by considering the cardinality of the set of integral isoderiveds which may be stated explicitly as the product of the weak compositions of the components,

$$
\left|D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right|=\prod_{(R, C) \in T^{-1}} \frac{\left((A * T)_{R}+|C|-1\right)!}{(A * T)_{R}!(|C|-1)!}
$$

It is shown in 'Integral iso-sets and entropy', above, that the integral isoderiveds log-cardinality varies against the size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
& \ln \left|D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right| \sim \\
& \quad-\left((z+v) \times \operatorname{entropy}\left(A * T+V^{\mathrm{C}} * T\right)\right. \\
& \left.\quad-z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)\right)
\end{aligned}
$$

In the domain where the size is greater than the volume, $z>v$, the integral iso-deriveds log-cardinality varies against the volume scaled component cardinality size relative entropy,

$$
\ln \left|D_{U, i, T, z}^{-1}(A * T)\right| \sim-v \times \operatorname{entropyRelative}\left(V^{\mathrm{C}} * T, A * T\right)
$$

In the domain where the size is less than or equal to the volume, $z \leq v$, the integral iso-deriveds log-cardinality varies against the size scaled component size cardinality relative entropy,

$$
\ln \left|D_{U, i, T, z}^{-1}(A * T)\right| \sim-z \times \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)
$$

In both domains the integral iso-deriveds log-cardinality varies against the relative entropy. That is, integral iso-deriveds log-cardinality is minimised when (a) the cross entropy is maximised and (b) the component entropy is minimised. The cross entropy is maximised when high size components are low cardinality components and low size components are high cardinality components.

The log likelihood varies against the iso-derived log-cardinality,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) & \propto \ln \frac{Q_{\mathrm{m}, U}(A, z)(A)}{\sum_{B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T)} Q_{\mathrm{m}, U}(A, z)(B)} \\
& \sim-\ln \left|D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|
\end{aligned}
$$

So the log likelihood varies with the size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \sim \\
& \quad \begin{aligned}
(z+v) \times \operatorname{entropy}(A * T & \left.+V^{\mathrm{C}} * T\right) \\
& \quad-z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)
\end{aligned}
\end{aligned}
$$

In the domain where the size is greater than the volume, $z>v$, the $\log$ likelihood varies with the volume scaled component cardinality size relative entropy,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \sim v \times \operatorname{entropyRelative}\left(V^{\mathrm{C}} * T, A * T\right)
$$

The volume scaled component cardinality size relative entropy approximates to the negative logarithm of the cartesian derived multinomial probability with respect to the derived, so in this domain the log likelihood varies against the cartesian derived multinomial probability,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \sim-\ln \hat{Q}_{\mathrm{m}, U}(A * T, v)\left(V^{\mathrm{C}} * T\right)
$$

The sample histogram is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, so even if the sample is not completely effective, $A_{\mathrm{o}}^{\mathrm{F}}<V_{\mathrm{o}}^{\mathrm{C}}$, the component size of effective components is always at least equal to the component cardinality, $\forall(R, C) \in$ $T_{\mathrm{o}}^{-1}\left(\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)_{R}>0 \Longrightarrow\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)_{R} \geq|C|\right)$, and this domain, where the log likelihood varies with the component cardinality size relative entropy, applies.

In the domain where the size is less than or equal to the volume, $z \leq v$, the log likelihood varies with the size scaled component size cardinality relative entropy,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \sim z \times \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)
$$

The size scaled component size cardinality relative entropy approximates to the negative logarithm of the derived multinomial probability with respect to the cartesian derived, so in this domain the log likelihood varies against the derived multinomial probability,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \sim-\ln \hat{Q}_{\mathrm{m}, U}\left(V^{\mathrm{C}} * T, z\right)(A * T)
$$

If the size is less than the volume, $z_{0}<v_{0}$, the effective volume is necessarily less than cartesian, $A_{\mathrm{o}}^{\mathrm{F}}<V_{\mathrm{o}}^{\mathrm{C}}$, so sometimes the sample merely approximates to the naturalisation, $A_{\mathrm{o}} \approx A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$.

In classical modelled induction, where (i) the history probability function is iso-derived historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{\mathrm{o}}}$, given some substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, if it is the case that (ii) the sample histogram is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the isoderived conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, so, if it is also the case that (iii) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{\mathrm{o}}$, and such that (iv) the scaled probability sample histogram is integral, $A_{0, z_{\mathrm{h}}} \in \mathcal{A}_{\mathfrak{i}}$, then the log likelihood of the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) & \sim \\
\left(z_{\mathrm{o}}+v_{\mathrm{o}}\right) \times \operatorname{entropy}\left(A_{\mathrm{o}}\right. & \left.* T_{\mathrm{o}}+V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right) \\
& -z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)-v_{\mathrm{o}} \times \operatorname{entropy}\left(V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)
\end{aligned}
$$

In the case where the size is greater than the volume, $z_{0}>v_{\mathrm{o}}$, the log likelihood of the iso-derived conditional stuffed historical probability distribution
at the maximum likelihood estimate varies with the volume scaled component cardinality size relative entropy,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) & \sim v_{\mathrm{o}} \times \text { entropyRelative }\left(V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}, A_{\mathrm{o}} * T_{\mathrm{o}}\right) \\
& \sim-\ln \hat{Q}_{\mathrm{m}, U}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, v_{\mathrm{o}}\right)\left(V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)
\end{aligned}
$$

In the case where the size is less than the volume, $z_{0}<v_{\mathrm{o}}$, but the sample approximates to the naturalisation, $A_{\mathrm{o}} \approx A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, the log likelihood of the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the size scaled component size cardinality relative entropy,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) & \sim z_{\mathrm{o}} \times \text { entropyRelative }\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right) \\
& \sim-\ln \hat{Q}_{\mathrm{m}, U}\left(V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
\end{aligned}
$$

In other words, the log likelihood of the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the size scaled component size cardinality cross entropy,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \text { entropy } \operatorname{Cross}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)
$$

and against the size scaled derived entropy

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

So, in this case, the log likelihood is maximised when (a) the derived entropy is minimised, and (b) high size components are low cardinality components and low size components are high cardinality components.

This case, where the sample is approximately natural, $A_{\mathrm{o}} \approx A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, and the maximum likelihood estimate is approximately equal to the naturalisation, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)} \approx A_{\mathrm{o}}$, may be compared to the case where the sample is not natural, $A_{\mathrm{o}} \neq A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, and the maximum likelihood estimate is not equal to the naturalisation, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)} \neq A_{\mathrm{o}}$. In the natural case the log likelihood varies with the size scaled component size cardinality relative entropy,

$$
\begin{aligned}
& A_{\mathrm{o}} \approx A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger} \Longrightarrow \\
& \quad \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \text { entropyRelative }\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)
\end{aligned}
$$

whereas in the non-natural case the log likelihood varies against the size scaled component size cardinality relative entropy,

$$
\begin{aligned}
& A_{\mathrm{o}} \neq A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger} \Longrightarrow \\
& \quad \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-z_{\mathrm{o}} \times \operatorname{entropyRelative}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)
\end{aligned}
$$

Now consider the multinomial probability terms that appear in the numerator and denominator of the iso-derived conditional generalised multinomial probability distribution. The logarithm of the iso-derived conditional multinomial probability at the maximum likelihood estimate, where the sample is natural, $A=A * T * T^{\dagger}$, is in proportion to the logarithm of the sample multinomial probability in the numerator divided by the sum of the iso-derived multinomial probabilities in the denominator,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \propto \ln \frac{\hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right)}{\sum_{B \in D_{U, i, T, z}^{-1}(A * T)} \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)(B)}
$$

Given integral iso-derived histogram $B \in D_{U, i, T, z}^{-1}(A * T)$ the logarithm of the generalised multinomial probability, where the distribution histogram is natural, $\ln \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)(B)$, can be re-written in terms of components,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)(B) \\
& \quad=\ln z!-z \ln z-\sum_{S \in B^{\mathrm{FS}}} \ln B_{S}!+\sum_{S \in B^{\mathrm{FS}}} B_{S} \ln \left(A * T * T^{\dagger}\right)_{S} \\
& \quad=\ln z!-z \ln z-\sum_{(\cdot, C) \in T^{-1}} \sum_{S \in C^{\mathrm{S}}} \ln B_{S}!+\sum_{(R, \cdot) \in T^{-1}}(A * T)_{R} \ln \frac{(A * T)_{R}}{\left(V^{\mathrm{C}} * T\right)_{R}}
\end{aligned}
$$

In the case of natural distribution histogram, $A=A * T * T^{\dagger}$, the permutorial term, $\sum_{(R, \cdot) \in T^{-1}}(A * T)_{R} \ln (A * T)_{R} /\left(V^{\mathrm{C}} * T\right)_{R}$, does not depend on the isoderived, $B$, only on the distribution histogram, $A$. That is, the permutorial term is constant for all iso-derived. The permutorial term is proportional to the size scaled component size cardinality relative entropy,

$$
\sum_{(R, \cdot) \in T^{-1}}(A * T)_{R} \ln \frac{(A * T)_{R}}{\left(V^{\mathrm{C}} * T\right)_{R}} \propto z \times \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)
$$

The logarithm of the multinomial probability of the iso-derived, $\ln \hat{Q}_{\mathrm{m}, U}(A * T *$ $\left.T^{\dagger}, z\right)(B)$, may be compared to the logarithm of the multinomial probability of the derived, $\ln \hat{Q}_{\mathrm{m}, U}(A * T, z)(A * T)$,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, U}(A * T, z)(A * T) \\
& \quad=\ln z!-z \ln z-\sum_{(R, \cdot) \in T^{-1}} \ln (A * T)_{R}!+\sum_{(R, \cdot) \in T^{-1}}(A * T)_{R} \ln (A * T)_{R}
\end{aligned}
$$

The permutorial term of the derived is proportional to the negative size scaled derived entropy,

$$
\begin{aligned}
\sum_{(R, \cdot) \in T^{-1}}(A * T)_{R} \ln (A * T)_{R} & \propto z \times \operatorname{expected}(\hat{A} * T)(\hat{A} * T) \\
& =-z \times \operatorname{entropy}(A * T)
\end{aligned}
$$

The numerator is the sample multinomial probability. In the case where the iso-derived equals the sample histogram, $B=A$, the multinomial term, $\sum_{(,, C) \in T^{-1}} \sum_{S \in C^{\mathrm{S}}} \ln B_{S}!$, simplifies to $\sum_{(R, \cdot) \in T^{-1}}\left(V^{\mathrm{C}} * T\right)_{R} \ln \left((A * T)_{R} /\left(V^{\mathrm{C}} *\right.\right.$ $T)_{R}$ )!, and the multinomial probability is maximised,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right) \\
& \quad=\ln z!-z \ln z-\sum_{(R, \cdot) \in T^{-1}}\left(V^{\mathrm{C}} * T\right)_{R} \ln \frac{(A * T)_{R}}{\left(V^{\mathrm{C}} * T\right)_{R}}! \\
&
\end{aligned}
$$

The difference between multinomial probabilities is the difference in multinomial terms, and varies with the difference in size scaled entropies,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right)-\ln \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)(B) \\
& \quad=\sum_{(\cdot, C) \in T^{-1}} \sum_{S \in C^{\mathrm{S}}} \ln B_{S}!-\sum_{(R, \cdot) \in T^{-1}}\left(V^{\mathrm{C}} * T\right)_{R} \ln \frac{(A * T)_{R}}{\left(V^{\mathrm{C}} * T\right)_{R}}! \\
& \sim z \times \operatorname{entropy}\left(A * T * T^{\dagger}\right)-z \times \operatorname{entropy}(B)
\end{aligned}
$$

The sample multinomial probability can be re-written,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right) \\
& \quad=\ln z!-z \ln z-\sum_{S \in A^{\mathrm{FS}}} \ln A_{S}!+\sum_{S \in A^{\mathrm{FS}}} A_{S} \ln A_{S} \\
& =\ln z!-z \ln z-\sum_{(R, \cdot) \in T^{-1}}\left(V^{\mathrm{C}} * T\right)_{R} \ln \frac{(A * T)_{R}}{\left(V^{\mathrm{C}} * T\right)_{R}}! \\
& \quad+\sum_{(R, \cdot) \in T^{-1}}\left(V^{\mathrm{C}} * T\right)_{R} \frac{(A * T)_{R}}{\left(V^{\mathrm{C}} * T\right)_{R}} \ln \frac{(A * T)_{R}}{\left(V^{\mathrm{C}} * T\right)_{R}}
\end{aligned}
$$

In the case where the cartesian derived is uniform, $\forall(R, \cdot) \in T^{-1}\left(\left(V^{\mathrm{C}} * T\right)_{R}=\right.$ $\left.v / w^{\prime}\right)$ where $w^{\prime}=\left|T^{-1}\right|$, the sample multinomial probability can be written in terms of the derived multinomial probability,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right) \\
& =\ln z!-z \ln z-\frac{v}{w^{\prime}} \ln \frac{z w^{\prime}}{v}!+z \ln \frac{z w^{\prime}}{v}+ \\
& \quad \frac{v}{w^{\prime}} \ln \hat{Q}_{\mathrm{m}, U}\left(A * T, \frac{z w^{\prime}}{v}\right)\left(1 / Z_{v / w^{\prime}} * A * T\right) \\
& \approx \ln z!-z \ln z-\frac{v}{w^{\prime}} \ln \frac{z w^{\prime}}{v}!+z \ln \frac{z w^{\prime}}{v}+\ln \hat{Q}_{\mathrm{m}, U}(A * T, z)(A * T)
\end{aligned}
$$

where $Z_{v / w^{\prime}}=\operatorname{scalar}\left(v / w^{\prime}\right)$.
The component size cardinality relative entropy is the component size cardinality cross entropy minus the component size entropy or derived entropy,

$$
\begin{aligned}
& \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)= \\
& \quad \text { entropyCross }\left(A * T, V^{\mathrm{C}} * T\right)-\operatorname{entropy}(A * T)
\end{aligned}
$$

When the cartesian derived is uniform, $\operatorname{ran}\left(\hat{V}^{\mathrm{C}} * T\right)=\left\{1 / w^{\prime}\right\}$, the component size cardinality cross entropy is a constant, $\ln w^{\prime}$, and the component size cardinality relative entropy is in proportion to the negative derived entropy.

$$
\operatorname{expected}(\hat{A} * T)\left(\ln \frac{\hat{A} * T}{Z_{1 / w^{\prime}}}\right)=\ln w^{\prime}-\operatorname{entropy}(A * T)
$$

In the case where the cartesian derived is uniform, the derived multinomial probability varies most closely to the sample multinomial probability and so, although the sample multinomial probability also appears in the denominator, the iso-derived conditional multinomial probability varies with the derived multinomial probability,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \sim \ln \hat{Q}_{\mathrm{m}, U}(A * T, z)(A * T)
$$

In the case where the cartesian derived is not uniform and the cross entropy is greater than the logarithm of the possible derived volume, entropyCross( $A *$ $\left.T, V^{\mathrm{C}} * T\right)>\ln w^{\prime}$, the relative entropy exceeds the uniform cartesian derived relative entropy,

$$
\text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)>\operatorname{expected}(\hat{A} * T)\left(\ln \frac{\hat{A} * T}{Z_{1 / w^{\prime}}}\right)
$$

and the permutorial term of the sample multinomial probability exceeds that of the scaled derived multinomial probability,

$$
\sum_{(R, \cdot) \in T^{-1}}(A * T)_{R} \ln \frac{(A * T)_{R}}{\left(V^{\mathrm{C}} * T\right)_{R}}>\sum_{(R, \cdot) \in T^{-1}}(A * T)_{R} \ln \frac{(A * T)_{R}}{v / w^{\prime}}
$$

In this case the scaled logarithm of the derived multinomial probability, plus constants, is necessarily less than the logarithm of the sample multinomial probability

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right) \\
& >\ln z!-z \ln z-\frac{v}{w^{\prime}} \ln \frac{z w^{\prime}}{v}!+z \ln \frac{z w^{\prime}}{v}+ \\
& \frac{v}{w^{\prime}} \ln \hat{Q}_{\mathrm{m}, U}\left(A * T, \frac{z w^{\prime}}{v}\right)\left(1 / Z_{v / w^{\prime}} * A * T\right)
\end{aligned}
$$

and so the scaled logarithm of the derived multinomial probability approximates more closely to the lower entropy iso-derived that are not equal to the sample, $B \neq A$,

$$
\begin{aligned}
\exists B & \in D_{U, i, T, z}^{-1}(A * T) \\
& \left(\ln \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)(A)-\frac{v}{w^{\prime}} \ln \hat{Q}_{\mathrm{m}, U}\left(A * T, \frac{z w^{\prime}}{v}\right)\left(1 / Z_{v / w^{\prime}} * A * T\right)\right. \\
& \left.>\ln \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)(B)-\frac{v}{w^{\prime}} \ln \hat{Q}_{\mathrm{m}, U}\left(A * T, \frac{z w^{\prime}}{v}\right)\left(1 / Z_{v / w^{\prime}} * A * T\right)\right)
\end{aligned}
$$

In this case of high relative entropy, the derived multinomial probability still varies with the sample multinomial probability, but varies more closely to the other iso-derived that appear in the denominator, so now the iso-derived conditional multinomial probability varies against the derived multinomial probability,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \sim-\ln \hat{Q}_{\mathrm{m}, U}(A * T, z)(A * T)
$$

The degree of anti-correlation varies with the relative entropy.
In the third case where the cartesian derived is not uniform but the cross entropy is less than the logarithm of the possible derived volume, entropy $\operatorname{Cross}(A *$ $\left.T, V^{\mathrm{C}} * T\right)<\ln w^{\prime}$, the relative entropy is less than the uniform cartesian derived relative entropy,

$$
\text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)<\operatorname{expected}(\hat{A} * T)\left(\ln \frac{\hat{A} * T}{Z_{1 / w^{\prime}}}\right)
$$

Now the scaled logarithm of the derived multinomial probability, plus constants, is necessarily greater than the logarithm of the sample multinomial probability

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right) \\
& <\ln z!-z \ln z-\frac{v}{w^{\prime}} \ln \frac{z w^{\prime}}{v}!+z \ln \frac{z w^{\prime}}{v}+ \\
& \quad \frac{v}{w^{\prime}} \ln \hat{Q}_{\mathrm{m}, U}\left(A * T, \frac{z w^{\prime}}{v}\right)\left(1 / Z_{v / w^{\prime}} * A * T\right)
\end{aligned}
$$

and so the sample is the closest of the iso-derived. In this case of low relative entropy, the iso-derived conditional multinomial probability varies with the derived multinomial probability,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \sim \ln \hat{Q}_{\mathrm{m}, U}(A * T, z)(A * T)
$$

As the cross entropy tends to the derived entropy, the relative entropy tends to zero, so the derived and cartesian derived become perfectly synchronised and the sample tends to uniform, $\hat{A}=\hat{V}^{\mathrm{C}}$.

In classical modelled induction, where (i) the history probability function is iso-derived historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{\mathrm{o}}}$, given some substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, if it is the case that (ii) the sample histogram is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the isoderived conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, so, if it is also the case that (iii) the component size cardinality relative entropy is high, entropy $\operatorname{Cross}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)>\ln w_{\mathrm{o}}^{\prime}$, (iv) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{\mathrm{o}}$, and such that (v) the scaled probability sample histogram is integral, $A_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the log likelihood of the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate varies against the derived multinomial probability,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\ln \hat{Q}_{\mathrm{m}, U}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

Consider further the multinomial probability terms that appear in the numerator and denominator of the iso-derived conditional generalised multinomial probability distribution where the distribution histogram is natural, $A * T * T^{\dagger}$. It is shown above that that the logarithm of the generalised multinomial probability, re-written in terms of components, is,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)(B) \\
& \quad=\ln z!-z \ln z-\sum_{(\cdot, C) \in T^{-1}} \sum_{S \in C^{\mathrm{S}}} \ln B_{S}!+\sum_{(R, \cdot) \in T^{-1}}(A * T)_{R} \ln \frac{(A * T)_{R}}{\left(V^{\mathrm{C}} * T\right)_{R}}
\end{aligned}
$$

The permutorial term is constant for all iso-derived, so the iso-derived conditional multinomial probability simplifies to

$$
\frac{\hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right)}{\sum_{B \in D_{U, i, T, z}^{-1}}^{-1}(A * T)} \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)(B) \quad=1 / \sum_{B \in D_{U, i, T, z}^{-1}(A * T)} \prod_{S \in V^{\mathrm{CS}}} \frac{A_{S}!}{B_{S}!}
$$

The minimum terms in the denominator are such that the iso-derived histogram $B \in D_{U, i, T, z}^{-1}(A * T)$ is singleton in all of its components, $\forall(\cdot, C) \in$ $T^{-1}\left(\left|(B * C)^{\mathrm{F}}\right|=1\right)$. The logarithm of a minimum term approximates to the
size scaled component size cardinality cross entropy,

$$
\begin{aligned}
\ln \prod_{S \in V^{\mathrm{CS}}} \frac{A_{S}!}{B_{S}!} & =\sum_{(R, \cdot) \in T^{-1}}\left(V^{\mathrm{C}} * T\right)_{R} \ln \frac{(A * T)_{R}}{\left(V^{\mathrm{C}} * T\right)_{R}}!-\sum_{(R, \cdot) \in T^{-1}} \ln (A * T)_{R}! \\
& \approx-\sum_{(R, \cdot) \in T^{-1}}(A * T)_{R} \ln \left(V^{\mathrm{C}} * T\right)_{R} \\
& \propto z \times \operatorname{entropyCross}\left(A * T, V^{\mathrm{C}} * T\right)
\end{aligned}
$$

So, in the case where the size is greater than the volume, $z>v$, and the sample is natural, $A=A * T * T^{\dagger}$, the logarithm of the iso-derived conditional multinomial probability varies against the size scaled component size cardinality cross entropy,

$$
\ln \frac{\hat{Q}_{\mathrm{m}, U}(A, z)(A)}{\sum_{B \in D_{U, i, T, z}^{-1}(A * T)} \hat{Q}_{\mathrm{m}, U}(A, z)(B)} \sim-z \times \operatorname{entropyCross}\left(A * T, V^{\mathrm{C}} * T\right)
$$

This is somewhat contrary to relationship with respect to the iso-derived cardinality where it was shown that the logarithm of the iso-derived conditional multinomial probability varies with the volume scaled component cardinality size cross entropy,

$$
\ln \frac{\hat{Q}_{\mathrm{m}, U}(A, z)(A)}{\sum_{B \in D_{U, i, T, z}^{-1}(A * T)} \hat{Q}_{\mathrm{m}, U}(A, z)(B)} \sim v \times \operatorname{entropyCross}\left(V^{\mathrm{C}} * T, A * T\right)
$$

However, note that the logarithm of the cardinality of the singleton-component iso-derived is only $\sum_{(R,) \in T^{-1}} \ln \left(V^{\mathrm{C}} * T\right)_{R}$, which is much smaller than the logarithm of the cardinality of the iso-derived, approximately $\sum_{(R, \cdot) \in T^{-1}}\left(V^{\mathrm{C}} *\right.$ $T)_{R} \ln \left((A * T)_{R} /\left(V^{\mathrm{C}} * T\right)_{R}\right)$, especially in the case where the component cardinality size relative entropy is low. So the negative correlation between the iso-derived conditional multinomial probability and the size scaled component size cardinality cross entropy is weak.

Also, in the near-natural case where the trimmed sample is unit, $A * A^{\mathrm{F}}=A^{\mathrm{F}}$, the logarithm of a minimum term approximates to the size scaled derived entropy,

$$
\begin{aligned}
\ln \prod_{S \in V^{\mathrm{CS}}} \frac{A_{S}!}{B_{S}!} & =-\sum_{(R, \cdot) \in T^{-1}} \ln (A * T)_{R}! \\
& \approx z \times \operatorname{entropy}(A * T)
\end{aligned}
$$

So, in this case where the size is less than the volume, $z<v$, and the sample is near-natural, $A \approx A * T * T^{\dagger}$, the logarithm of the iso-derived conditional multinomial probability varies against the size scaled derived entropy,

$$
\ln \frac{\hat{Q}_{\mathrm{m}, U}(A, z)(A)}{\sum_{B \in D_{U, i, T, z}^{-1}(A * T)} \hat{Q}_{\mathrm{m}, U}(A, z)(B)} \sim-z \times \operatorname{entropy}(A * T)
$$

which agrees with the relationship with respect to the iso-derived cardinality where it was shown that the logarithm of the iso-derived conditional multinomial probability varies with the size scaled component size cardinality relative entropy,

$$
\ln \frac{\hat{Q}_{\mathrm{m}, U}(A, z)(A)}{\sum_{B \in D_{U, i, T, z}^{-1}(A * T)} \hat{Q}_{\mathrm{m}, U}(A, z)(B)} \sim z \times \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)
$$

In section 'Derived history space', above, the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)$, is constructed,

$$
C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)=
$$ coderHistorySubstrateDerivedSpecialising $\left(U, X, T, D_{\mathrm{S}}, D_{\mathrm{X}}\right)$

$$
\in \operatorname{coders}\left(\mathcal{H}_{U, V, X}\right)
$$

where $\mathcal{H}_{U, V, X}=\left\{H: H \in \mathcal{H}_{U, X}, \operatorname{vars}(H)=V\right\}$. The space of the specialising coder is

$$
\begin{aligned}
\text { space }\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)\right)(H)= & \operatorname{spaceIds}(|X|,|H|)+ \\
& \text { spaceCountsDerived }(U)(A, T)+ \\
& \text { spaceClassification }(A * T)+ \\
& \text { spaceEventsPartition }(A, T) \\
= & \operatorname{spaceIds}(|X|,|H|)+ \\
& \ln \frac{\left(z+w^{\prime}-1\right)!}{z!\left(w^{\prime}-1\right)!}+ \\
& \ln z!-\sum_{R \in(A * T)^{\mathrm{s}}} \ln (A * T)_{R}!+ \\
& \sum_{(R, C) \in T^{-1}}(A * T)_{R} \ln |C|
\end{aligned}
$$

The space of the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)$, varies (i) with the possible derived volume, $w^{\prime}$, where the possible derived
volume is less than the size, $w^{\prime}<z$, otherwise with the size scaled log possible derived volume, $z \ln w^{\prime}$, and (ii) against the size scaled component size cardinality relative entropy,

$$
\begin{aligned}
C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H) & \sim \\
& \left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right) \\
& -z \times \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)
\end{aligned}
$$

So the space of the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)$, is minimised when (a) the possible derived volume is minimised, (b) the derived entropy or component size entropy is minimised, and (c) high size components are low cardinality components and low size components are high cardinality components.

In the domain where the size is less than or equal to the volume, $z \leq v$, the integral iso-deriveds log-cardinality varies against the size scaled component size cardinality relative entropy. The sum of the derived classification space and the partitioned events space varies against the size scaled component size cardinality relative entropy. So the integral iso-deriveds log-cardinality varies with the sum of the derived classification space and the partitioned events space,

$$
\begin{aligned}
\ln \left|D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right| \sim & -z \times \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right) \\
\sim & \text { spaceClassification }(A * T)+ \\
& \text { spaceEventsPartition }(A, T)
\end{aligned}
$$

So in this domain the log likelihood varies against the specialising space.
Conjecture that in the case where the size is less than the volume, $z_{0}<v_{\mathrm{o}}$, but the sample approximates to the naturalisation, $A_{\mathrm{o}} \approx A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, the log likelihood of the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate varies against the specialising derived substrate history coder space,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\operatorname{space}\left(C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)\left(H_{\mathrm{o}}\right)
$$

The iso-derived conditional stuffed historical probability distribution log likelihood is maximised and the specialising derived substrate history coder space is minimised by varying the transform such that (i) the derived entropy is low, and (ii) high counts are in low cardinality components and high cardinality components have low counts.

In section 'Derived history space', above, the specialising-canonical space difference, $2 C_{\mathrm{G}, V, T, \mathrm{H}}(T)^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, is shown to be characterised by certain properties. The specialising-canonical space difference varies (i) with twice the possible derived volume, $2 w^{\prime}$, where $w^{\prime}<z$, otherwise with twice the size scaled $\log$ possible derived volume, $2 z \ln w^{\prime}$, (ii) with the size scaled derived entropy, (iii) against twice the size scaled component size cardinality cross entropy and (iv) against the size scaled size expected component entropy,

$$
\begin{aligned}
2 C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}} & (H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H) \sim \\
& 2\left(\left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right)\right) \\
& +z \times \operatorname{entropy}(A * T) \\
& -2 z \times \operatorname{entropyCross}\left(A * T, V^{\mathrm{C}} * T\right) \\
& -z \times \operatorname{entropyComponent}(A, T)
\end{aligned}
$$

So the specialising-canonical space difference, $2 C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)-$ $C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, is minimised when (a) the possible derived volume is minimised, (b) the derived entropy is minimised, (c) high size components are low cardinality components and low size components are high cardinality components, and (d) the expected component entropy is maximised.

The canonical term, $C_{\mathrm{H}, V}^{\mathrm{s}}(H)+C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, is independent of the model, $T$, so properties of the specialising-canonical space difference, $2 C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H)$ $C_{\mathrm{H}, V}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, are also properties of the specialising space, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H)$. So conjecture that in classical modelled induction where the size is less than the volume, $z_{0}<v_{\mathrm{o}}$, but the sample approximates to the naturalisation, $A_{\mathrm{o}} \approx A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, the log likelihood of the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate varies against the specialising-canonical space difference,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) & \sim \\
& -\left(2 C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)-C_{\mathrm{H}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)-C_{\mathrm{G}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right)
\end{aligned}
$$

In the special case where the histogram is natural, $A=A * T * T^{\dagger} \Longrightarrow$ $\tilde{E}=\hat{A}^{\mathrm{D}(T)}=\hat{A}$, and the component size cardinality cross entropy is greater than the logarithm of the possible derived volume, entropyCross $\left(A * T, V^{\mathrm{C}} *\right.$ $T)>\ln w^{\prime}$, so the relative entropy is high, conjecture that the iso-derived conditional multinomial probability at the maximum likelihood estimate varies
with the underlying-derived relative multinomial probability,
$\frac{\hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right)}{\sum_{B \in D_{U, i, T, z}^{-1}(A * T)} \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)(B)} \sim \frac{\hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right)}{\hat{Q}_{\mathrm{m}, U}(A * T, z)(A * T)}$
This may be generalised to cases where the histogram is not natural, $A \neq$ $A * T * T^{\dagger}$, but only approximated to the naturalisation, $A \approx A * T * T^{\dagger}$, such that the relative space with respect to the naturalisation, spaceRelative $(A *$ $\left.T * T^{\dagger}\right)(A)$, is small,

$$
\frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in D_{U, i, T, z}^{-1}(A * T)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)} \sim \frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\hat{Q}_{\mathrm{m}, U}(E * T, z)(A * T)}
$$

In the case of a full functional transform, $T_{\mathrm{s}}=\left\{\{w\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: w \in V\right\}^{\mathrm{T}}$, this correlation is exact, $\sum_{B \in D_{U, i, T, z}^{-1}\left(A * T_{\mathrm{s}}\right)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)=\hat{Q}_{\mathrm{m}, U}\left(E * T_{\mathrm{s}}, z\right)\left(A * T_{\mathrm{s}}\right)$, because $D_{U, \mathrm{i}, T_{\mathrm{s}}, z}^{-1}\left(A * T_{\mathrm{s}}\right)=\{A\}$. At the other extreme of a unary transform, $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$, the correlation is also exact, $\sum_{B \in D_{U, i, T \mathrm{u}}-\frac{z}{2}\left(A * T_{\mathrm{u}}\right)} \hat{Q}_{\mathrm{m}, U}(E, z)(B)=$ $\hat{Q}_{\mathrm{m}, U}\left(E * T_{\mathrm{u}}, z\right)\left(A * T_{\mathrm{u}}\right)=1$, because $D_{U, \mathrm{i}, T_{\mathrm{u}}, z}^{-1}\left(A * T_{\mathbf{u}}\right)=\mathcal{A}_{U, \mathrm{i}, V, z}$.

The numerator of the underlying-derived relative multinomial probability corresponds to the unknown underlying, while the denominator corresponds to the known derived. Thus, in the case of high component size cardinality relative entropy, the sum sensitivity of the iso-derived conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T, U}$, is conjectured to vary with the unknown-known multinomial probability distribution sum sensitivity difference,

$$
\begin{aligned}
& \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U}(E, z)\right)\right) \sim \\
& \quad \quad \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right)-\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(E * T, z)\right)\right)
\end{aligned}
$$

and so the sum sensitivity of the iso-derived conditional stuffed historical probability distribution is sometimes less than or equal to the sum sensitivity of the stuffed historical probability distribution,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U}(E, z)\right)\right) & \\
& \leq \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}(E, z)\right)\right)
\end{aligned}
$$

In the case of a full functional transform, $T_{\mathrm{s}}$, the iso-derived historically distributed history probability is a constant, so the iso-derived conditional stuffed historical probability distribution sum sensitivity is zero,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{s}}, U}(E, z)\right)\right)=0
$$

Here the underlying is known and so the unknown-known multinomial probability distribution sum sensitivity difference is also zero,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right)=\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}\left(E * T_{\mathrm{s}}, z\right)\right)\right)
$$

In the case of a unary transform, $T_{\mathrm{u}}$, the iso-derived conditional stuffed historical probability distribution sum sensitivity equals the stuffed historical probability distribution sum sensitivity,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{u}}, U}(E, z)\right)\right)=\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}(E, z)\right)\right)
$$

Here the derived multinomial probability distribution sum sensitivity is undefined, because the derived volume is singular, $w=1$, and so the unknownknown multinomial probability distribution sum sensitivity difference is undefined.

Given a transform $T \in \mathcal{T}_{U, V}$ the multinomial probability can be written in terms of its component multinomial probabilities,

$$
\begin{aligned}
& \hat{Q}_{\mathrm{m}, U}(E, z)(A) \\
& \quad=\frac{z!}{\prod_{S \in V^{\mathrm{CS}}} A_{S}!} \prod_{S \in V^{\mathrm{CS}}} \hat{E}_{S}^{A_{S}} \\
& \quad=\frac{z!}{\prod_{(R, \cdot) \in T^{-1}}(A * T)_{R}!} \prod_{(R, C) \in T^{-1}} \frac{(A * T)_{R}!}{\prod_{S \in C^{S}}(A * C)_{S}!} \prod_{S \in C^{\mathrm{S}}}(\hat{E} * C)_{S}^{(A * C)_{S}} \\
& \quad=\frac{z!}{\prod_{(R,) \in T^{-1}}(A * T)_{R}!} \prod_{(R, C) \in T^{-1}} \hat{Q}_{\mathrm{m}, U}\left(E * C,(A * T)_{R}\right)(A * C)
\end{aligned}
$$

where the distribution histogram is completely effective, $E^{\mathrm{F}}=V^{\mathrm{C}}$. The derived multinomial probability is

$$
\begin{aligned}
\hat{Q}_{\mathrm{m}, U}(E * T, z)(A * T) & =\frac{z!}{\prod_{R \in\left(V^{\mathrm{C}} * T\right)^{\mathrm{FS}}}(A * T)_{R}!} \prod_{R \in\left(V^{\mathrm{C}} * T\right)^{\mathrm{FS}}}(\hat{E} * T)_{R}^{(A * T)_{R}} \\
& =\frac{z!}{\prod_{(R,) \in T^{-1}}(A * T)_{R}!} \prod_{(R,) \in T^{-1}}(\hat{E} * T)_{R}^{(A * T)_{R}}
\end{aligned}
$$

So the underlying-derived relative multinomial probability can be rewritten in terms of components,

$$
\frac{\hat{Q}_{\mathrm{m}, U}(E, z)(A)}{\hat{Q}_{\mathrm{m}, U}(E * T, z)(A * T)}=\frac{\prod_{(R, C) \in T^{-1}} \hat{Q}_{\mathrm{m}, U}\left(E * C,(A * T)_{R}\right)(A * C)}{\prod_{(R, \cdot) \in T^{-1}}(\hat{E} * T)_{R}^{(A * T)_{R}}}
$$

The unknown-known multinomial probability distribution sum sensitivity difference has several properties corresponding to the numerators and denominators of each side of this equation.

First, the unknown-known sum sensitivity difference varies with the sum sensitivity of the numerator of the left hand side, which is the multinomial probability distribution sum sensitivity,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right)=\sum_{S \in V^{\mathrm{CS}}} \frac{z}{\hat{E}_{S}\left(1-\hat{E}_{S}\right)}
$$

As shown above, the multinomial probability distribution sum sensitivity varies against the scaled entropy, so the iso-derived conditional stuffed historical probability distribution sum sensitivity varies against the underlying entropy

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U}(E, z)\right)\right) & \sim \sum_{S \in V^{\mathrm{CS}}} \frac{z}{\hat{E}_{S}\left(1-\hat{E}_{S}\right)} \\
& \sim-z \times \operatorname{entropy}(E)
\end{aligned}
$$

The underlying entropy, entropy $(E)$, is independent of the transform, $T$, and so remains constant during any optimisation of the sum sensitivity by varying the transform.

Second, the unknown-known sum sensitivity difference varies against the sum sensitivity of the denominator of the left hand side, which is the derived multinomial probability distribution sum sensitivity,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(E * T, z)\right)\right)=\sum_{(R, \cdot) \in T^{-1}} \frac{z}{(\hat{E} * T)_{R}\left(1-(\hat{E} * T)_{R}\right)}
$$

so the iso-derived conditional stuffed historical probability distribution sum sensitivity varies with the derived entropy,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U}(E, z)\right)\right) & \sim-\sum_{(R,,) \in T^{-1}} \frac{z}{(\hat{E} * T)_{R}\left(1-(\hat{E} * T)_{R}\right)} \\
& \sim z \times \operatorname{entropy}(E * T)
\end{aligned}
$$

Third, the unknown-known sum sensitivity difference varies with the sum sensitivity of the numerator of the right hand side, which is the sum of the
unknown multinomial probability distribution sum sensitivities,

$$
\begin{aligned}
& \sum_{(R, C) \in T^{-1}} \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}\left(E * C,(A * T)_{R}\right)\right)\right)= \\
& \quad \sum_{(R, C) \in T^{-1}} \sum_{S \in C^{S}} \frac{(A * T)_{R}}{\hat{E}_{S}\left(1-\hat{E}_{S}\right)}
\end{aligned}
$$

so the iso-derived conditional stuffed historical probability distribution sum sensitivity varies against the unknown size scaled expected component entropy,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U}(E, z)\right)\right) \sim-z \times \operatorname{entropyComponent}(E, T)
$$

Fourth, the denominator of the right hand side, $\prod_{(R, \cdot) \in T^{-1}}(\hat{E} * T)_{R}^{(A * T)_{R}}$, is the permutorial part of the derived multinomial probability, $\hat{Q}_{\mathrm{m}, U}(E * T, z)(A * T)$. The other part is the multinomial coefficient, $z!/ \prod_{R \in(A * T)^{\mathrm{FS}}}(A * T)_{R}!$, which does not depend on the distribution histogram, $E$. So the sum sensitivity of the denominator of the right hand side varies with the sum sensitivity of the denominator of the left hand side, which is the derived multinomial probability distribution sum sensitivity, $\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(E * T, z)\right)\right)$. Again, the iso-derived conditional stuffed historical probability distribution sum sensitivity varies with the derived entropy, entropy $(E * T)$.

In classical modelled induction, where (i) the history probability function is iso-derived historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{o}}$, given some substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, if it is the case that (ii) the sample histogram is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the isoderived conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, so, if it is also the case that (iii) the component size cardinality relative entropy is high, entropy $\operatorname{Cross}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)>\ln w_{\mathrm{o}}^{\prime}$, (iv) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{0}$, and such that (v) the scaled probability sample histogram is integral, $A_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the sum sensitivity of the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate (a) is less than or equal to the sum sensitivity of the stuffed historical probability distribution at the maximum likelihood estimate,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\right.\right. & \left.\left.\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \\
\leq & \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)
\end{aligned}
$$

(b) varies with the derived entropy,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{o}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

and (c) varies against the unknown size scaled expected component entropy,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) & \sim \\
& \sim z_{\mathrm{o}} \times \operatorname{entropyComponent}\left(A_{\mathrm{o}}, T_{\mathrm{o}}\right)
\end{aligned}
$$

The derived entropy varies with the derived classification space, and so varies with the specialising derived substrate history coder space, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H)$. Conjecture that in the case where the sample equals the naturalisation, $A_{\mathrm{o}}=$ $A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, the sum sensitivity of the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the specialising derived substrate history coder space,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim \operatorname{space}\left(C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)\left(H_{\mathrm{o}}\right)
$$

Both the iso-derived conditional stuffed historical probability distribution sum sensitivity and the specialising derived substrate history coder space are minimised by varying the transform such that the derived entropy is low.

Also, the specialising-canonical space difference, $2 C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)-$ $C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, varies with derived entropy and against the size scaled expected component entropy, so conjecture that in the case where the sample is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, the sum sensitivity of the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the specialising-canonical space difference,

$$
\begin{aligned}
& \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}},}, z_{\mathrm{o}}\right)\right)\right) \sim \\
& \qquad 2 C_{\mathrm{G}, V_{o}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)-C_{\mathrm{H}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)-C_{\mathrm{G}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)
\end{aligned}
$$

Both the iso-derived conditional stuffed historical probability distribution sum sensitivity and the specialising-canonical space difference are minimised by varying the transform such that (a) the derived entropy is low and (b) the underlying components have high entropy.

Altogether, in classical modelled induction where the size is less than the volume, $z_{\mathrm{o}}<v_{\mathrm{o}}$, but the sample approximates to the naturalisation, $A_{\mathrm{o}} \approx$ $A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, and the relative entropy is high, the sum sensitivity has similar properties as the log-likelihood but with the correlations reversed. Conjecture that in this case the sum sensitivity varies against the log-likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

That is, in the high relative entropy natural case, the maximisation of the log-likelihood also tends to minimise the sum sensitivity to the maximum likelihood estimate. This is opposite to the relationship between the sum sensitivity and the log-likelihood in classical non-modelled induction, which was found to be weakly positively correlated.

In the case where there are ineffective possible derived states, $\left|\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{F}}\right|<$ $w_{\mathrm{o}}^{\prime}$ where $w_{\mathrm{o}}^{\prime}=\left|T_{\mathrm{o}}^{-1}\right|$, the distribution histogram is known to be incompletely effective, $E_{\mathrm{o}}^{\mathrm{F}}<V_{\mathrm{o}}^{\mathrm{C}}$. The states known to be ineffective are in the ineffective components,

$$
\forall(R, C) \in T_{\mathrm{o}}^{-1}\left(\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)_{R}=0 \Longrightarrow E_{\mathrm{o}} * C=C^{\mathrm{Z}}\right)
$$

Now the classical modelled induction assumption of a completely effective sample histogram, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$, can be weakened to requiring only that (i) there are at least two effective states, $\left|A_{\mathrm{o}}^{\mathrm{F}}\right|>1$, and (ii) the components of effective derived states are effective, $\forall(R, C) \in T_{\mathrm{o}}^{-1}\left(\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)_{R}>0 \Longrightarrow\right.$ $\left.\left(A_{\mathrm{o}} * C\right)^{\mathrm{F}}=C\right)$. The maximum likelihood estimate is unchanged, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$. Although the coordinate has smaller dimension, $\left(\hat{A}_{\mathrm{o}} * A_{\mathrm{o}}^{\mathrm{F}}\right)^{\square} \in \mathcal{R}_{(0,1)}^{\left|A_{\mathrm{o}}^{\mathrm{F}}\right|} \neq \mathcal{R}_{(0,1)}^{v_{\mathrm{o}}}$, there is no effective normalising factor, $1 / \operatorname{size}\left(\tilde{E}_{\mathrm{o}} * A_{\mathrm{o}}^{\mathrm{F}}\right)=1$, and both the log likelihood and the sum sensitivity are the same as for the case of completely effective derived histogram.

In the case where the requirement of completely effective effective components does not hold, $\exists(R, C) \in T_{\mathrm{o}}^{-1}\left(\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)_{R}>0 \wedge\left(A_{\mathrm{o}} * C\right)^{\mathrm{F}}<C\right)$, then there is an unknown effective normalising factor for each of the incompletely effective components, $\operatorname{size}\left(\tilde{E}_{\mathrm{o}} * C\right) / \operatorname{size}\left(\tilde{E}_{\mathrm{o}} * C * A_{\mathrm{o}}^{\mathrm{F}}\right)$.

Note, however, that the maximisation of the log likelihood or the minimisation of the sum sensitivity tend to maximise the component size cardinality relative entropy and so components with larger sizes tend to have smaller volumes and the cardinality of ineffective component states, $C \backslash\left(A_{\mathrm{o}} * C\right)^{\mathrm{F}}$, tends to be minimised.

In the case where the histogram is naturalised, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, the effective components are completely effective, $\forall(R, C) \in T_{\mathrm{o}}^{-1}\left(\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)_{R}>\right.$ $\left.0 \Longrightarrow\left(A_{\mathrm{o}} * C\right)^{\mathrm{F}}=C\right)$, and so there are no unknown effective normalising factors.

In the case where there are ineffective possible derived states, but there are at least two effective derived states, $1<\left|\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{F}}\right|<w_{\mathrm{o}}^{\prime}$, then the
derived coordinate has smaller, but not unit, dimension, $\left(\hat{A}_{\mathrm{o}} * T_{\mathrm{o}} *\left(A_{\mathrm{o}} *\right.\right.$ $\left.\left.T_{\mathrm{o}}\right)^{\mathrm{F}}\right)^{\square} \notin\left\{\{1\}, \mathcal{R}_{(0,1)}^{w_{\mathrm{o}}^{\prime}}\right\}$, and the derived multinomial probability distribution sum sensitivity is,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}} * T_{\mathrm{o}} *\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{F}}, z_{\mathrm{o}}\right)\right)\right)=z_{R \in\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{FS}}} \frac{z_{\mathrm{o}}}{\left(\hat{A}_{\mathrm{o}} * T_{\mathrm{o}}\right)_{R}\left(1-\left(\hat{A}_{\mathrm{o}} * T_{\mathrm{o}}\right)_{R}\right)}
$$

In the case where the derived histogram is known, the derived effective normalising factor is known to be one, $1 / \operatorname{size}\left(\tilde{E}_{\mathrm{o}} * T_{\mathrm{o}} *\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{F}}\right)=1$. If, however, the knowledge of the derived histogram is less than certain and there is some doubt about the effectiveness of weakly effective states, it may be noted that as the effectiveness of the derived states decreases, the derived entropy decreases and the derived sensitivity increases, tending to infinity in the limit,

$$
\lim _{\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)_{R} \rightarrow 0} \frac{z_{\mathrm{o}}}{\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)_{R}\left(1-\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)_{R}\right)}=\infty
$$

In this domain of low derived entropy the variation of the derived sensitivity remains against the derived entropy as ineffectiveness increases. That is, even in the case of uncertain derived histogram, $\hat{A}_{\mathrm{o}} * T_{\mathrm{o}} \approx \hat{E}_{\mathrm{o}} * T_{\mathrm{o}}$, the isoderived conditional stuffed historical probability distribution sum sensitivity continues to vary with the derived entropy,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim z \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

Just as for non-modelled classical induction the sum sensitivity of the isoderived conditional stuffed historical probability distribution at the maximum likelihood estimate, $\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)$, can be related to queries on the maximum likelihood estimate of the distribution histogram, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, in the special case where (i) the sample histogram is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, and (ii) the component size cardinality relative entropy is high, entropy $\operatorname{Cross}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)>\ln w_{\mathrm{o}}^{\prime}$. In the case of classical modelled induction, the given substrate transform must be such that its contraction has underlying variables that are a subset of the query variables, und $\left(T_{\mathrm{o}}^{\%}\right) \subseteq$ $K$. In the case where the query histogram consists of one effective state, $Q=\left\{\left(S_{Q}, 1\right)\right\}$, there exists an effective derived state $R_{Q}$, where $\left\{R_{Q}\right\}=$ $\left(Q * T_{\mathrm{o}}^{\%}\right)^{\mathrm{FS}}$. The corresponding underlying component is $C_{Q}=T_{\mathrm{o}}^{-1}\left(R_{Q}\right)$. In this case the application of the query via the model equals the application via the component directly, $\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)=\left(A_{\mathrm{o}} *\right.$ $\left.C_{Q}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)$. If the possible derived volume is non singular, $w_{\mathrm{o}}^{\prime}>1$, the query histogram itself cannot be drawn from the distribution history,
$\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}}, 1\right)\left(Q *\{N\}^{\mathrm{U}}\right)=0$, where $N \in\left(V_{\mathrm{o}} \backslash K\right)^{\mathrm{CS}}$, because the query derived probability histogram is not equal to the known derived distribution probability histogram, $\hat{Q} *\{N\}^{\mathrm{U}} * T_{\mathrm{o}} \neq \hat{A}_{\mathrm{o}} * T_{\mathrm{o}}$. The application of the query must be in terms of a modified sample histogram,

$$
\begin{aligned}
& \left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)= \\
& \quad\left\{\left(N,\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{Q, N}\right)\right)^{1 / z_{\mathrm{o}}}\right): N \in\left(V_{\mathrm{o}} \backslash K\right)^{\mathrm{CS}}\right. \\
& \left.\quad A_{Q, N}=A_{\mathrm{o}}-\left(A_{\mathrm{o}} * C_{Q}\right)+\left(\left(A_{\mathrm{o}} * C_{Q}\right) \% K *\{N\}^{\mathrm{U}}\right)\right\}^{\wedge}
\end{aligned}
$$

where his $=$ histogram. If the sample histogram is completely effective, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$, the modified sample histogram, $A_{Q, N}$, can be drawn from the distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{o}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{Q, N}\right)>0$, because its derived is equal to the known derived, $A_{Q, N} * T_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}}$. The modified sample histogram is in the iso-deriveds, $A_{Q, N} \in D_{U, \mathrm{i}, T_{\mathrm{o}}, z_{\mathrm{o}}}^{-1}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)$, and so only the numerator of the iso-derived conditional stuffed historical probability has changed,

$$
\frac{\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{Q, N}\right)}{\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}} U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}=\frac{\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{Q, N}\right)}{\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}
$$

In the case of (i) a completely effective histogram, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}} \Longrightarrow Q^{\mathrm{F}} \leq$ $\left(A_{0} \% K\right)^{\mathrm{F}}$, and (ii) a self transform with respect to query variables, $T_{\mathrm{s}}=$ $K^{\mathrm{CS}\{ \} V_{0} \mathrm{~T}}$, the query application via the model equals the estimated transformed conditional product,

$$
\left(Q * T_{\mathrm{s}}^{\%} * \operatorname{his}\left(T_{\mathrm{s}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)=\hat{Q} * T_{\hat{A}_{\mathrm{o}}, K}^{\prime} \in \mathcal{A} \cap \mathcal{P}
$$

As for non-modelled classical induction, the model application depends on the geometric scaling of the historical distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)$, so the query sensitivity to the distribution histogram varies with the sum sensitivity of the historical distribution at the maximum likelihood estimate divided by the sample size,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}}
$$

Although the query application via the model is sometimes not equal to the estimated transformed conditional product, the query sensitivity to the distribution histogram is sometimes lower,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\right.\right. & \left.\left.\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}} \\
& \leq \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}}
\end{aligned}
$$

Similarly, where the size is less than the volume, $z_{\mathrm{o}}<v_{\mathrm{o}}$, the model likelihood of the distribution histogram is sometimes higher,

$$
\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z\right)\left(A_{Q, N}\right) \geq \hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z\right)\left(A_{Q, N}\right)
$$

In other words, querying via the known derived of the model sometimes reduces the sensitivity to the unknown and increases the likelihood at the cost of modifying the query.

If it is known that the sample is not natural, $A_{\mathrm{o}} \neq A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, for example, if it is known that the label variables are a function of the query variables

$$
\operatorname{split}\left(K, E_{\mathrm{o}}^{\mathrm{FS}}\right) \in K^{\mathrm{CS}} \rightarrow\left(V_{\mathrm{o}} \backslash K\right)^{\mathrm{CS}}
$$

then in some cases the states of the modified query, $A_{Q, N}$, may be ineffective in the effective sample component,

$$
\left(A_{Q, N} * C_{Q}\right)^{\mathrm{F}} \not \leq\left(A_{\mathrm{o}} * C_{Q}\right)^{\mathrm{F}}
$$

In these cases there is an unknown normalising factor for the component,

$$
\operatorname{size}\left(\tilde{E}_{\mathrm{o}} * C_{Q}\right) / \operatorname{size}\left(\tilde{E}_{\mathrm{o}} * C_{Q} * A_{\mathrm{o}}^{\mathrm{F}}\right)
$$

but there is not necessarily an unknown normalising factor in the query variables

$$
\operatorname{size}\left(\tilde{E}_{\mathrm{o}} * C_{Q} \% K\right) / \operatorname{size}\left(\tilde{E}_{\mathrm{o}} * C_{Q} \% K * A_{\mathrm{o}}^{\mathrm{F}}\right)
$$

That is, even if the non-modelled query is ineffective, $Q^{\mathrm{F}} \cap A_{\mathrm{o}}^{\mathrm{F}} \% K=\emptyset$, if the derived is effective, $\left(Q * T_{\mathrm{o}}\right)^{\mathrm{F}} \leq\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{F}}$, then it is necessarily the case that the query, $Q$, may be carried out via the model by modifying it to $A_{Q, N}$, which for some $N$ there exists a drawn history, $\exists N \in\left(V_{\mathrm{o}} \backslash\right.$ $K)^{\mathrm{CS}}\left(\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{Q, N}\right)>0\right)$, subject to the unknown normalising factor if $\left(\left(A_{\mathrm{o}} * C_{Q}\right) \% K\right)^{\mathrm{F}}<\left(C_{Q} \% K\right)^{\mathrm{F}}$.

### 5.5.2 Necessary derived functional definition set

So far the discussion of classical modelled induction has considered the case where the known model is a transform. Consider extending the model first to functional definition sets and then to fud decompositions.

Given some known substrate fud, $F_{\mathrm{o}} \in \mathcal{F}_{U, V_{\mathrm{o}}}$, such that there exists a top transform, $\exists T \in F_{\mathrm{o}}\left(\operatorname{der}(T)=\operatorname{der}\left(F_{\mathrm{o}}\right)\right)$, the derived histogram set of the distribution probability histogram is $\left\{\hat{E}_{\mathrm{h}} * T_{F_{\mathrm{o}}}: T \in F_{\mathrm{o}}\right\}$, where $T_{F}:=$ depends $(F, \operatorname{der}(T))^{\mathrm{T}}$. In classical functional definition set induction, while the distribution probability histogram, $\hat{E}_{\mathrm{h}}$, remains unknown, the derived distribution probability histogram set, $\left\{\hat{E}_{\mathrm{h}} * T_{F_{\mathrm{o}}}: T \in F_{\mathrm{o}}\right\}$, is known and necessary. That is, the history probability function, $P$, is historically distributed
but constrained such that all drawn histories have a derived probability histogram equal to the known derived distribution probability histogram for each of the transforms of the fud, $\forall T \in F_{\mathrm{o}}\left(\hat{A}_{H} * T_{F_{\mathrm{o}}}=\hat{E}_{\mathrm{h}} * T_{F_{\mathrm{o}}}\right)$. Define the iso-fud historically distributed history probability function $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, F_{\mathrm{o}}} \in\left(\mathcal{H}_{U, X}: \rightarrow\right.$ $\left.\mathrm{Q}_{[0,1]}\right) \cap \mathcal{P}$,

$$
\begin{aligned}
& P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, F_{\mathrm{o}}}:= \\
& \qquad \begin{array}{l}
\left(\bigcup \left\{\left\{(H, 1): H \subseteq H_{\mathrm{h}} \% V_{H},|H|=z_{H},\right.\right.\right. \\
\left.\forall T \in F_{\mathrm{o}}\left(\hat{A}_{H} * T_{F_{\mathrm{o}}}=\hat{E}_{\mathrm{h}} * T_{F_{\mathrm{o}}}\right)\right\} \wedge \\
\left.\left.V_{H} \subseteq V_{\mathrm{h}}, z_{H} \in\left\{1 \ldots z_{\mathrm{h}}\right\}\right\}\right)^{\wedge} \cup \\
\left\{(H, 0): H \in \mathcal{H}_{U, X}, \exists T \in F_{\mathrm{o}}\left(\hat{A}_{H} * T_{F_{\mathrm{o}}} \neq \hat{E}_{\mathrm{h}} * T_{F_{\mathrm{o}}}\right)\right\} \cup \\
\left\{(H, 0): H \in \mathcal{H}_{U, X}, H \nsubseteq H_{\mathrm{h}} \% V_{H}\right\} \cup\{(\emptyset, 0)\}
\end{array}
\end{aligned}
$$

In classical functional definition set induction the history probability function is iso-fud historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, F_{\mathrm{o}}}$.

If the fud is a singleton, $F_{\mathrm{o}}=\left\{T_{\mathrm{o}}\right\}$, classical functional definition set induction reduces to classical transform induction, $P_{U, X, H_{\mathrm{h}}, \mathrm{d},\left\{T_{\mathrm{o}}\right\}}=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{o}}$.

The iso-fud historical probability may be expressed in terms of a histogram distribution,

$$
\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{o}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right) \propto \sum\left(P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, F_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}\right)
$$

where the iso-fud conditional stuffed historical probability distribution is defined

$$
\begin{aligned}
\hat{Q}_{\mathrm{h}, \mathrm{~d}, F, U} & (E, z) \\
:= & \left\{\left(A, \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum_{B \in D_{U, \mathrm{i}, F, z}^{-1}\left(\left\{A * T_{F}: T \in F\right\}\right)} Q_{\mathrm{h}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \leq E\right\}^{\wedge} \cup \\
& \left\{(A, 0): A \in \mathcal{A}_{U, \mathrm{i}, \mathrm{i}, z}, A \not \leq E\right\}
\end{aligned}
$$

which is defined if $z \leq \operatorname{size}(E)$. The derived histogram set valued integral histogram function $D_{U, i, F, z}$ is defined

$$
D_{U, \mathbf{i}, F, z}=\left\{\left(A,\left\{A * T_{F}: T \in F\right\}\right): A \in \mathcal{A}_{U, \mathbf{i}, V, z}\right\}
$$

The finite set of iso-fuds of derived histogram set $\left\{A * T_{F}: T \in F\right\}$ is

$$
D_{U, i, F, z}^{-1}\left(\left\{A * T_{F}: T \in F\right\}\right)=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, \forall T \in F\left(B * T_{F}=A * T_{F}\right)\right\}
$$

In this case the top transform exists, $\exists T \in F(\operatorname{der}(T)=\operatorname{der}(F))$, so the set of iso-fuds is a law-like subset of the iso-deriveds,

$$
D_{U, F, z}^{-1}\left(\left\{A * T_{F}: T \in F\right\}\right) \subseteq D_{U, F^{\mathrm{T}}, z}^{-1}\left(A * F^{\mathrm{T}}\right)
$$

and therefore necessary derived fud is stricter than necessary derived. That is, a history can only be drawn in classical functional definition set induction if it can be drawn in classical transform induction for the transform of the fud, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, F_{\mathrm{o}}}(H)>0 \Longrightarrow P_{U, X, H_{\mathrm{h}}, \mathrm{d}, F_{\mathrm{o}}^{\mathrm{T}}}(H)>0$.

The iso-fud conditional generalised multinomial probability distribution is defined

$$
\begin{aligned}
& \hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}(E, z) \\
& :=\left\{\left(A, \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in D_{\bar{U}, i, F, z}^{-1}\left(\left\{A * T_{F}: T \in F\right\}\right)} Q_{\mathrm{m}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A^{\mathrm{F}} \leq E^{\mathrm{F}}\right\}^{\wedge} \cup \\
& \left\{(A, 0): A \in \mathcal{A}_{U, i, V, z}, A^{\mathrm{F}} \not \leq E^{\mathrm{F}}\right\}
\end{aligned}
$$

which is defined if $\operatorname{size}(E)>0$.
It is assumed that the distribution history size, $z_{\mathrm{h}}$, is large with respect to the sample size $z_{\mathrm{o}}=\operatorname{size}\left(A_{\mathrm{o}}\right)$, so that, in the limit, the iso-fud historical probability, $\hat{Q}_{\mathrm{h}, \mathrm{d}, F_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$, approximates to the iso-fud multinomial probability, $\hat{Q}_{\mathrm{m}, \mathrm{d}, F_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$. That is, if $z_{\mathrm{o}} \ll z_{\mathrm{h}}$ then

$$
\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \approx \hat{Q}_{\mathrm{m}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

where $E_{\mathrm{o}}=E_{\mathrm{h}} \% V_{\mathrm{o}}$.
In the case of completely effective sample histogram, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$, the maximisation for known fud, $F_{\mathrm{o}}$, of the iso-fud conditional generalised multinomial probability parameterised by the complete congruent histograms of unit size is a singleton of the rational maximum likelihood estimate

$$
\left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}\right\}\right)
$$

In the case where the maximisation of the iso-fud conditional generalised multinomial probability distribution is a singleton, it is equal to the normalised fud-dependent, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{DF}^{\left(F_{o}\right)}}$, where the fud-dependent $A^{\mathrm{D}_{\mathrm{F}}(F)} \in$ $\mathcal{A}_{U, V, z}$ is defined in 'Likely histograms', above, as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the
histogram, $A$, conditional that it is an iso-fud,

$$
\begin{aligned}
& \left\{A^{\mathrm{D}_{\mathrm{F}}(F)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(E, \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum Q_{\mathrm{m}, U}(E, z)(B): B \in D_{U, \mathrm{i}, F, z}^{-1}\left(D_{U, F, z}(A)\right)}\right): E \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The independent analogue is the fud-independent, $A^{\mathrm{E}_{\mathrm{F}}(F)} \in \mathcal{A}_{U, V, z}$, defined,

$$
\begin{aligned}
& \left\{A^{\mathrm{E}_{\mathrm{F}}(F)}\right\}= \\
& \quad \quad \operatorname{maxd}\left(\left\{\left(E, \sum\left(Q_{\mathrm{m}, U}(E, z)(B): B \in D_{U, \mathrm{i}, F, z}^{-1}\left(D_{U, F, z}(A)\right)\right)\right): E \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The fud-independent approximates to the arithmetic average of the naturalisations,

$$
A^{\mathrm{E}_{\mathrm{F}}(F)} \approx Z_{1 /|F|} * \sum_{T \in F} A * T_{F} * T_{F}^{\dagger}
$$

It is only in the case where the histogram equals the fud-independent that the maximum likelihood estimate is necessarily equal to the sample probability histogram,

$$
A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}\left(F_{\mathrm{o}}\right)} \Longrightarrow A_{\mathrm{o}}^{\mathrm{D}_{\mathrm{F}}\left(F_{\mathrm{o}}\right)}=A_{\mathrm{o}} \Longrightarrow \tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

Otherwise, the overall maximum likelihood estimate, which is the fud-dependent, is near the histogram, $\tilde{E}_{\mathrm{o}} \sim \hat{A}_{\mathrm{o}}$, only in as much as it is far the fudindependent, $\tilde{E}_{\mathrm{o}} \nsim \hat{A}_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}\left(F_{\mathrm{o}}\right)}$.

In classical functional definition set induction, where (i) the history probability function is iso-fud historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, F_{o}}$, given some substrate fud in the sample variables $F_{\mathrm{o}} \in \mathcal{F}_{U, V_{0}}$, such that there exists a top transform, $\exists T \in F_{\mathrm{o}}\left(\operatorname{der}(T)=\operatorname{der}\left(F_{\mathrm{o}}\right)\right)$, if it is the case that (ii) the sample histogram equals the fud-independent, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{EF}\left(F_{\mathrm{o}}\right)}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the iso-fud conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, F_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is

$$
\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

Given the known substrate fud, $F_{\mathrm{o}}$, consider the log likelihood of the isofud conditional generalised multinomial probability distribution, $\hat{Q}_{\mathrm{m}, \mathrm{d}, F_{o}, U}$, at the maximum likelihood estimate, in the special case where sample histogram equals the fud-independent, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}\left(F_{\mathrm{o}}\right)} \Longrightarrow \tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{D}_{\mathrm{F}}\left(F_{\mathrm{o}}\right)}=\hat{A}_{\mathrm{o}}$.

The set of iso-fuds is the intersection of the iso-deriveds of each transform

$$
D_{U, F, z}^{-1}\left(\left\{A * T_{F}: T \in F\right\}\right)=\bigcap_{T \in F} D_{U, T_{F}, z}^{-1}\left(A * T_{F}\right)
$$

So the cardinality of the set of integral iso-fuds is less than or equal to the product of the weak compositions of the components for any transform,

$$
\forall T \in F \quad\left(\left|D_{U, \mathbf{i}, F, z}^{-1}\left(D_{U, F, z}(A)\right)\right| \leq \prod_{(R, C) \in T_{F}^{-1}} \frac{\left(\left(A * T_{F}\right)_{R}+|C|-1\right)!}{\left(A * T_{F}\right)_{R}!(|C|-1)!}\right)
$$

and the logarithm of the integral iso-fuds cardinality is less or equal to the integral iso-deriveds log-cardinality for any transform,

$$
\forall T \in F\left(\ln \left|D_{U, i, F, z}^{-1}\left(D_{U, F, z}(A)\right)\right| \leq \ln \left|D_{U, i, T_{F}, z}^{-1}\left(A * T_{F}\right)\right|\right)
$$

In the case where the volume is much greater than one, $v \gg 1$, the integral iso-deriveds log-cardinality approximates to the negative size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
& \ln \left|D_{U, i, T, z}^{-1}(A * T)\right| \approx \\
& \quad-\left((z+v) \times \operatorname{entropy}\left(A * T+V^{\mathrm{C}} * T\right)\right. \\
& \left.\quad-z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)\right)
\end{aligned}
$$

In the domain where the size is greater than the volume, $z>v$, the integral iso-deriveds log-cardinality varies against the volume scaled component cardinality size relative entropy,

$$
\ln \left|D_{U, i, T, z}^{-1}(A * T)\right| \sim-v \times \operatorname{entropyRelative}\left(V^{\mathrm{C}} * T, A * T\right)
$$

In the domain where the size is less than or equal to the volume, $z \leq v$, the integral iso-deriveds log-cardinality varies against the size scaled component size cardinality relative entropy,

$$
\ln \left|D_{U, i, T, z}^{-1}(A * T)\right| \sim-z \times \text { entropyRelative }\left(A * T, V^{\mathrm{C}} * T\right)
$$

The log likelihood varies against the log iso-fud cardinality,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}(A, z)(A) & \propto \ln \frac{Q_{\mathrm{m}, U}(A, z)(A)}{\sum_{B \in D_{U, \mathrm{i}, F, z}^{-1}\left(D_{U, F, z}(A)\right)} Q_{\mathrm{m}, U}(A, z)(B)} \\
& \sim-\ln \left|D_{U, \mathrm{i}, F, z}^{-\mathrm{i}}\left(D_{U, F, z}(A)\right)\right|
\end{aligned}
$$

and so varies against the integral iso-deriveds log-cardinalities for all of the transforms

$$
\forall T \in F\left(\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}(A, z)(A) \sim-\ln \left|D_{U, \mathrm{i}, T_{F}, z}^{-1}\left(A * T_{F}\right)\right|\right)
$$

So the log likelihood varies with the sum of the size-volume scaled component size cardinality sum relative entropies,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}(A, z)(A) \sim \\
& \sum_{T \in F}\left((z+v) \times \operatorname{entropy}\left(A * T_{F}+V^{\mathrm{C}} * T_{F}\right)\right. \\
& \left.\quad-z \times \operatorname{entropy}\left(A * T_{F}\right)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T_{F}\right)\right)
\end{aligned}
$$

In the domain where the size is greater than the volume, $z>v$, the log likelihood varies with the sum of the volume scaled substrate component cardinality size relative entropies,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}(A, z)(A) \sim v \times \sum_{T \in F} \text { entropyRelative }\left(V^{\mathrm{C}} * T_{F}, A * T_{F}\right)
$$

and, in the domain where the size is less than or equal to the volume, $z \leq v$, the log likelihood varies with the sum of the size scaled substrate component size cardinality relative entropies,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}(A, z)(A) \sim z \times \sum_{T \in F} \text { entropyRelative }\left(A * T_{F}, V^{\mathrm{C}} * T_{F}\right)
$$

In classical functional definition set induction, where (i) the history probability function is iso-fud historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, F_{o}}$, given some substrate fud in the sample variables $F_{\mathrm{o}} \in \mathcal{F}_{U, V_{0}}$, such that there exists a top transform, $\exists T \in F_{\mathrm{o}}\left(\operatorname{der}(T)=\operatorname{der}\left(F_{\mathrm{o}}\right)\right)$, if it is the case that (ii) the sample histogram equals the fud-independent, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}\left(F_{\mathrm{o}}\right)}$, then the maximum likelihood estimate, $\tilde{E}_{0}$, of the unknown distribution probability histogram, $\hat{E}_{0}$, in the iso-fud conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, F_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, so, if it is also the case that (iii) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{0}$, and such that (iv) the scaled probability sample histogram is integral, $A_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the log likelihood of the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the sum of size-volume scaled component size cardinality sum relative entropies of all
transforms,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \\
& \begin{aligned}
& \sum_{T \in F_{\mathrm{o}}}\left(\left(z_{\mathrm{o}}+v_{\mathrm{o}}\right) \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}+V_{\mathrm{o}}^{\mathrm{o}} * T_{F_{\mathrm{o}}}\right)\right. \\
&\left.\quad-z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}\right)-v_{\mathrm{o}} \times \operatorname{entropy}\left(V_{\mathrm{o}}^{\mathrm{C}} * T_{F_{\mathrm{o}}}\right)\right)
\end{aligned}
\end{aligned}
$$

In the case where the size is greater than the volume, $z_{0}>v_{0}$, the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the sum of volume scaled component cardinality size relative entropies of all transforms,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim v_{\mathrm{o}} \times \sum_{T \in F_{\mathrm{o}}} \operatorname{entropyRelative}\left(V_{\mathrm{o}}^{\mathrm{C}} * T_{F_{\mathrm{o}}}, A_{\mathrm{o}} * T_{F_{\mathrm{o}}}\right)
$$

In the case where the size is less than the volume, $z_{\mathrm{o}}<v_{\mathrm{o}}$, but the sample histogram approximates to the fud-independent histogram, $A_{\mathrm{o}} \approx A_{\mathrm{o}}^{\mathrm{EF}_{\mathrm{F}}\left(F_{\mathrm{o}}\right)}$, or spaceRelative $\left(A_{\mathrm{o}}^{\mathrm{E} F}\left(F_{\mathrm{o}}\right)\right)\left(A_{\mathrm{o}}\right) \approx 0$, the log likelihood of the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate varies with sum of the size scaled component size cardinality relative entropies for all transforms,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \sum_{T \in F_{\mathrm{o}}} \operatorname{entropyRelative}\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{F_{\mathrm{o}}}\right)
$$

In other words, the log likelihood of the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the sum of the size scaled component size cardinality cross entropies of all transforms,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \sum_{T \in F_{\mathrm{o}}} \operatorname{entropyCross}\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{F_{\mathrm{o}}}\right)
$$

and against the sum of the size scaled derived entropies for all transforms

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-z_{\mathrm{o}} \times \sum_{T \in F_{\mathrm{o}}} \operatorname{entropy}\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}\right)
$$

So, in this case, the log likelihood is maximised when (a) the sum of the derived entropies of all transforms is minimised, and (b) high size components are low cardinality components and low size components are high cardinality components for all transforms.

It is shown in section 'Necessary derived', above, that in the case where (i) the sample is natural, $A=A * T * T^{\dagger}$, and (ii) the component size cardinality cross entropy is greater than the logarithm of the possible derived volume, entropy $\operatorname{Cross}\left(A * T, V^{\mathrm{C}} * T\right)>\ln w^{\prime}$, so that the relative entropy is high, then the logarithm of the iso-derived conditional multinomial probability varies against the logarithm of the derived multinomial probability,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \sim-\ln \hat{Q}_{\mathrm{m}, U}(A * T, z)(A * T)
$$

Extending the model from transform, $T$, to functional definition set, $F$, conjecture that in the case where (i) the sample histogram equals the fudindependent, $A=A^{\mathrm{E}_{\mathrm{F}}(F)}$, and (ii) the cross entropies are sufficient, $\forall T \in$ $F$ (entropyCross $\left(A * T_{F}, V^{\mathrm{C}} * T_{F}\right)>\ln \left|T_{F}^{-1}\right|$ ), the logarithm of the iso-fud conditional multinomial probability varies against the sum of the logarithms of the derived multinomial probabilities,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}(A, z)(A) \sim-\sum_{T \in F} \ln \hat{Q}_{\mathrm{m}, U}\left(A * T_{F}, z\right)\left(A * T_{F}\right)
$$

In classical functional definition set induction, where (i) the history probability function is iso-fud historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, F_{\mathrm{o}}}$, given some substrate fud in the sample variables $F_{\mathrm{o}} \in \mathcal{F}_{U, V_{o}}$, such that there exists a top transform, $\exists T \in F_{\mathrm{o}}\left(\operatorname{der}(T)=\operatorname{der}\left(F_{\mathrm{o}}\right)\right)$, if it is the case that (ii) the sample histogram equals the fud-independent, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}\left(F_{\mathrm{o}}\right)}$, then the maximum likelihood estimate, $\tilde{E}_{0}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the iso-fud conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, F_{o}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, so, if it is also the case that (iii) the component size cardinality relative entropies are high, $\forall T \in F_{\mathrm{o}}$ (entropyCross $\left(A_{\mathrm{o}} *\right.$ $\left.T_{F_{\mathrm{o}}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{F_{\mathrm{o}}}\right)>\ln \left|T_{F_{\mathrm{o}}}^{-1}\right|$ ), (iv) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{0}$, and such that (v) the scaled probability sample histogram is integral, $A_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the log likelihood of the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate varies against the sum of logarithms of the derived multinomial probabilities of the transforms,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\sum_{T \in F_{\mathrm{o}}} \ln \hat{Q}_{\mathrm{m}, U}\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}\right)
$$

In section 'Derived history space', above, the specialising fud substrate history coder is constructed
$C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)=$
coderHistorySubstrateFudSpecialising $\left(U, X, F, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, V, X}\right)$

In the law-like case where the fud has a top transform, $\exists T \in F\left(W_{T}=\right.$ $\operatorname{der}(F))$, the space is

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}\right. & (F))(H)= \\
& \text { spaceIds }(|X|,|H|)+ \\
& \text { spaceCountsDerived }(U)\left(A, F^{\mathrm{T}}\right)+ \\
& \text { spaceClassification }\left(A * F^{\mathrm{T}}\right)+ \\
& \sum_{T \in F} \text { spaceEventsPartition }\left(A * \operatorname{depends}\left(F, V_{T}\right)^{\mathrm{T}}, T\right)
\end{aligned}
$$

Let $w^{\prime}$ be the possible derived volume of the transform of the fud, $w^{\prime}=$ $\left|\left(F^{\mathrm{T}}\right)^{-1}\right|$. The space of the specialising fud substrate history coder, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)$, varies (i) with the possible fud derived volume, $w^{\prime}$, where the possible fud derived volume is less than the size, $w^{\prime}<z$, otherwise with the size scaled $\log$ possible fud derived volume, $z \ln w^{\prime}$, (ii) with the size scaled transform fud derived entropy and (iii) against the sum of the size scaled component size cardinality cross entropies of the transforms of the fud,

$$
\begin{aligned}
C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H) & \sim \\
& \left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right) \\
+ & z \times \operatorname{entropy}\left(A * F^{\mathrm{T}}\right) \\
- & z \times \sum_{T \in F} \operatorname{entropyCross}\left(A * T_{F}, V_{T}^{\mathrm{C}} * T\right)
\end{aligned}
$$

So the space of the specialising fud substrate history coder, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)$, is minimised when (a) the possible fud derived volume is minimised, (b) the derived entropy or component size entropy of the fud transform is minimised, and (c) high size components are low cardinality components and low size components are high cardinality components for each of the fud transforms.

In the domain where the size is less than or equal to the volume, $z \leq v$, the log likelihood varies with the sum of the size scaled substrate component size cardinality cross entropies,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}(A, z)(A) \sim z \times \sum_{T \in F} \operatorname{entropy} \operatorname{Cross}\left(A * T_{F}, V^{\mathrm{C}} * T_{F}\right)
$$

so conjecture that the log likelihood varies with the sum of the size scaled layer component size cardinality cross entropies,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}(A, z)(A) \sim z \times \sum_{T \in F} \text { entropy } \operatorname{Cross}\left(A * T_{F}, V_{T}^{\mathrm{C}} * T\right)
$$

In addition the log likelihood varies against size scaled fud transform derived entropy,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}(A, z)(A) \sim-z \times \operatorname{entropy}\left(A * F^{\mathrm{F}}\right)
$$

because the log likelihood varies against all of the transform derived entropies including that of the top transform. Together, conjecture that in this domain the log likelihood varies against the specialising space.

Conjecture that in the case where the size is less than the volume, $z_{0}<v_{\mathrm{o}}$, but the sample approximates to the fud-independent, $A_{\mathrm{o}} \approx A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}\left(F_{\mathrm{o}}\right)}$, the log likelihood of the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate varies against the specialising fud substrate history coder space,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\operatorname{space}\left(C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}^{V_{\mathrm{o}}}\right)\right)\left(H_{\mathrm{o}}\right)
$$

where $F^{V}$ is the expansion that adds a unary transform in the remaining underlying variables, $F \cup\left\{\left\{(V \backslash \operatorname{und}(F))^{\mathrm{CS}}\right\}^{\mathrm{T}}\right\}$. The iso-fud conditional stuffed historical probability distribution log likelihood is maximised and the specialising fud substrate history coder space is minimised by varying the fud such that (i) the fud transform derived entropy is low, and (ii) high counts are in low cardinality components and high cardinality components have low counts for all transforms.

In section 'Derived history space', above, the specialising-canonical space difference, $2 C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, is shown to be characterised by certain properties. The specialising-canonical space difference varies (i) with twice the total possible derived volume of the transforms, where the possible derived volumes are less than the size, otherwise with twice the total size scaled log possible derived volume, (ii) with the sum of the size scaled derived entropies, (iii) against twice the sum of the size scaled component size cardinality cross entropies and (iv) against the sum of the size scaled
size expected component entropies,

$$
\begin{aligned}
& 2 C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H) \sim \\
& \quad \sum_{T \in F} 2\left(\left(w_{T}^{\prime}: w_{T}^{\prime}<z\right)+\left(z \ln w_{T}^{\prime}: w_{T}^{\prime} \geq z\right)\right) \\
& \quad+\sum_{T \in F} z \times \operatorname{entropy}\left(A * T_{F}\right) \\
& \quad-\sum_{T \in F} 2 z \times \operatorname{entropyCross}\left(A * T_{F}, V_{T}^{\mathrm{C}} * T\right) \\
& \quad-\sum_{T \in F} z \times \operatorname{entropyComponent}\left(A * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}, T\right)
\end{aligned}
$$

where $w_{T}^{\prime}=\left|T^{-1}\right|$ and $T_{F}=\operatorname{dep}\left(F, W_{T}\right)^{\mathrm{T}}$. So the specialising-canonical space difference, $2 C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, is minimised when (a) the total possible derived volume is minimised, (b) the total derived entropy is minimised, (c) high size components are low cardinality components and low size components are high cardinality components for each transform, and (d) the total expected component entropy is maximised. It was also conjectured that when the specialising-canonical space difference is minimised, (i) the derived entropy decreases up the layers, (ii) the possible derived volume decreases up the layers, (iii) the expected component entropy increases up the layers, and (iv) the component size cardinality cross entropy increases up the layers. The canonical terms, $C_{\mathrm{H}, V}^{\mathrm{s}}(H)$ and $C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, are independent of the model, so these properties are also the properties of the specialising derived substrate history coder space, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)$.

So conjecture that in classical functional definition set induction where the size is less than the volume, $z_{0}<v_{0}$, but the sample approximates to the fud-independent, $A_{\mathrm{o}} \approx A_{\mathrm{o}}^{\mathrm{E}}{ }^{\mathrm{F}\left(F_{\mathrm{o}}\right)}$, the log likelihood of the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate varies against the specialising-canonical space difference,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) & \sim \\
& -\left(2 C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)-C_{\mathrm{H}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)-C_{\mathrm{G}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right)
\end{aligned}
$$

In the special case where (i) the sample histogram equals the fud-independent, $A=A^{\mathrm{E}_{\mathrm{F}}(F)} \Longrightarrow \tilde{E}=\hat{A}^{\mathrm{D}_{\mathrm{F}}(F)}=\hat{A}$, and (ii) the cross entropies are sufficient, $\forall T \in F$ (entropyCross $\left.\left(A * T_{F}, V^{\mathrm{C}} * T_{F}\right)>\ln \left|T_{F}^{-1}\right|\right)$, so that the relative entropies are high, conjecture that the iso-fud conditional multinomial probability at the maximum likelihood estimate varies with the product of the
underlying-derived relative multinomial probabilities,

$$
\frac{\hat{Q}_{\mathrm{m}, U}(A, z)(A)}{\sum_{B \in D_{U, i, F, z}^{-1}\left(\left\{A * T_{F}: T \in F\right\}\right)} \hat{Q}_{\mathrm{m}, U}(A, z)(B)} \sim \frac{\hat{Q}_{\mathrm{m}, U}(A, z)(A)}{\prod_{T \in F} \hat{Q}_{\mathrm{m}, U}\left(A * T_{F}, z\right)\left(A * T_{F}\right)}
$$

Following the reasoning in classical transform induction, above, the sum sensitivity of the iso-fud conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T, U}$, is conjectured to vary with the unknown-known multinomial probability distribution sum sensitivity difference,
$\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{d}, F, U}(E, z)\right)\right) \sim$
$\quad \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right)-\sum_{T \in F} \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}\left(E * T_{F}, z\right)\right)\right)$
The iso-fud conditional stuffed historical probability distribution sum sensitivity varies against the underlying entropy

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F, U}(E, z)\right)\right) \sim-z \times \operatorname{entropy}(E)
$$

The iso-fud conditional stuffed historical probability distribution sum sensitivity varies with the sum of the derived entropies,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F, U}(E, z)\right)\right) \sim \sum_{T \in F} z \times \operatorname{entropy}\left(E * T_{F}\right)
$$

The iso-fud conditional stuffed historical probability distribution sum sensitivity varies against the sum of the size scaled expected component entropies,

$$
\begin{aligned}
& \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F, U}(E, z)\right)\right) \sim \\
& \quad-\sum_{T \in F} z \times \operatorname{entropyComponent}\left(E * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}, T\right)
\end{aligned}
$$

where dep $=$ depends. In classical functional definition set induction, where (i) the history probability function is iso-fud historically distributed, $P=$ $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, F_{\mathrm{o}}}$, given some substrate fud in the sample variables $F_{\mathrm{o}} \in \mathcal{F}_{U, V_{\mathrm{o}}}$, such that there exists a top transform, $\exists T \in F_{\mathrm{o}}\left(\operatorname{der}(T)=\operatorname{der}\left(F_{\mathrm{o}}\right)\right)$, if it is the case that (ii) the sample histogram equals the fud-independent, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}\left(F_{\mathrm{o}}\right)}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the isofud conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, F_{o}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, so, if it is also the case that (iii) the component size cardinality relative entropies are high, $\forall T \in F_{\mathrm{o}}\left(\right.$ entropy $\left.\operatorname{Cross}\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{F_{\mathrm{o}}}\right)>\ln \left|T_{F_{\mathrm{o}}}^{-1}\right|\right)$,
(iv) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{\mathrm{o}}$, and such that (v) the scaled probability sample histogram is integral, $A_{o, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the sum sensitivity of the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate (a) is less than or equal to the sum sensitivity of the stuffed historical probability distribution at the maximum likelihood estimate,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\right.\right. & \left.\left.\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \\
\leq & \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)
\end{aligned}
$$

(b) varies with the total derived entropy,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim \sum_{T \in F_{\mathrm{o}}} z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}\right)
$$

and (c) varies against the total size scaled expected component entropy,

$$
\begin{aligned}
& \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim \\
& \quad-\sum_{T \in F_{\mathrm{o}}} z_{\mathrm{o}} \times \operatorname{entropyComponent}\left(A_{\mathrm{o}} * \operatorname{dep}\left(F_{\mathrm{o}}, V_{T}\right)^{\mathrm{T}}, T\right)
\end{aligned}
$$

Conjecture that in the natural case the sum sensitivity of the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the specialising fud substrate history coder space,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim C_{\mathrm{G}, V_{o}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)
$$

Both the iso-fud conditional stuffed historical probability distribution sum sensitivity and the specialising fud substrate history coder space are minimised by varying the fud such that the derived entropy is low.

Also, conjecture that the sum sensitivity of the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the specialising-canonical space difference,

$$
\begin{aligned}
& \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim \\
& \quad 2 C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)-C_{\mathrm{H}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)-C_{\mathrm{G}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)
\end{aligned}
$$

Both the iso-fud conditional stuffed historical probability distribution sum sensitivity and the specialising-canonical space difference are minimised by varying the fud such that (a) the derived entropy is low and (b) the underlying components have high entropy.

Altogether, in classical functional definition set induction where the size is less than the volume, $z_{\mathrm{o}}<v_{\mathrm{o}}$, but the sample approximates to the fudindependent, $A_{\mathrm{o}} \approx A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}\left(F_{\mathrm{o}}\right)}$, and the relative entropies are high, the sum sensitivity has similar properties as the log-likelihood but with the correlations reversed. Conjecture that in this case the sum sensitivity varies against the log-likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{0}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{0}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

That is, in the natural case, the maximisation of the log-likelihood also tends to minimise the sum sensitivity to the maximum likelihood estimate.

The sum sensitivity of the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)
$$

can be related to queries on the maximum likelihood estimate of the distribution histogram, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, in the special case where (i) the sample histogram equals the fud-independent, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}\left(F_{\mathrm{o}}\right)}$, and (ii) the component size cardinality relative entropies are high, $\forall T \in F_{\mathrm{o}}$ (entropy $\operatorname{Cross}\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{F_{\mathrm{o}}}\right)>$ $\left.\ln \left|T_{F_{\mathrm{o}}}^{-1}\right|\right)$. In the case of classical functional definition set induction, the given substrate fud must be such that its set of underlying variables is a subset of the query variables, $\operatorname{und}\left(F_{\mathrm{o}}\right) \subseteq K$. In the case where the query histogram consists of one effective state, $Q=\left\{\left(S_{Q}, 1\right)\right\}$, there exists an effective derived state for each of the transforms, $\left\{R_{Q}: T \in F_{\mathrm{o}},\left\{R_{Q}\right\}=\left(Q * T_{F_{0}}\right)^{\mathrm{FS}}\right\}$. The corresponding underlying component is the intersection $C_{Q}=\bigcap\left\{T_{F_{\mathrm{o}}}^{-1}\left(R_{Q}\right)\right.$ : $\left.T \in F_{\mathrm{o}},\left\{R_{Q}\right\}=\left(Q * T_{F_{\mathrm{o}}}\right)^{\mathrm{FS}}\right\}$. This component is a subset of that for transform induction, $C_{Q} \subseteq\left(F_{\mathrm{o}}^{\mathrm{T}}\right)^{-1}\left(R_{Q}\right)$ where $\left\{R_{Q}\right\}=\left(Q * F_{\mathrm{o}}^{\mathrm{T}}\right)^{\mathrm{FS}}$. In this case the application of the query via the model equals the application via the component directly, $\bigcap\left\{Q * T_{F_{\mathrm{o}}} * \operatorname{his}\left(T_{F_{\mathrm{o}}}\right) * A_{\mathrm{o}} \% V_{\mathrm{o}}: T \in\right.$ $\left.F_{\mathrm{o}}\right\}^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)=\left(A_{\mathrm{o}} * C_{Q}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)$. If any possible derived volume is non singular, $\left|T_{F_{0}}^{-1}\right|>1$ where $T \in F_{\mathrm{o}}$, the query histogram itself cannot be drawn from the distribution history, $\hat{Q}_{\mathrm{h}, \mathrm{d}, F_{o}, U}\left(A_{\mathrm{o}}, 1\right)\left(Q *\{N\}^{\mathrm{U}}\right)=0$, where $N \in\left(V_{\mathrm{o}} \backslash K\right)^{\mathrm{CS}}$, because at least one query derived probability histogram is not equal to the corresponding known derived distribution probability histogram, $\exists T \in F_{\mathrm{o}}\left(\hat{Q} *\{N\}^{\mathrm{U}} * T_{F_{\mathrm{o}}} \neq \hat{A}_{\mathrm{o}} * T_{F_{\mathrm{o}}}\right)$. The application of the query must be in terms of a modified sample histogram,

$$
\begin{aligned}
& \bigcap\left\{Q * T_{F_{\mathrm{o}}} * \operatorname{his}\left(T_{F_{\mathrm{o}}}\right) * A_{\mathrm{o}} \% V_{\mathrm{o}}: T \in F_{\mathrm{o}}\right\}^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)= \\
& \left\{\left(N,\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{Q, N}\right)\right)^{1 / z_{\mathrm{o}}}\right): N \in\left(V_{\mathrm{o}} \backslash K\right)^{\mathrm{CS}},\right. \\
& \left.\quad A_{Q, N}=A_{\mathrm{o}}-\left(A_{\mathrm{o}} * C_{Q}\right)+\left(\left(A_{\mathrm{o}} * C_{Q}\right) \% K *\{N\}^{\mathrm{U}}\right)\right\}^{\wedge}
\end{aligned}
$$

where his $=$ histogram. If the sample histogram is completely effective, $A_{\mathrm{o}}^{\mathrm{F}}=$ $V_{\mathrm{o}}^{\mathrm{C}}$, the modified sample histogram, $A_{Q, N}$, can be drawn from the distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{Q, N}\right)>0$, because the modified sample histogram is an iso-fud, $\forall T \in F_{\mathrm{o}}\left(A_{Q, N} * T_{F_{\mathrm{o}}}=A_{\mathrm{o}} * T_{F_{\mathrm{o}}}\right)$. The model application depends on the geometric scaling of the historical distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)$, so the query sensitivity to the distribution histogram varies with the sum sensitivity of the historical distribution at the maximum likelihood estimate divided by the sample size,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{o}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}}
$$

Although the query application via the model is sometimes not equal to the estimated transformed conditional product, the query sensitivity to the distribution histogram is sometimes lower,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\right.\right. & \left.\left.\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}} \\
\leq & \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}}
\end{aligned}
$$

Similarly, where the size is less than the volume, $z_{0}<v_{\mathrm{o}}$, the model likelihood of the distribution histogram is sometimes higher,

$$
\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{o}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z\right)\left(A_{Q, N}\right) \geq \hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z\right)\left(A_{Q, N}\right)
$$

In other words, querying via the known derived of the model sometimes reduces the sensitivity to the unknown and increases the likelihood at the cost of modifying the query.

### 5.5.3 Necessary derived functional definition set decomposition

The last section extended the model from transforms to functional definition sets. Now extend further to functional definition set decompositions. This discussion is very similar to that of the previous section, except that now the fuds are contingent on the slice.

Given some non-empty known substrate fud decomposition, $D_{\mathrm{o}} \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}$, such that there exists a top transform for all of the fuds, $\forall F \in \operatorname{fuds}\left(D_{\mathrm{o}}\right) \exists T \in$ $F(\operatorname{der}(T)=\operatorname{der}(F))$, the component derived set of the distribution probability histogram is $\left\{\left(C,\left\{\hat{E}_{\mathrm{h}} * C * T_{F}: T \in F\right\}\right):(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right)\right\}$, where $\operatorname{cont}(D)=\operatorname{elements}(\operatorname{contingents}(D))$ and $T_{F}:=\operatorname{depends}(F, \operatorname{der}(T))^{\mathrm{T}}$. In classical functional definition set decomposition induction, while the distribution probability histogram, $\hat{E}_{\mathrm{h}}$, remains unknown, the component derived distribution probability set, $\left\{\left(C,\left\{\hat{E}_{\mathrm{h}} * C * T_{F}: T \in F\right\}\right):(C, F) \in\right.$
$\left.\operatorname{cont}\left(D_{\mathrm{o}}\right)\right\}$, is known and necessary. That is, the history probability function, $P$, is historically distributed but constrained such that all drawn histories have a derived probability histogram equal to the known derived distribution probability histogram for each of the transforms of the fud for each slice, $\forall(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right) \forall T \in F\left(\hat{A}_{H} * C * T_{F}=\hat{E}_{\mathrm{h}} * C * T_{F}\right)$. Define the iso-fud-decomposition historically distributed history probability function $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, D_{\mathrm{o}}} \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}$,
$P_{U, X, H_{\mathrm{h}}, \mathrm{d}, D_{\mathrm{o}}}:=$

$$
\begin{aligned}
& \left(\bigcup \left\{\begin{array}{l}
\bigcup(H, 1): H \subseteq H_{\mathrm{h}} \% V_{H},|H|=z_{H}, \\
\left.\forall(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right) \forall T \in F\left(\hat{A}_{H} * C * T_{F}=\hat{E}_{\mathrm{h}} * C * T_{F}\right)\right\}^{\wedge}
\end{array} \quad \begin{array}{l}
\left.\left.\quad V_{H} \subseteq V_{\mathrm{h}}, z_{H} \in\left\{1 \ldots z_{\mathrm{h}}\right\}\right\}\right)^{\wedge} \cup \\
\begin{array}{l}
\left\{(H, 0): H \in \mathcal{H}_{U, X},\right.
\end{array} \\
\left.\quad \exists(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right) \exists T \in F\left(\hat{A}_{H} * C * T_{F} \neq \hat{E}_{\mathrm{h}} * C * T_{F}\right)\right\} \cup \\
\left\{(H, 0): H \in \mathcal{H}_{U, X}, H \nsubseteq H_{\mathrm{h}} \% V_{H}\right\} \cup\{(\emptyset, 0)\}
\end{array}\right.\right.
\end{aligned}
$$

In classical functional definition set decomposition induction the history probability function is iso-fud-decomposition historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, D_{\mathrm{o}}}$.

If the decomposition only has a root node, $D_{\mathrm{o}}=\left\{\left(\left(\emptyset, F_{\mathrm{o}}\right), \emptyset\right)\right\}$, classical functional definition set decomposition induction reduces to classical functional definition set induction, $P_{U, X, H_{\mathrm{h}}, \mathrm{d},\left\{\left(\left(\emptyset, F_{\mathrm{o}}\right), \emptyset\right)\right\}}=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, F_{\mathrm{o}}}$. If the root fud is a singleton, $F_{\mathrm{o}}=\left\{T_{\mathrm{o}}\right\}$, classical functional definition set decomposition induction reduces to classical derived induction, $P_{U, X, H_{\mathrm{h}}, \mathrm{d},\left\{\left(\left(\emptyset,\left\{T_{o}\right\}\right), \emptyset\right)\right\}}=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{o}}$.

The iso-fud-decomposition historical probability may be expressed in terms of a histogram distribution,
$\hat{Q}_{\mathrm{h}, \mathrm{d}, D_{0}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right) \propto \sum\left(P_{U, X, H_{\mathrm{h}}, \mathrm{d}, D_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}\right)$
where the iso-fud-decomposition conditional stuffed historical probability distribution is defined

$$
\begin{aligned}
\hat{Q}_{\mathrm{h}, \mathrm{~d}, D, U}( & (E, z) \\
:= & \left\{\left(A, \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum_{B \in D_{U, \mathrm{i}, D, \mathrm{~F}, z}^{-1}\left(D_{U, D, \mathrm{~F}, z}(A)\right)} Q_{\mathrm{h}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \leq E\right\}^{\wedge} \cup \\
& \left\{(A, 0): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \nsubseteq E\right\}
\end{aligned}
$$

which is defined if $z \leq \operatorname{size}(E)$. The component-derived-set function valued function of the substrate histograms $D_{U, D, \mathrm{~F}, z} \in \mathcal{A}_{U, V, z} \rightarrow\left(\mathcal{A}_{U} \rightarrow \mathrm{P}\left(\mathcal{A}_{U}\right)\right)$ is
defined
$D_{U, D, \mathrm{~F}, z}=\left\{\left(A,\left\{\left(C,\left\{A * C * T_{F}: T \in F\right\}\right):(C, F) \in \operatorname{cont}(D)\right\}\right): A \in \mathcal{A}_{U, V, z}\right\}$
The finite set of iso-fud-decompositions of component-derived-set $D_{U, D, F, z}(A)$ is

$$
\begin{aligned}
& D_{U, \mathrm{i}, D, \mathrm{~F}, z}^{-1}\left(D_{U, D, \mathrm{~F}, z}(A)\right)= \\
& \quad\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, \forall(C, F) \in \operatorname{cont}(D) \forall T \in F\left(B * C * T_{F}=A * C * T_{F}\right)\right\}
\end{aligned}
$$

In this case the top transform exists for all fuds, $\forall F \in \operatorname{fuds}(D) \exists T \in$ $F(\operatorname{der}(T)=\operatorname{der}(F))$, so the set of iso-fud-decompositions is a law-like subset of the iso-deriveds,

$$
D_{U, D, \mathrm{~F}, z}^{-1}\left(D_{U, D, \mathrm{~F}, z}(A)\right) \subseteq D_{U, D^{\mathrm{T}}, z}^{-1}\left(A * D^{\mathrm{T}}\right)
$$

and therefore necessary derived fud decomposition is stricter than necessary derived. That is, a history can only be drawn in classical functional definition set decomposition induction if it can be drawn in classical transform induction for the transform of the fud decomposition, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, D_{\mathrm{o}}}(H)>0 \Longrightarrow$ $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, D_{o}^{\mathrm{T}}}(H)>0$.

The set of iso-fud-decompositions is also a law-like subset of the iso-fuds for the root node,

$$
\begin{aligned}
D_{U, D, \mathrm{~F}, z}^{-1}\left(D_{U, D, \mathrm{~F}, z}(A)\right) & \subseteq D_{U, F, z}^{-1}\left(\left\{A * T_{F}: T \in F\right\}\right) \\
& \subseteq D_{U, F^{\mathrm{T}}, z}^{-1}\left(A * F^{\mathrm{T}}\right)
\end{aligned}
$$

where $\{((\emptyset, F), \cdot)\}=D$.
The iso-fud-decomposition conditional generalised multinomial probability distribution is defined

$$
\begin{aligned}
& \hat{Q}_{\mathrm{m}, \mathrm{~d}, D, U}(E, z) \\
&:=\left\{\left(A, \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in D_{U U, \mathrm{i}, \mathrm{~F}, z}^{-1}\left(D_{U, D, \mathrm{~F}, z}(A)\right)} Q_{\mathrm{m}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A^{\mathrm{F}} \leq E^{\mathrm{F}}\right\}^{\wedge} \cup \\
&\left\{(A, 0): A \in \mathcal{A}_{U, \mathbf{i}, V, z}, A^{\mathrm{F}} \not \leq E^{\mathrm{F}}\right\}
\end{aligned}
$$

which is defined if $\operatorname{size}(E)>0$.
It is assumed that the distribution history size, $z_{\mathrm{h}}$, is large with respect to the sample size $z_{\mathrm{o}}=\operatorname{size}\left(A_{\mathrm{o}}\right)$, so that, in the limit, the iso-fud-decomposition
historical probability, $\hat{Q}_{\mathrm{h}, \mathrm{d}, D_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$, approximates to the iso-fuddecomposition multinomial probability, $\hat{Q}_{\mathrm{m}, \mathrm{d}, D_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$. That is, if $z_{\mathrm{o}} \ll z_{\mathrm{h}}$ then

$$
\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \approx \hat{Q}_{\mathrm{m}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

where $E_{\mathrm{o}}=E_{\mathrm{h}} \% V_{\mathrm{o}}$.
In the case of completely effective sample histogram, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$, the maximisation for known fud decomposition, $D_{\mathrm{o}}$, of the iso-fud-decomposition conditional generalised multinomial probability parameterised by the complete congruent histograms of unit size is a singleton of the rational maximum likelihood estimate

$$
\left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}\right\}\right)
$$

In the case where the maximisation of the iso-fud-decomposition conditional generalised multinomial probability distribution is a singleton, it is equal to the normalised fud-decomposition-dependent, $\tilde{E}_{\mathrm{O}}=\hat{A}_{\mathrm{o}}^{\mathrm{DD}, \mathrm{F}}{ }^{\left(D_{\mathrm{o}}\right)}$, where the fud-decomposition-dependent $A^{\mathrm{D}_{\mathrm{D}, \mathrm{F}}(D)} \in \mathcal{A}_{U, V, z}$ is defined in 'Likely histograms', above, as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, $A$, conditional that it is an iso-fud-decomposition,

$$
\begin{aligned}
& \left\{A^{\mathrm{D}_{\mathrm{D}, \mathrm{~F}(D)}(D)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(E, \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum Q_{\mathrm{m}, U}(E, z)(B): B \in D_{U, \mathrm{i}, D, \mathrm{~F}, z}^{-1}\left(D_{U, D, \mathrm{~F}, z}(A)\right)}\right): E \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The independent analogue is the fud-decomposition-independent, $A^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}(D)} \in$ $\mathcal{A}_{U, V, z}$, defined,

$$
\begin{aligned}
& \left\{A^{\mathrm{E}_{\mathrm{D}, \mathrm{~F}}(D)}\right\}= \\
& \quad \quad \operatorname{maxd}\left(\left\{\left(E, \sum\left(Q_{\mathrm{m}, U}(E, z)(B): B \in D_{U, \mathrm{i}, D, \mathrm{~F}, z}^{-1}\left(D_{U, D, \mathrm{~F}, z}(A)\right)\right)\right): E \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The fud-decomposition-independent approximates to the scaled sum of the slice arithmetic average of the naturalisations,

$$
A^{\mathrm{E}_{\mathrm{D}, \mathrm{~F}}(D)} \approx Z_{z} *\left(\sum_{(C, F) \in \operatorname{cont}(D)}\left(Z_{1 /|F|} * \sum_{T \in F} A * C * T_{F} * T_{F}^{\dagger}\right)\right)^{\wedge}
$$

It is only in the case where the histogram equals the fud-decompositionindependent that the maximum likelihood estimate is necessarily equal to the sample probability histogram,

$$
A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{~F}}\left(D_{\mathrm{o}}\right)} \Longrightarrow A_{\mathrm{o}}^{\mathrm{D}_{\mathrm{D}, \mathrm{~F}}\left(D_{\mathrm{o}}\right)}=A_{\mathrm{o}} \Longrightarrow \tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

Otherwise, the overall maximum likelihood estimate, which is the fud decomposition dependent, is near the histogram, $\tilde{E}_{\mathrm{o}} \sim \hat{A}_{\mathrm{o}}$, only in as much as it is far the fud-decomposition-independent, $\tilde{E}_{\mathrm{o}} \nsim \hat{\mathrm{A}}_{\mathrm{o}}^{\mathrm{E}, \mathrm{F}\left(D_{\mathrm{o}}\right)}$.

In classical functional definition set decomposition induction, where (i) the history probability function is iso-fud-decomposition historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, D_{\mathrm{o}}}$, given some substrate fud decomposition in the sample variables $D_{\mathrm{o}} \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}$, such that there exists a top transform for all of the fuds, $\forall F \in \operatorname{fuds}\left(D_{\mathrm{o}}\right) \exists T \in F(\operatorname{der}(T)=\operatorname{der}(F))$, if it is the case that (ii) the sample histogram equals the fud-decomposition-independent, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}\left(D_{\mathrm{o}}\right)}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the iso-fud-decomposition conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, D_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is

$$
\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

Given the known substrate fud decomposition, $D_{\mathrm{o}}$, consider the log likelihood in the special case where sample histogram equals the fud-decompositionindependent, $A_{\mathrm{O}}={A_{\mathrm{O}}^{\mathrm{E}, \mathrm{F}}}_{\mathrm{E}_{\mathrm{D}}\left(D_{\mathrm{o}}\right)} \Longrightarrow \tilde{E}_{\mathrm{O}}=\hat{A}_{\mathrm{o}}^{\mathrm{D}_{\mathrm{D}, \mathrm{F}}\left(D_{\mathrm{O}}\right)}=\hat{A}_{\mathrm{o}}$.

In classical functional definition set decomposition induction, if it is the case that (ii) the sample histogram equals the fud-decomposition-independent, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}\left(D_{\mathrm{o}}\right)}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{O}}$, in the iso-fud-decomposition conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, D_{0}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, so, if it is also the case that (iii) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{\mathrm{o}}$, and such that (iv) the scaled probability sample histogram is integral, $A_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the log likelihood of the iso-fud-decomposition conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the sum of size-volume scaled component size cardinality sum relative entropies of all transforms for all slices,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \\
& \sum_{(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right)} \sum_{T \in F}\left(\left(z_{A_{\mathrm{o}} * C}+|C|\right) \times \operatorname{entropy}\left(A_{\mathrm{o}} * C * T_{F}+C * T_{F}\right)\right. \\
& \left.\quad-z_{A_{\mathrm{o}} * C} \times \operatorname{entropy}\left(A_{\mathrm{o}} * C * T_{F}\right)-|C| \times \operatorname{entropy}\left(C * T_{F}\right)\right)
\end{aligned}
$$

In the case where the size is greater than the volume, $z_{0}>v_{\mathrm{o}}$, the iso-fud-decomposition conditional stuffed historical probability distribution at the
maximum likelihood estimate varies with the sum of volume scaled component cardinality size relative entropies of all transforms for all slices,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim
$$

In the case where the size is less than the volume, $z_{0}<v_{\mathrm{o}}$, but the sample histogram approximates to the fud-decomposition-independent histogram, $A_{\mathrm{o}} \approx A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}\left(D_{\mathrm{o}}\right)}$, or spaceRelative $\left(A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}\left(D_{\mathrm{o}}\right)}\right)\left(A_{\mathrm{o}}\right) \approx 0$, the log likelihood of the iso-fud-decomposition conditional stuffed historical probability distribution at the maximum likelihood estimate varies with sum of the size scaled component size cardinality relative entropies of all transforms for all slices,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim
$$

So, in this case, the log likelihood is maximised when (a) the sum of the derived entropies of all transforms for all slices is minimised, and (b) high size components are low cardinality components and low size components are high cardinality components for all transforms for all slices.

If it is also the case that the component size cardinality relative entropies are high, $\forall(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right) \forall T \in F\left(\right.$ entropy $\operatorname{Cross}\left(A_{\mathrm{o}} * C * T_{F}, C * T_{F}\right)>$ $\ln \left|T_{F}^{-1}\right|$ ), then the log likelihood of the iso-fud-decomposition conditional stuffed historical probability distribution at the maximum likelihood estimate varies against the sum of logarithms of the derived multinomial probabilities of the transforms for all slices,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \\
& \quad-\sum_{(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right)} \sum_{T \in F} \ln \hat{Q}_{\mathrm{m}, U}\left(A_{\mathrm{o}} * C * T_{F}, z_{A_{\mathrm{o}} * C}\right)\left(A_{\mathrm{o}} * C * T_{F}\right)
\end{aligned}
$$

In section 'Derived history space', above, the specialising fud decomposition substrate history coder $C_{\mathrm{G}, V, \mathrm{D}, \mathrm{F}, \mathrm{H}}(F) \in \operatorname{coders}\left(\mathcal{H}_{U, V, X}\right)$ is constructed

$$
\begin{aligned}
& C_{\mathrm{G}, V, \mathrm{D}, \mathrm{~F}, \mathrm{H}}(F)= \\
& \quad \text { coderHistorySubstrateFudDecompSpecialising }\left(U, X, F, D_{\mathrm{S}}, D_{\mathrm{X}}\right)
\end{aligned}
$$

Conjecture that, in the case where the size is less than the volume, $z_{\mathrm{o}}<v_{\mathrm{o}}$, but the sample approximates to the fud-decomposition-independent, $A_{\mathrm{o}} \approx$
$A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}\left(D_{\mathrm{o}}\right)}$, the log likelihood of the iso-fud-decomposition conditional stuffed historical probability distribution at the maximum likelihood estimate varies against the specialising fud decomposition substrate history coder space,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\operatorname{space}\left(C_{\mathrm{G}, V_{o}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D_{\mathrm{o}}^{V_{\mathrm{o}}}\right)\right)\left(H_{\mathrm{o}}\right)
$$

where $D^{V}$ is the expansion that adds a unary transform in the remaining underlying variables to the leaf fuds in the decomposition tree such that the fud of each path of the application tree has complete coverage of the substrate,

$$
\forall L \in \operatorname{paths}\left(D^{*}\right)\left(\bigcup_{(\cdot,(F, \cdot)) \in L} V_{F}=V\right)
$$

where $V_{F}=\operatorname{und}(F)$.
Conjecture that, in this case, the log likelihood of the iso-fud-decomposition conditional stuffed historical probability distribution at the maximum likelihood estimate varies against the specialising-canonical space difference,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) & \sim \\
& -\left(2 C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D_{\mathrm{o}}^{V_{\mathrm{o}} \mathrm{~s}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)-C_{\mathrm{H}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)-C_{\mathrm{G}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right)
\end{aligned}
$$

In classical functional definition set decomposition induction, where (i) the history probability function is iso-fud-decomposition historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, D_{\mathrm{o}}}$, given some substrate fud decomposition in the sample variables $D_{\mathrm{o}} \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}$, such that there exists a top transform for all of the fuds, $\forall F \in \operatorname{fuds}\left(D_{\mathrm{o}}\right) \exists T \in F(\operatorname{der}(T)=\operatorname{der}(F))$, if it is the case that (ii) the sample histogram equals the fud-decomposition-independent, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}, \mathrm{F}\left(D_{\mathrm{o}}\right)}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the iso-fud-decomposition conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, D_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, so, if it is also the case that (iii) the component size cardinality relative entropies are high, $\forall(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right) \forall T \in$ $F$ (entropyCross $\left.\left(A_{\mathrm{o}} * C * T_{F}, C * T_{F}\right)>\ln \left|T_{F}^{-1}\right|\right)$, (iv) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{0}$, and such that (v) the scaled probability sample histogram is integral, $A_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the sum sensitivity of the iso-fud-decomposition conditional stuffed historical probability distribution at the maximum likelihood estimate (a) is less than or equal to the sum sensitivity of the stuffed historical probability distribution at the maximum likelihood estimate,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\right.\right. & \left.\left.\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \\
\leq & \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)
\end{aligned}
$$

(b) varies with the total derived entropy,

$$
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\sum_{(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right)}\left(z_{A_{\mathrm{o}} * C} \times \sum_{T \in F} \operatorname{entropy}\left(A_{\mathrm{o}} * C * T_{F}\right)\right)\right.\right.
$$

and (c) varies against the total size scaled expected component entropy,
$\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim$

$$
-\sum_{(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right)}\left(z_{A_{\mathrm{o}} * C} \times \sum_{T \in F} \text { entropyComponent }\left(A_{\mathrm{o}} * C * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}, T\right)\right)
$$

Conjecture that in the natural case the sum sensitivity of the iso fud decomposition conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the specialising fud decomposition substrate history coder space,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D_{\mathrm{o}}^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)
$$

Also, conjecture that the sum sensitivity of the iso-fud-decomposition conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the specialising-canonical space difference,

$$
\begin{aligned}
& \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim \\
& 2 C_{\mathrm{G}, V_{o}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D_{\mathrm{o}}^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)-C_{\mathrm{H}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)-C_{\mathrm{G}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)
\end{aligned}
$$

So conjecture that in the case where the size is less than the volume, $z_{\mathrm{o}}<v_{\mathrm{o}}$, but the sample approximates to the fud-independent, $A_{o} \approx A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}\left(D_{\mathrm{o}}\right)}$, the sum sensitivity varies against the log-likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

That is, in the natural case, the maximisation of the log-likelihood also tends to minimise the sum sensitivity to the maximum likelihood estimate.

The sum sensitivity of the iso-fud-decomposition conditional stuffed historical probability distribution at the maximum likelihood estimate,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)
$$

can be related to queries on the maximum likelihood estimate of the distribution histogram, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, in the special case where (i) the sample histogram
equals the fud-decomposition-independent, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}\left(D_{\mathrm{o}}\right)}$, and (ii) the component size cardinality relative entropies are high, $\forall(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right) \forall T \in$ $F$ (entropyCross $\left.\left(A_{\mathrm{o}} * C * T_{F}, C * T_{F}\right)>\ln \left|T_{F}^{-1}\right|\right)$. In the case of classical functional definition set decomposition induction, the given substrate fud decomposition must be such that its set of underlying variables is a subset of the query variables, $\operatorname{und}\left(D_{\mathrm{o}}\right) \subseteq K$. In the case where the query histogram consists of one effective state, $Q=\left\{\left(S_{Q}, 1\right)\right\}$, there exists an effective derived state for each of the transforms along one of the slice paths, $\left\{\left(C, R_{Q}\right):(C, F) \in \operatorname{cont}\left(D_{\circ}\right), Q * C \neq \emptyset, T \in F,\left\{R_{Q}\right\}=\left(Q * T_{F}\right)^{\mathrm{FS}}\right\}$. The corresponding underlying component is the intersection

$$
\begin{aligned}
& C_{Q}=\bigcap\left\{C * T_{F}^{-1}\left(R_{Q}\right):\right. \\
&\left.(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right), Q * C \neq \emptyset, T \in F,\left\{R_{Q}\right\}=\left(Q * T_{F}\right)^{\mathrm{FS}}\right\}
\end{aligned}
$$

This component is a subset of that for transform induction, $C_{Q} \subseteq\left(D_{\mathrm{o}}^{\mathrm{T}}\right)^{-1}\left(R_{Q}\right)$ where $\left\{R_{Q}\right\}=\left(Q * D_{\mathrm{o}}^{\mathrm{T}}\right)^{\mathrm{FS}}$. In this case the application of the query via the model equals the application via the component directly, $\bigcap\left\{Q * T_{F} * \operatorname{his}\left(T_{F}\right) *\right.$ $\left.\left(A_{\mathrm{o}} * C\right) \% V_{\mathrm{o}}:(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right), Q * C \neq \emptyset, T \in F\right\}^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)=\left(A_{\mathrm{o}} *\right.$ $\left.C_{Q}\right)^{\wedge} \%\left(V_{o} \backslash K\right)$. If any possible derived volume is non singular, $\left|T_{F}^{-1}\right|>1$, where $(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right), Q * C \neq \emptyset$ and $T \in F$, the query histogram itself cannot be drawn from the distribution history, $\hat{Q}_{\mathrm{h}, \mathrm{d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}}, 1\right)\left(Q *\{N\}^{\mathrm{U}}\right)=$ 0 , where $N \in\left(V_{\mathrm{o}} \backslash K\right)^{\mathrm{CS}}$, because at least one query derived probability histogram is not equal to the corresponding known derived distribution probability histogram, $\exists(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right) \exists T \in F\left(\hat{Q} * C *\{N\}^{\mathrm{U}} * T_{F} \neq \hat{A}_{\mathrm{o}} * C * T_{F}\right)$. The application of the query must be in terms of a modified sample histogram,

$$
\begin{aligned}
& \bigcap\left\{Q * T_{F} * \operatorname{his}\left(T_{F}\right) *\left(A_{\mathrm{o}} * C\right) \% V_{\mathrm{o}}:\right. \\
& \left.(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right), Q * C \neq \emptyset, T \in F\right\}^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right) \\
& =\left\{\left(N,\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{Q, N}\right)\right)^{1 / z_{\mathrm{o}}}\right): N \in\left(V_{\mathrm{o}} \backslash K\right)^{\mathrm{CS}},\right. \\
& \left.A_{Q, N}=A_{\mathrm{o}}-\left(A_{\mathrm{o}} * C_{Q}\right)+\left(\left(A_{\mathrm{o}} * C_{Q}\right) \% K *\{N\}^{\mathrm{U}}\right)\right\}^{\wedge}
\end{aligned}
$$

where his $=$ histogram. If the sample histogram is completely effective, $A_{o}^{\mathrm{F}}=$ $V_{\mathrm{o}}^{\mathrm{C}}$, the modified sample histogram, $A_{Q, N}$, can be drawn from the distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{Q, N}\right)>0$, because the modified sample histogram is an iso-fud-decomposition, $\forall(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right) \forall T \in F\left(A_{Q, N} * C * T_{F}=A_{\mathrm{o}} * C *\right.$ $\left.T_{F}\right)$. The model application depends on the geometric scaling of the historical distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)$, so the query sensitivity to the distribution histogram varies with the sum sensitivity of the historical distribution at the maximum likelihood estimate divided by the sample size,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}}
$$

Although the query application via the model is sometimes not equal to the estimated transformed conditional product, the query sensitivity to the distribution histogram is sometimes lower,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\right.\right. & \left.\left.\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}} \\
& \leq \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}}
\end{aligned}
$$

Similarly, where the size is less than the volume, $z_{0}<v_{\mathrm{o}}$, the model likelihood of the distribution histogram is sometimes higher,

$$
\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z\right)\left(A_{Q, N}\right) \geq \hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z\right)\left(A_{Q, N}\right)
$$

In other words, querying via the known derived of the model sometimes reduces the sensitivity to the unknown and increases the likelihood at the cost of modifying the query.

### 5.5.4 Unknown necessary derived

In the discussion above of classical modelled induction, the iso-set conditional stuffed historical probability distribution likelihood and sum sensitivity relations are correlations rather than approximations or equivalences. In the case where the models are transforms, the variation over both (i) the set of probability distribution substrate histograms, $\mathcal{A}_{U, V_{o}, 1}$, and (ii) the set of substrate transforms, $\mathcal{T}_{U, V_{o}}$, has been informally implicit in the correlations. In the discussion above, the model, $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, is known and the derived, $\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}$, is both necessary and known. Optimisation can be done to find the maximum likelihood estimate of the distribution histogram for known model,

$$
\left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}\right\}\right)
$$

Now consider the case where the derived is still necessary, $\hat{A}_{\mathrm{o}} * T_{\mathrm{o}}=\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}$, but the model, $T_{\mathrm{o}}$, is unknown and so the derived is unknown. Here the transform, $T$, is considered to be a parameter of the iso-derived conditional generalised multinomial probability distribution, $\hat{Q}_{\mathrm{m}, \mathrm{d}, T, U}(E, z)$, along with the distribution histogram, $E$. Note, however, that while the distribution histogram, $E$, can be mapped to a real vector, $\hat{E}^{\square} \in \mathbf{R}^{v}$, in the iso-derived conditional generalised multinomial parameterised probability density function, $\operatorname{mdtppdf}(T, z)\left(\hat{E}^{\square}\right) \in\left(\mathbf{R}^{v}: \rightarrow \mathbf{R}\right)$, and hence can be a continuous argument to the iso-derived conditional generalised multinomial likelihood function, $\operatorname{mdtlf}(T, z)\left(A^{\square}\right) \in\left(\mathbf{R}^{v} \rightarrow \mathbf{R}\right)$, there is no straightforward mapping $\hat{T}^{】}$ for the transform. Another problem is that the iso-derived conditional generalised multinomial probability, $\hat{Q}_{\mathrm{m}, \mathrm{d}, T, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$, is not explicitly constrained so that the derived is necessary, $\hat{A}_{\mathrm{o}} * T=\hat{E}_{\mathrm{h}} * T$. However, the
maximum likelihood estimate for the pair $\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right)$ can be defined as an optimisation of the multinomial probability conditional on the iso-derived where both the distribution histogram and transform are treated as arguments to a likelihood function,

$$
\begin{aligned}
& \left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right) \\
& \qquad \operatorname{maxd}\left(\left\{\left((E, T), \frac{Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in D_{U, \mathrm{i}, T, z_{\mathrm{o}}}^{-1}\left(A_{\mathrm{o}} * T\right)} Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)(B)}\right)\right.\right. \\
& \left.\left.\quad E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}, T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
\end{aligned}
$$

The sensitivity to parameter is now with respect to the pair, $(E, T)$, and not just with respect to the distribution histogram, $E$. Again, there is no mapping of the transform to a coordinate, $\hat{T}^{\square}$, so the sensitivity with respect to the distribution-transform pair at the maximum likelihood estimate, ( $\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}$ ), may be approximated as the sum of (i) the sum sensitivity of the iso-derived conditional multinomial probability distribution at the maximum likelihood estimate,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{~d}, \tilde{T}_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}}, z_{\mathrm{o}}\right)\right)\right)
$$

and (ii) the negative logarithm of the cardinality of the maximum likelihood estimate models,

$$
-\ln \left|\max \left(\left\{\left(T, \frac{Q_{\mathrm{m}, U}\left(\tilde{E}_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in D_{U, i, T, z_{\mathrm{o}}}^{-1}\left(A_{\mathrm{o}} * T\right)} Q_{\mathrm{m}, U}\left(\tilde{E}_{\mathrm{o}}, z_{\mathrm{o}}\right)(B)}\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)\right|
$$

Although the maximum likelihood estimate and the sensitivity with respect to the pair, $\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right)$, can be defined, there is, however, no singular solution to the optimisation with respect to the distribution probability histogram, $E$,

$$
\left.\left.\left.\begin{array}{rl}
\operatorname{maxd}\left(\left\{\left((E, T), \frac{Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{}\right.\right.\right. & \sum_{B \in D_{U, i, T, z_{\mathrm{o}}}^{-1}\left(A_{\mathrm{o}} * T\right)} Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)(B)
\end{array}\right): \quad E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}, T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right) \supseteq \mathcal{A}_{U, V_{\mathrm{o}}, 1} \times\left\{T_{\mathrm{s}}\right\}
$$

where $T_{\mathrm{s}}$ is a self transform, for example the self partition transform, $T_{\mathrm{s}}=$ $V^{\mathrm{CS}\{ \} \mathrm{T}}$ or the full functional transform, $T_{\mathrm{s}}=\left\{\{w\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: w \in V\right\}^{\mathrm{T}}$. When the transform is a self transform the denominator equals the numerator, $\sum_{B \in D_{U, i, T_{\mathrm{s}}, z}^{-1}\left(A * T_{\mathrm{s}}\right)} Q_{\mathrm{m}, U}(E, z)(B)=Q_{\mathrm{m}, U}(E, z)(A)$, and the solution is degenerate. That is, the maximisation does not yield a single maximum likelihood estimate for the distribution probability histogram, $\tilde{E}_{\mathrm{o}}$.

In the case where the derived is necessary but unknown, the maximum likelihood estimate for the model, $\tilde{T}_{\mathrm{o}}$, is just the self transform, $\tilde{T}_{\mathrm{o}}=T_{\mathrm{s}}$, which is the trivial case where everything is known.

### 5.5.5 Uniform possible derived induction

This singular solution for unknown transform can be addressed by making the transform more like a continuous vector. That is, by avoiding discontinuities in the history probability function. Consider the case where it is unknown if the given histogram, $A_{0}$, is a sample histogram drawn from the distribution histogram, $E_{\mathrm{h}}$, so, in some cases $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{\mathrm{o}}}\left(H_{\mathrm{o}}\right)=0$. That is, it is known that some derived is necessary, $\exists B \in \mathcal{A}_{U, \mathrm{i}, V_{\mathrm{o}}, z_{\mathrm{o}}}\left(\hat{B} * T_{\mathrm{o}}=\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)$, but not whether the given derived histogram is necessary, $\hat{A}_{\mathrm{o}} * T_{\mathrm{o}}=\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}$.

In the necessary given derived case, a probability function $P_{\mathrm{d}} \in\left(\mathcal{A}_{\mathrm{i}} \rightarrow\right.$ $\left.\mathrm{Q}_{[0,1]}\right) \cap \mathcal{P}$ of the derived can be defined as

$$
P_{\mathrm{d}}=\left\{\left(Z_{\mathrm{o}} * \hat{E}_{\mathrm{h}} * T_{\mathrm{o}}, 1\right)\right\} \cup\left(\left(\operatorname{ran}\left(D_{U, \mathbf{i}, T_{\mathrm{o}}, z_{\mathrm{o}}}\right) \backslash\left\{Z_{\mathrm{o}} * \hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right\}\right) \times\{0\}\right)
$$

where $Z_{\mathrm{o}} * \hat{E}_{\mathrm{h}} * T_{\mathrm{o}} \in \mathcal{A}_{\mathrm{i}}$ and $Z_{\mathrm{o}}=\operatorname{scalar}\left(z_{\mathrm{o}}\right)$. That is, the sample derived is certain, $P_{\mathrm{d}}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)=P_{\mathrm{d}}\left(Z_{\mathrm{o}} * \hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)=1$. The expected iso-derived probability in this probability function, $P_{\mathrm{d}}$, is that of the necessary iso-derived,

$$
\begin{aligned}
& \operatorname{expected}\left(P_{\mathrm{d}},\left\{\left(A^{\prime}, \sum_{B \in D_{U, i, T_{\mathrm{o}}, z_{\mathrm{o}}}^{-1}\left(A^{\prime}\right)} Q_{\mathrm{m}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)(B)\right): A^{\prime} \in \operatorname{ran}\left(D_{\left.U, \mathrm{i}, T_{\mathrm{o}}, z_{\mathrm{o}}\right)}\right)\right\}\right) \\
&=\sum_{B \in D_{U, i, T_{\mathrm{o}}, z_{\mathrm{o}}}^{-1}\left(Z_{\mathrm{o}} * \hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)} Q_{\mathrm{m}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)(B)
\end{aligned}
$$

In the not necessary given derived case, the probability of the sample derived is not certain, $P_{\mathrm{d}, \mathrm{p}}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right) \notin\{0,1\}$. In the absence of further knowledge it is assumed that the given derived, $\hat{A}_{\mathrm{o}} * T_{\mathrm{o}}$, is at least possible and that the probability function $P_{\mathrm{d}, \mathrm{p}} \in\left(\mathcal{A}_{\mathrm{i}} \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}$ of the derived is uniform,

$$
P_{\mathrm{d}, \mathrm{p}}=\operatorname{ran}\left(D_{U, \mathrm{i}, T_{\mathrm{o}}, z_{\mathrm{o}}}\right) \times\left\{1 /\left|\operatorname{ran}\left(D_{U, \mathrm{i}, T_{\mathrm{o}}, z_{\mathrm{o}}}\right)\right|\right\}
$$

Now the expected iso-derived probability in this probability function, $P_{\mathrm{d}, \mathrm{p}}$, is

$$
\begin{aligned}
\operatorname{expected}\left(P_{\mathrm{d}, \mathrm{p}},\left\{\left(A^{\prime}, \sum_{B \in D_{U, \mathbf{i}, T_{\mathrm{o}}, z_{\mathrm{o}}}^{-1}\left(A^{\prime}\right)} Q_{\mathrm{m}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)(B)\right): A^{\prime}\right.\right. & \left.\left.\in \operatorname{ran}\left(D_{U, \mathbf{i}, T_{\mathrm{o}}, z_{\mathrm{o}}}\right)\right\}\right) \\
& =1 /\left|\operatorname{ran}\left(D_{U, \mathbf{i}, T_{\mathrm{o}}, z_{\mathrm{o}}}\right)\right|
\end{aligned}
$$

This is to assume that the choice of derived per se is arbitrary. This relaxation of the constraint that the sample be necessarily drawn from the iso-derived of the distribution, $P_{\mathrm{d}}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)=1$, to the constraint that the sample be possibly drawn from the iso-derived of the distribution, $P_{\mathrm{d}, \mathrm{p}}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)>0$, is
equivalent to assuming that the sample is drawn from the uniform possible iso-derived historically distributed history probability function $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, T_{o}} \in$ $\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}$, which is defined as the solution to

$$
\begin{aligned}
& P_{U, X, H_{\mathrm{h}, \mathrm{~d}, \mathrm{p}, T_{\mathrm{o}}}:=}^{(\bigcup \mid} \begin{array}{l}
\quad \\
\qquad\left\{\left\{\left(H, 1 / \sum\left(P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, T_{\mathrm{o}}}(G):\right.\right.\right.\right. \\
\left.\left.G \subseteq H_{\mathrm{h}} \% V_{H},|G|=z_{H}, A_{G} * T_{\mathrm{o}}=A_{H} * T_{\mathrm{o}}\right)\right): \\
\\
\left.H \subseteq H_{\mathrm{h}} \% V_{H},|H|=z_{H}\right\}^{\wedge}: \\
\left.\left.V_{H} \subseteq V_{\mathrm{h}}, z_{H} \in\left\{1 \ldots z_{\mathrm{h}}\right\}\right\}\right)^{\wedge} \cup \\
\left\{(H, 0): H \in \mathcal{H}_{U, X}, H \nsubseteq H_{\mathrm{h}} \% V_{H}\right\} \cup\{(\emptyset, 0)\}
\end{array}
\end{aligned}
$$

All iso-derived subsets of the distribution history for a given set of variables and size are defined as equally probable,
$\forall V \subseteq V_{\mathrm{h}} \forall H, G \subseteq H_{\mathrm{h}} \% V$

$$
\left(A_{G} * T_{\mathrm{o}}=A_{H} * T_{\mathrm{o}} \Longrightarrow P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, T_{\mathrm{o}}}(G)=P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, T_{\mathrm{o}}}(H)\right)
$$

The uniform possible iso-derived historically distributed history probability function is such that given a drawn history $H \in \mathcal{H}_{U, X}$

$$
\begin{aligned}
& \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right)= \\
& \frac{\sum P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, T_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}}{\sum P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, T_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, V_{G}=V_{H},|G|=z_{H}}
\end{aligned}
$$

The possible history probability function, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, T_{\mathrm{o}}}$, is related to the isoderived conditional historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{o}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)$, in the same way as for the necessary case, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{\mathrm{o}}}$, except that the normalising fraction is restored. In the case where all derived are possible the normalising fraction is $1 /\left|\operatorname{ran}\left(D_{U, \mathrm{i}, T_{\mathrm{o}}, z_{H}}\right)\right|$,

$$
\begin{aligned}
& \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right)= \\
& \\
& \frac{1}{\left|\operatorname{ran}\left(D_{U, \mathrm{i}, T_{o}, z_{H}}\right)\right|} \frac{Q_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right)}{\sum_{B \in D_{U, \mathrm{i}, T_{o}, z_{H}}^{-1}\left(A_{H} * T_{\mathrm{o}}\right)} Q_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)(B)}
\end{aligned}
$$

Any historically drawn history is possible,

$$
\forall H \subseteq H_{\mathrm{h}} \% V_{H}\left(H \neq \emptyset \Longrightarrow P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, T_{\mathrm{o}}}(H)>0\right)
$$

but sometimes the probability is lower than in the necessary case,

$$
\forall H \subseteq H_{\mathrm{h}} \% V_{H}\left(P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, T_{\mathrm{o}}}(H)>0 \Longleftrightarrow P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, T_{\mathrm{o}}}(H) \leq P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, T_{\mathrm{o}}}(H)\right)
$$

Now it can be seen that the history probability function is more continuous in the sense that the uniform possible domain may be larger than the necessary domain,

$$
\begin{aligned}
\left|\left\{H: H \in \mathcal{H}_{U, X}, P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, T_{⿱}}(H)>0\right\}\right| & \geq \\
& \left|\left\{H: H \in \mathcal{H}_{U, X}, P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, T_{\mathrm{o}}}(H)>0\right\}\right|
\end{aligned}
$$

The uniform possible log likelihood has similar properties to the necessary log likelihood.
$\ln \hat{Q}_{\mathrm{m}, \mathrm{d}, T, U}(E, z)(A)=\ln \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in D_{U, i, T, z}^{-1}(A * T)} Q_{\mathrm{m}, U}(E, z)(B)}-\ln \left|\operatorname{ran}\left(D_{U, \mathbf{i}, T, z}\right)\right|$
The cardinality of the derived, $\left|\operatorname{ran}\left(D_{U, \mathbf{i}, T, z}\right)\right|$, is equal to the cardinality of the possible derived substrate histograms,

$$
\left|\operatorname{ran}\left(D_{U, \mathrm{i}, T, z}\right)\right|=\frac{\left(z+w^{\prime}-1\right)!}{z!\left(w^{\prime}-1\right)!}
$$

where $w^{\prime}=\left|T^{-1}\right|$. So the additional term in the uniform possible log likelihood, $-\ln \left|\operatorname{ran}\left(D_{U, i, T, z}\right)\right|$, varies against the possible derived volume, $w^{\prime}$, where the possible derived volume is less than the size, $w^{\prime}<z$, otherwise against the size scaled $\log$ possible derived volume, $z \ln w^{\prime}$,

$$
\begin{aligned}
-\ln \left|\operatorname{ran}\left(D_{U, \mathbf{i}, T, z}\right)\right| & =-\operatorname{spaceCountsDerived}(U)(A, T) \\
& \sim-\left(\left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right)\right)
\end{aligned}
$$

In the case where the sample is natural, $A=A * T * T^{\dagger}$, the uniform possible log likelihood varies (i) against the possible derived volume, $w^{\prime}$, where the possible derived volume is less than the size, $w^{\prime}<z$, otherwise against the size scaled $\log$ possible derived volume, $z \ln w^{\prime}$, and (ii) with the size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \sim \\
& -\left(\left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right)\right) \\
& +(z+v) \times \operatorname{entropy}\left(A * T+V^{\mathrm{C}} * T\right) \\
& \quad-z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)
\end{aligned}
$$

Note that the meaning of possible in possible derived volume, $w^{\prime}$, is that the derived state is effective, whereas the meaning of possible in uniform possible log likelihood, $\ln \hat{Q}_{\mathrm{m}, \mathrm{d}, T, U}(A, z)(A)$, is that the distribution frequency is effective or non-zero.

In the case where the cross entropy is greater than the logarithm of the possible derived volume, entropyCross $\left(A * T, V^{\mathrm{C}} * T\right)>\ln w^{\prime}$, so that the component size cardinality relative entropy is high, the iso-derived conditional multinomial probability varies against the derived multinomial probability,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) \sim-\ln \hat{Q}_{\mathrm{m}, U}(A * T, z)(A * T)
$$

and the sum sensitivity is less than or equal to the multinomial sum sensitivity,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)\right)\right) \leq \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(A, z)\right)\right)
$$

In the case where size is greater than the volume, $z>v$, the uniform possible log likelihood varies (i) against the possible derived volume, $w^{\prime}$, where the possible derived volume is less than the size, $w^{\prime}<z$, otherwise against the size scaled $\log$ possible derived volume, $z \ln w^{\prime}$, and (ii) with the volume scaled component cardinality size relative entropy,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) & \sim \\
& -\left(\left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right)\right) \\
& +v \times \operatorname{entropyRelative}\left(V^{\mathrm{C}} * T, A * T\right)
\end{aligned}
$$

In the case where the sample is near natural, $A \approx A * T * T^{\dagger}$, and the size is less than or equal to the volume, $z \leq v$, the uniform possible log likelihood varies (i) against the possible derived volume, $w^{\prime}$, where the possible derived volume is less than the size, $w^{\prime}<z$, otherwise against the size scaled log possible derived volume, $z \ln w^{\prime}$, and (ii) with the size scaled component size cardinality relative entropy,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A) & \sim \\
& -\left(\left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right)\right) \\
& +z \times \operatorname{entropyRelative}\left(A * T, V^{\mathrm{C}} * T\right)
\end{aligned}
$$

In this case the correlation properties of uniform possible derived induction relate to the correlation properties of the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)$, more closely than those of necessary derived induction. The specialising space varies (i) with the possible derived volume, $w^{\prime}$, where the possible derived volume is less than the size, $w^{\prime}<z$, otherwise with the size scaled $\log$ possible derived volume, $z \ln w^{\prime}$, and (ii) against the size scaled component size cardinality relative entropy,

$$
\begin{aligned}
C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H) & \sim \\
& \left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right) \\
& -z \times \operatorname{entropyRelative}\left(A * T, V^{\mathrm{C}} * T\right)
\end{aligned}
$$

In classical uniform possible modelled induction, where (i) the history probability function is uniform possible iso-derived historically distributed, $P=$ $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, T_{\mathrm{o}}}$, given some substrate transform in the sample variables $T_{\mathrm{o}} \in$ $\mathcal{T}_{U, V_{0}}$, if it is the case that (ii) the sample equals the naturalisation, $A_{\mathrm{o}}=$ $A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{O}}$, in the iso-derived conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, so, if it is also the case that (iii) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{0}$, and such that (iv) the scaled probability sample histogram is integral, $A_{0, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the log likelihood of the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate (a) varies against the possible derived volume, $w_{\mathrm{o}}^{\prime}$, where the possible derived volume is less than the size, $w_{\mathrm{o}}^{\prime}<z_{0}$, otherwise against the size scaled $\log$ possible derived volume, $z_{0} \ln w_{\mathrm{o}}^{\prime}$,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\left(\left(w_{\mathrm{o}}^{\prime}: w_{\mathrm{o}}^{\prime}<z_{\mathrm{o}}\right)+\left(z_{\mathrm{o}} \ln w_{\mathrm{o}}^{\prime}: w^{\prime} \geq z_{\mathrm{o}}\right)\right)
$$

and (b) with the size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) & \sim \\
\left(z_{\mathrm{o}}+v_{\mathrm{o}}\right) \times \operatorname{entropy}\left(A_{\mathrm{o}}\right. & \left.* T_{\mathrm{o}}+V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right) \\
& -z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)-v_{\mathrm{o}} \times \operatorname{entropy}\left(V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)
\end{aligned}
$$

So the uniform possible log likelihood is maximised when (a) the possible derived volume is minimised, (b) the component entropy is minimised, and (c) high size components are low cardinality components and low size components are high cardinality components.

If, in addition, the component size cardinality relative entropy is high,

$$
\operatorname{entropy} \operatorname{Cross}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)>\ln w_{\mathrm{o}}^{\prime}
$$

the sum sensitivity of the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate is less than or equal to the sum sensitivity of the stuffed historical probability distribution at the maximum likelihood estimate,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\right.\right. & \left.\left.\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \\
\leq & \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)
\end{aligned}
$$

In the case where the size is greater than the volume, $z_{\mathrm{o}}>v_{\mathrm{o}}$, the log likelihood of the iso-derived conditional stuffed historical probability distribution
at the maximum likelihood estimate varies with the volume scaled component cardinality size relative entropy,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim v_{\mathrm{o}} \times \text { entropyRelative }\left(V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}, A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

In the case where the size is less than the volume, $z_{0}<v_{0}$, but the sample approximates to the naturalisation, $A_{\mathrm{o}} \approx A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, the log likelihood of the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate (a) varies against the possible derived volume, $w_{\mathrm{o}}^{\prime}$, where the possible derived volume is less than the size, $w_{\mathrm{o}}^{\prime}<z_{\mathrm{o}}$, otherwise against the size scaled log possible derived volume, $z_{0} \ln w_{\mathrm{o}}^{\prime}$,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\left(\left(w_{\mathrm{o}}^{\prime}: w_{\mathrm{o}}^{\prime}<z_{\mathrm{o}}\right)+\left(z_{\mathrm{o}} \ln w_{\mathrm{o}}^{\prime}: w^{\prime} \geq z_{\mathrm{o}}\right)\right)
$$

(b) varies with the size scaled component size cardinality relative entropy,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \text { entropyRelative }\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)
$$

so (c) varies against the specialising derived substrate history coder space,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\operatorname{space}\left(C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)\left(H_{\mathrm{o}}\right)
$$

So the uniform possible log likelihood is maximised, in this case, when (a) the possible derived volume is minimised, (b) the derived entropy is minimised, (c) high size components are low cardinality components and low size components are high cardinality components, and (d) the expected component entropy is maximised.

Conjecture that, in the case of high component size cardinality relative entropy, the sum sensitivity of the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the specialising derived substrate history coder space,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim \operatorname{space}\left(C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)\left(H_{\mathrm{o}}\right)
$$

and so the sum sensitivity of the iso-derived conditional stuffed historical probability distribution varies against the log-likelihood of the iso-derived conditional stuffed historical probability distribution

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

As described in section 'Necessary derived', the sum sensitivity of the isoderived conditional stuffed historical probability distribution at the maximum likelihood estimate, $\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)$, can be related to queries on the maximum likelihood estimate of the distribution histogram, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, in the special case where (i) the sample histogram is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, and (ii) the component size cardinality relative entropy is high, entropy $\operatorname{Cross}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)>\ln w_{\mathrm{o}}^{\prime}$. In the case of classical modelled induction, the given substrate transform must be such that its contraction has underlying variables that are a subset of the query variables, und $\left(T_{\mathrm{o}}^{\%}\right) \subseteq$ $K$. In the case where the query histogram consists of one effective state, $Q=\left\{\left(S_{Q}, 1\right)\right\}$, there exists an effective derived state $R_{Q}$, where $\left\{R_{Q}\right\}=$ $\left(Q * T_{\mathrm{o}}^{\%}\right)^{\mathrm{FS}}$. The corresponding underlying component is $C_{Q}=T_{\mathrm{o}}^{-1}\left(R_{Q}\right)$. If the possible derived volume is non singular, $w_{o}^{\prime}>1$, the query histogram itself cannot be drawn from the distribution history, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}}, 1\right)\left(Q *\{N\}^{\mathrm{U}}\right)=0$, where $N \in\left(V_{\mathrm{o}} \backslash K\right)^{\mathrm{CS}}$, because the query derived probability histogram is not equal to a uniform possible derived distribution probability histogram, $\hat{Q} *\{N\}^{\mathrm{U}} * T_{\mathrm{o}} \neq \hat{A}_{\mathrm{o}} * T_{\mathrm{o}}$. The application of the query must be in terms of a modified sample histogram,

$$
\begin{aligned}
& \left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)= \\
& \quad\left\{\left(N,\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{Q, N}\right)\right)^{1 / z_{\mathrm{o}}}\right): N \in\left(V_{\mathrm{o}} \backslash K\right)^{\mathrm{CS}},\right. \\
& \left.\quad A_{Q, N}=A_{\mathrm{o}}-\left(A_{\mathrm{o}} * C_{Q}\right)+\left(\left(A_{\mathrm{o}} * C_{Q}\right) \% K *\{N\}^{\mathrm{U}}\right)\right\}^{\wedge}
\end{aligned}
$$

The model application depends on the geometric scaling of the historical distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{o}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)$, so the query sensitivity to the distribution histogram varies with the sum sensitivity of the historical distribution at the maximum likelihood estimate divided by the sample size,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}}
$$

Now consider the case where the model, $T_{\mathrm{o}}$, is unknown. The maximum likelihood estimate for the pair ( $\tilde{E}_{0}, \tilde{T}_{\mathrm{o}}$ ) in the uniform possible case is

$$
\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right) \in \operatorname{maxd}\left(\left\{\left((E, T), \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}, T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

If there is a unique maximum for the distribution probability histogram, $\tilde{E}_{\mathrm{o}}$, this can be rewritten in terms of the derived-dependent,

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}\left(A_{\mathrm{o}}^{\mathrm{D}(T)}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

Strictly speaking, this is only the case for the subset of substrate transforms, $\mathcal{T}_{U, V_{\mathrm{o}}}$, for which the derived-dependent histogram, $A_{\mathrm{o}}^{\mathrm{D}(T)}$, is defined,

$$
\begin{aligned}
& \left\{T: T \in \mathcal{T}_{U, V_{\mathrm{o}}},\right. \\
& \left.\quad\left|\max \left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}\left(D, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum Q_{\mathrm{m}, U}\left(D, z_{\mathrm{o}}\right)(B): B \in D_{U, \mathbf{i}, T, z_{\mathrm{o}}}^{-1}\left(A_{\mathrm{o}} * T\right)}\right): D \in \mathcal{A}_{U, V_{\mathrm{o}}, z_{\mathrm{o}}}\right\}\right)\right|=1\right\}
\end{aligned}
$$

Even if the derived-dependent histogram, $A_{\mathrm{o}}^{\mathrm{D}(T)}$ is defined, the maximum likelihood estimate for the model, $\tilde{T}_{\mathrm{o}}$, is not necessarily computable because the derived-dependent histogram, $A_{\mathrm{o}}^{\mathrm{D}(T)}$, is sometimes not computable.

If the optimisation is restricted to natural transforms, $A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger} \Longrightarrow$ $A_{\mathrm{o}}^{\mathrm{D}(T)}=A_{\mathrm{o}}$, then the optimisation is

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger}\right\}\right)
$$

In this case, all the derived are possible because the distribution equals the sample, so the optimisation is

$$
\begin{array}{r}
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \frac{1}{\left|\operatorname{ran}\left(D_{\left.U, \mathrm{i}, T, z_{\mathrm{o}}\right)}\right)\right|} \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in D_{U, i, T, z_{\mathrm{o}}}^{-1}\left(A_{\mathrm{o}} * T\right)} Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)(B)}\right):\right.\right. \\
\left.\left.T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger}\right\}\right)
\end{array}
$$

Now, the set of maximum likelihood estimates for the model, $\tilde{T}_{\mathrm{o}}$, is computable.

In this case, the numerator, $Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$, is constant.
The maximum likelihood estimate for the model is not self, $\tilde{T}_{\mathrm{o}} \neq T_{\mathrm{s}}$, if

$$
\frac{1}{\left|\operatorname{ran}\left(D_{U, \mathrm{i}, \tilde{T}_{\mathrm{o}}, z_{\mathrm{o}}}\right)\right|} \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in D_{U, i, \tilde{\mathrm{~T}}_{\mathrm{o}}, z_{\mathrm{o}}}^{-1}\left(A_{\mathrm{o}} * \tilde{T}_{\mathrm{o}}\right)} Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)(B)}>\frac{1}{\left|\operatorname{ran}\left(\mathcal{A}_{U, \mathrm{i}, V_{\mathrm{o}}, z_{\mathrm{o}}}\right)\right|}
$$

which is the case if the iso-derived conditional multinomial probability is greater than the inverted average iso-derived cardinality,

$$
\frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in D_{U, i, \tilde{T}_{\mathrm{o}}, z_{\mathrm{o}}}^{-1}\left(A_{\mathrm{o}} * \tilde{T}_{\mathrm{o}}\right)} Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)(B)}>\frac{\left|\operatorname{ran}\left(D_{U \mathrm{i}, \tilde{T}_{\mathrm{o}}, z_{\mathrm{o}}}\right)\right|}{\left|\operatorname{dom}\left(D_{U, \mathrm{i}, \tilde{T}_{\mathrm{o}}, z_{\mathrm{o}}}\right)\right|}
$$

The sample is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, so the permutorial term is constant for all iso-derived, and the iso-derived conditional multinomial probability
simplifies,

$$
\frac{\hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right)}{\sum_{B \in D_{U, i, T, z}^{-1}(A * T)} \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)(B)}=1 / \sum_{B \in D_{U, i, T, z}^{-1}(A * T)} \prod_{S \in V^{\mathrm{CS}}} \frac{A_{S}!}{B_{S}!}
$$

The maximum likelihood estimate for the model is not self, $\tilde{T}_{\mathrm{o}} \neq T_{\mathrm{s}}$, if

$$
\sum_{B \in D_{U, i, 1}^{-1}, \tilde{T}_{o}, z_{0}}\left(A_{o} * \tilde{T}_{o}\right) \prod_{S \in V_{o}^{C S}} \frac{A_{o}(S)!}{B_{S}!}<\frac{\left|\operatorname{dom}\left(D_{U, i, i, \tilde{T}_{o}, z_{o}}\right)\right|}{\left|\operatorname{ran}\left(D_{U, i, \tilde{T}_{o}, z_{o}}\right)\right|}
$$

The terms of the sum are less than or equal to one, $\prod_{S \in V^{\mathrm{CS}}} A_{S}!/ B_{S}!\leq 1$, so the model is not self at least in the case where the iso-derived cardinality is less than the average iso-derived cardinality,

$$
\left|D_{U, \mathrm{i}, \tilde{T}_{\mathrm{o}}, z_{\mathrm{o}}}^{-1}\left(A_{\mathrm{o}} * \tilde{T}_{\mathrm{o}}\right)\right|<\frac{\left|\operatorname{dom}\left(D_{U \mathrm{i}, \tilde{T}_{\mathrm{o}}}\right)\right|}{\left|\operatorname{ran}\left(D_{U, \mathrm{i}, \tilde{T}_{\mathrm{o}}, z_{\mathrm{o}}}\right)\right|}
$$

The sample is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, so the maximum likelihood estimate for the model is not unary, $\tilde{T}_{\mathrm{o}} \neq T_{\mathrm{u}}$, if the sample is not cartesian, $\hat{A}_{\mathrm{o}} \neq \hat{V}_{\mathrm{o}}^{\mathrm{C}}$.

In some cases the maximum likelihood estimate for the model is neither self nor unary, $\tilde{T}_{\mathrm{o}} \notin\left\{T_{\mathrm{s}}, T_{\mathrm{u}}\right\}$.

In classical uniform possible modelled induction, where (i) the history probability function is uniform possible iso-derived historically distributed, $P=$ $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, T_{\mathrm{o}}}$, given some unknown substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, if it is the case that (ii) the sample histogram is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, then the maximum likelihood estimate of the distribution histogram, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the iso-derived conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, and, if it is also the case that (iii) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{0}$, and such that (iv) the scaled probability sample histogram is integral, $A_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the maximum likelihood estimate of the model, $\tilde{T}_{\mathrm{o}}$, in the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate of the distribution, $\tilde{E}_{\mathrm{o}}$, is

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger}\right\}\right)
$$

and in some cases the maximum likelihood estimate for the model, $\tilde{T}_{\mathrm{o}}$, is non-trivial,

$$
\tilde{T}_{\mathrm{o}} \notin\left\{T_{\mathrm{s}}, T_{\mathrm{u}}\right\}
$$

In the case where the component size cardinality relative entropy is high, entropy $\operatorname{Cross}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)>\ln \left|T_{\mathrm{o}}^{-1}\right|$, the sum sensitivity of the isoderived conditional stuffed historical probability distribution at the maximum likelihood estimate of the distribution-model pair is less than or equal to the sum sensitivity of the stuffed historical probability distribution at the maximum likelihood estimate,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{T}_{\mathrm{o}}, U}( \right.\right. & \left.\left.\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \\
\leq & \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)
\end{aligned}
$$

In the case where the size is less than the volume, $z_{0}<v_{0}$, the sample is sometimes not natural. In this case the search must be constrained, such that the sample is near natural, by a limit $u$ to the relative space of the sample with respect to its naturalisation. The maximum likelihood estimate of the model, $\tilde{T}_{\mathrm{o}}$, in the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate of the distribution, $\tilde{E}_{\mathrm{o}}$, is

$$
\begin{aligned}
& \tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}},\right.\right. \\
& \left.\left.\quad \text { spaceRelative }\left(A_{\mathrm{o}} * T * T^{\dagger}\right)\left(A_{\mathrm{o}}\right) \leq u\right\}\right)
\end{aligned}
$$

Note that the choice of the limit, $u$, is not necessary in the stricter case where the trimmed sample is unit, $\operatorname{trim}\left(A_{\mathrm{o}}\right)=A_{\mathrm{o}}^{\mathrm{F}}$. In this case the sample history is bijective, $H_{\mathrm{o}} \in X \leftrightarrow V_{\mathrm{o}}^{\mathrm{CS}}$. That is, each event has a unique state. Often, in these cases, the size is much less than the volume, $z_{0} \ll v_{\mathrm{o}}$. In this case of sparse histogram, where $A_{\mathrm{o}} * A_{\mathrm{o}}^{\mathrm{F}}=A_{\mathrm{o}}^{\mathrm{F}}$, all transforms are near natural, so the maximum likelihood estimate of the model, $\tilde{T}_{\mathrm{o}}$, simplifies to

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

In this case, the over-fitted effective self transform is the solution to the optimisation,

$$
A_{\mathrm{o}} * A_{\mathrm{o}}^{\mathrm{F}}=A_{\mathrm{o}}^{\mathrm{F}} \Longrightarrow \tilde{T}_{\mathrm{o}}=\left(A_{\mathrm{o}}^{\mathrm{FS}\{ \}} \cup\left\{V_{\mathrm{o}}^{\mathrm{CS}} \backslash A_{\mathrm{o}}^{\mathrm{FS}}\right\}\right)^{\mathrm{T}}
$$

The effective self transform is self only for effective states, $A_{\mathrm{o}}^{\mathrm{FS}\{ \}}$. It has a remainder component for all of the ineffective states, $V_{\mathrm{o}}^{\mathrm{CS}} \backslash A_{\mathrm{o}}^{\mathrm{FS}}$. The derived volume is $z_{0}+1$.

In the case where the size is less than the volume, $z_{0}<v_{0}$, the properties of the maximisation of the log likelihood, $\ln \hat{Q}_{\mathrm{m}, \mathrm{d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}}, z\right)\left(A_{\mathrm{o}}\right)$, are consistent with the properties of the minimisation of the sum sensitivity, $\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}}, z\right)\right)\right)$. So conjecture that in classical uniform
possible modelled induction, where the size is less than the volume, but the sample is near natural, and the relative entropy is high, the sum sensitivity varies against the log likelihood, and the optimisation tends to minimise the sensitivity to the distribution, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{T}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

Similarly, the query sensitivity to the distribution,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{T}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}}
$$

is also minimised by the optimisation of log-likelihood.
There is no mapping of the transform to a coordinate, $\hat{T}^{\square}$, so the sensitivity to the model, $\tilde{T}_{\mathrm{o}}$ cannot be calculated directly as the Fisher information of a centrally distributed real likelihood function. Instead the sensitivity to the model is defined as the negative logarithm of the cardinality of the maximum likelihood estimate models,

$$
-\ln \left|\max \left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger}\right\}\right)\right|
$$

Although there is an anti-correlation between the log-likelihood and the sensitivity to the distribution, it is not necessarily the case that there is also an anti-correlation between the log-likelihood and the sensitivity to the model.

### 5.5.6 Uniform possible derived functional definition set induction

Again, consider extending the model for uniform possible derived induction from transforms to functional definition sets.

Given some known substrate fud, $F_{\mathrm{o}} \in \mathcal{F}_{U, V_{\mathrm{o}}}$, such that there exists a top transform, $\exists T \in F_{\mathrm{o}}\left(\operatorname{der}(T)=\operatorname{der}\left(F_{\mathrm{o}}\right)\right)$, the derived histogram set of the distribution probability histogram is $\left\{\hat{E}_{\mathrm{h}} * T_{F_{\mathrm{o}}}: T \in F_{\mathrm{o}}\right\}$, where $T_{F}:=$ depends $(F, \operatorname{der}(T))^{\mathrm{T}}$. Consider the case where it is unknown if the given histogram, $A_{\mathrm{o}}$, is a sample histogram drawn from the distribution histogram, $E_{\mathrm{h}}$, so, in some cases $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, F_{\mathrm{o}}}\left(H_{\mathrm{o}}\right)=0$. That is, it is known that some derived histogram set is necessary, $\exists B \in \mathcal{A}_{U, \mathrm{i}, V_{0}, z_{0}} \forall T \in F_{\mathrm{o}}\left(\hat{B} * T_{F_{\mathrm{o}}}=\hat{E}_{\mathrm{h}} * T_{F_{\mathrm{o}}}\right)$, but not whether the given derived histogram set is necessary, $\forall T \in F_{\mathrm{o}}\left(\hat{A} * T_{F_{\mathrm{o}}}=\right.$ $\hat{E}_{\mathrm{h}} * T_{F_{\mathrm{o}}}$ ). In the absence of further knowledge it is assumed that the given derived histogram set, $\left\{\hat{E}_{\mathrm{h}} * T_{F_{\mathrm{o}}}: T \in F_{\mathrm{o}}\right\}$ is at least possible and that the probability function of the derived histogram set is uniform. This relaxation of the constraint that the sample be necessarily drawn from the iso-fud of
the distribution to the constraint that the sample be possibly drawn from the iso-fud of the distribution is equivalent to assuming that the sample is drawn from the uniform possible iso-fud historically distributed history probability function $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, F_{\mathrm{o}}} \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}$, which is defined as the solution to
$P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, F_{\mathrm{o}}}:=$

$$
\begin{aligned}
& \left(\bigcup \left\{\left\{\left(H, 1 / \sum\left(P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, F_{\mathrm{o}}}(G):\right.\right.\right.\right.\right. \\
& G \subseteq H_{\mathrm{h}} \% V_{H},|G|=z_{H} \\
& \left.\left.\forall T \in F_{\mathrm{o}}\left(A_{G} * T_{F_{\mathrm{o}}}=A_{H} * T_{F_{\mathrm{o}}}\right)\right)\right): \\
& \\
& \left.H \subseteq H_{\mathrm{h}} \% V_{H},|H|=z_{H}\right\}^{\wedge}: \\
& \left.\left.\quad V_{H} \subseteq V_{\mathrm{h}}, z_{H} \in\left\{1 \ldots z_{\mathrm{h}}\right\}\right\}\right)^{\wedge} \cup \\
& \left\{(H, 0): H \in \mathcal{H}_{U, X}, H \nsubseteq H_{\mathrm{h}} \% V_{H}\right\} \cup\{(\emptyset, 0)\}
\end{aligned}
$$

All iso-fud subsets of the distribution history for a given set of variables and size are defined as equally probable,
$\forall V \subseteq V_{\mathrm{h}} \forall H, G \subseteq H_{\mathrm{h}} \% V$

$$
\left(\forall T \in F_{\mathrm{o}}\left(A_{G} * T_{F_{\mathrm{o}}}=A_{H} * T_{F_{\mathrm{o}}}\right) \Longrightarrow P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, F_{\mathrm{o}}}(G)=P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, F_{\mathrm{o}}}(H)\right)
$$

The uniform possible iso-fud historically distributed history probability function is such that given a drawn history $H \in \mathcal{H}_{U, X}$

$$
\begin{aligned}
\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right)= \\
\frac{\sum P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, F_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}}{\left.\sum P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, F_{\mathrm{o}}} G\right): G \in \mathcal{H}_{U, X}, V_{G}=V_{H},|G|=z_{H}}
\end{aligned}
$$

The possible history probability function, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, F_{\mathrm{o}}}$, is related to the iso-fud conditional historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, F_{o}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)$, in the same way as for the necessary case, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, F_{\mathrm{o}}}$, except that the normalising fraction is restored. In the case where all derived histogram sets are possible the normalising fraction is $1 /\left|\operatorname{ran}\left(D_{U, \mathbf{i}, F_{\mathrm{o}}, z_{H}}\right)\right|$,

$$
\begin{aligned}
& \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{o}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right)= \\
& \\
& \frac{1}{\left|\operatorname{ran}\left(D_{U, \mathrm{i}, F_{o}, z_{H}}\right)\right|} \frac{Q_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right)}{\sum_{B \in D_{U, i, F_{o}, z_{H}}^{-1}\left(D_{U, F_{o}, z_{H}}\left(A_{H}\right)\right)} Q_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)(B)}
\end{aligned}
$$

Any historically drawn history is possible,

$$
\forall H \subseteq H_{\mathrm{h}} \% V_{H}\left(H \neq \emptyset \Longrightarrow P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, F_{\mathrm{o}}}(H)>0\right)
$$

but sometimes the probability is lower than in the necessary case,

$$
\forall H \subseteq H_{\mathrm{h}} \% V_{H}\left(P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, F_{\mathrm{o}}}(H)>0 \Longleftrightarrow P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, F_{\mathrm{o}}}(H) \leq P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, F_{\mathrm{o}}}(H)\right)
$$

The uniform possible log likelihood has similar properties to the necessary log likelihood.

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}(E, z)(A)= \\
& \quad \ln \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in D_{U, i, F, z}^{-1}\left(D_{U, F, z}(A)\right)} Q_{\mathrm{m}, U}(E, z)(B)}-\ln \left|\operatorname{ran}\left(D_{U, \mathbf{i}, F, z}\right)\right|
\end{aligned}
$$

The cardinality of the derived histogram sets, $\left|\operatorname{ran}\left(D_{U, \mathbf{i}, F, z}\right)\right|$, is greater than or equal to the cardinality of the possible derived substrate histograms of the fud transform,

$$
\begin{aligned}
\left|\operatorname{ran}\left(D_{U, \mathrm{i}, F, z}\right)\right| & \geq\left|\operatorname{ran}\left(D_{U, \mathrm{i}, F^{\mathrm{T}}, z}\right)\right| \\
& =\frac{\left(z+\left|\left(F^{\mathrm{T}}\right)^{-1}\right|-1\right)!}{z!\left(\left|\left(F^{\mathrm{T}}\right)^{-1}\right|-1\right)!}
\end{aligned}
$$

So the additional term in the uniform possible log likelihood, $-\ln \left|\operatorname{ran}\left(D_{U, \mathrm{i}, F, z}\right)\right|$, varies, for each transform $T \in F$, against the possible derived volume, $\left|T_{F}^{-1}\right|$, where the possible derived volume is less than the size, $\left|T_{F}^{-1}\right|<z$, otherwise against the size scaled $\log$ possible derived volume, $z \ln \left|T_{F}^{-1}\right|$,

$$
\begin{aligned}
-\ln \left|\operatorname{ran}\left(D_{U, \mathrm{i}, F, z}\right)\right| & \sim \\
& -\sum_{T \in F}\left(\left(\left|T_{F}^{-1}\right|:\left|T_{F}^{-1}\right|<z\right)+\left(z \ln \left|T_{F}^{-1}\right|:\left|T_{F}^{-1}\right| \geq z\right)\right)
\end{aligned}
$$

The fud-independent, $A^{\mathrm{E}_{\mathrm{F}}(F)} \in \mathcal{A}_{U, V, z}$, is defined,

$$
\begin{aligned}
& \left\{A^{\mathrm{E}(F)}\right\}= \\
& \quad \quad \operatorname{maxd}\left(\left\{\left(E, \sum\left(Q_{\mathrm{m}, U}(E, z)(B): B \in D_{U, \mathrm{i}, F, z}^{-1}\left(D_{U, F, z}(A)\right)\right)\right): E \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The fud-independent approximates to the arithmetic average of the naturalisations,

$$
A^{\mathrm{E}_{\mathrm{F}}(F)} \approx Z_{1 /|F|} * \sum_{T \in F} A * T_{F} * T_{F}^{\dagger}
$$

In the case where the sample is equal to the fud-independent, $A=A^{\mathrm{E}_{\mathrm{F}}(F)}$, the uniform possible log likelihood varies (i) against the sum of the possible derived volumes or size scaled log possible derived volumes, and (ii) with
the sum of the size-volume scaled component size cardinality sum relative entropies,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}(A, z)(A) \sim \\
& \quad-\sum_{T \in F}\left(\left(\left|T_{F}^{-1}\right|:\left|T_{F}^{-1}\right|<z\right)+\left(z \ln \left|T_{F}^{-1}\right|:\left|T_{F}^{-1}\right| \geq z\right)\right) \\
& +\sum_{T \in F}\left((z+v) \times \operatorname{entropy}\left(A * T_{F}+V^{\mathrm{C}} * T_{F}\right)\right. \\
& \left.\quad-z \times \operatorname{entropy}\left(A * T_{F}\right)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T_{F}\right)\right)
\end{aligned}
$$

In the case where the cross entropies are sufficient, $\forall T \in F$ (entropyCross $(A *$ $\left.\left.T_{F}, V^{\mathrm{C}} * T_{F}\right)>\ln \left|T_{F}^{-1}\right|\right)$, the logarithm of the iso-fud conditional multinomial probability varies against the sum of the logarithms of the derived multinomial probabilities,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}(A, z)(A) \sim-\sum_{T \in F} \ln \hat{Q}_{\mathrm{m}, U}\left(A * T_{F}, z\right)\left(A * T_{F}\right)
$$

and the sum sensitivity is less than or equal to the multinomial sum sensitivity,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}(A, z)\right)\right) \leq \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(A, z)\right)\right)
$$

In the case where size is greater than the volume, $z>v$, the uniform possible log likelihood varies (i) against the sum of the possible derived volumes or size scaled log possible derived volumes, and (ii) with the sum of the volume scaled component cardinality size relative entropies,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}(A, z)(A) \sim \\
& \quad-\sum_{T \in F}\left(\left(\left|T_{F}^{-1}\right|:\left|T_{F}^{-1}\right|<z\right)+\left(z \ln \left|T_{F}^{-1}\right|:\left|T_{F}^{-1}\right| \geq z\right)\right) \\
& \quad+v \times \sum_{T \in F} \operatorname{entropyRelative}\left(V^{\mathrm{C}} * T_{F}, A * T_{F}\right)
\end{aligned}
$$

In the case where the sample is near natural, $A \approx A^{\mathrm{E}_{\mathrm{F}}(F)}$, and the size is less than or equal to the volume, $z \leq v$, the uniform possible log likelihood varies (i) against the sum of the possible derived volumes or size scaled log possible derived volumes, and (ii) with the sum of the size scaled component size cardinality relative entropies,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}(A, z)(A) \sim \\
& \quad-\sum_{T \in F}\left(\left(\left|T_{F}^{-1}\right|:\left|T_{F}^{-1}\right|<z\right)+\left(z \ln \left|T_{F}^{-1}\right|:\left|T_{F}^{-1}\right| \geq z\right)\right) \\
& \quad+z \times \sum_{T \in F} \text { entropyRelative }\left(A * T_{F}, V^{\mathrm{C}} * T_{F}\right)
\end{aligned}
$$

In this case the correlation properties of uniform possible fud induction relate to the correlation properties of the specialising fud substrate history coder, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)$, more closely than those of necessary fud induction. The specialising space varies (i) with the possible fud derived volume, $\left|\left(F^{\mathrm{T}}\right)^{-1}\right|$, or the size scaled $\log$ possible fud derived volume, $z \ln \left|\left(F^{\mathrm{T}}\right)^{-1}\right|$, (ii) with the size scaled fud transform derived entropy and (iii) against the sum of the size scaled component size cardinality cross entropies of the transforms of the fud,

$$
\begin{aligned}
& C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H) \sim \\
& \quad\left(\left|\left(F^{\mathrm{T}}\right)^{-1}\right|:\left|\left(F^{\mathrm{T}}\right)^{-1}\right|<z\right)+\left(z \ln \left|\left(F^{\mathrm{T}}\right)^{-1}\right|:\left|\left(F^{\mathrm{T}}\right)^{-1}\right| \geq z\right) \\
& \quad+z \times \operatorname{entropy}\left(A * F^{\mathrm{T}}\right) \\
& \quad-z \times \sum_{T \in F} \operatorname{entropyCross}\left(A * T_{F}, V_{T}^{\mathrm{C}} * T\right)
\end{aligned}
$$

In classical uniform possible functional definition set induction, where (i) the history probability function is uniform possible iso-fud historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, F_{\mathrm{o}}}$, given some substrate fud in the sample variables $F_{\mathrm{o}} \in$ $\mathcal{F}_{U, V_{\mathrm{o}}}$, such that there exists a top transform, $\exists T \in F_{\mathrm{o}}\left(\operatorname{der}(T)=\operatorname{der}\left(F_{\mathrm{o}}\right)\right)$, if it is the case that (ii) the sample equals the fud-independent, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}\left(F_{\mathrm{o}}\right)}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the iso-fud conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, F_{0}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, so, if it is also the case that (iii) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{0}$, and such that (iv) the scaled probability sample histogram is integral, $A_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the log likelihood of the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate (a) varies against the sum of the possible derived volumes or size scaled log possible derived volumes

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \\
& \quad-\sum_{T \in F_{\mathrm{o}}}\left(\left(\left|T_{F_{\mathrm{o}}}^{-1}\right|:\left|T_{F_{\mathrm{o}}}^{-1}\right|<z_{\mathrm{o}}\right)+\left(z_{\mathrm{o}} \ln \left|T_{F_{\mathrm{o}}}^{-1}\right|:\left|T_{F_{\mathrm{o}}}^{-1}\right| \geq z_{\mathrm{o}}\right)\right)
\end{aligned}
$$

and (b) with the sum of the size-volume scaled component size cardinality sum relative entropies,
$\ln \hat{Q}_{\mathrm{h}, \mathrm{d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim$

$$
\begin{aligned}
&+\sum_{T \in F_{\mathrm{o}}}\left(\left(z_{\mathrm{o}}+v_{\mathrm{o}}\right) \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}+V_{\mathrm{o}}^{\mathrm{C}} * T_{F_{\mathrm{o}}}\right)\right. \\
&\left.-z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}\right)-v_{\mathrm{o}} \times \operatorname{entropy}\left(V_{\mathrm{o}}^{\mathrm{C}} * T_{F_{\mathrm{o}}}\right)\right)
\end{aligned}
$$

So the uniform possible log likelihood is maximised when (a) the total possible derived volume is minimised, (b) the sum of the derived entropy of all transforms is minimised, and (c) high size components are low cardinality components and low size components are high cardinality components for all transforms.

If, in addition, the component size cardinality relative entropies are high,

$$
\forall T \in F_{\mathrm{o}}\left(\text { entropy } \operatorname{Cross}\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{F_{\mathrm{o}}}\right)>\ln \left|T_{F_{\mathrm{o}}}^{-1}\right|\right)
$$

the sum sensitivity of the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate is less than or equal to the sum sensitivity of the stuffed historical probability distribution at the maximum likelihood estimate,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\right.\right. & \left.\left.\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \\
& \leq \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)
\end{aligned}
$$

The query sensitivity, $\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}}$, is also lower.
In the case where the size is greater than the volume, $z_{0}>v_{0}$, the log likelihood of the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the volume scaled component cardinality size relative entropies,
$\ln \hat{Q}_{\mathrm{h}, \mathrm{d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim v_{\mathrm{o}} \times \sum_{T \in F_{\mathrm{o}}} \operatorname{entropyRelative}\left(V_{\mathrm{o}}^{\mathrm{C}} * T_{F_{\mathrm{o}}}, A_{\mathrm{o}} * T_{F_{\mathrm{o}}}\right)$
In the case where the size is less than the volume, $z_{0}<v_{\mathrm{o}}$, but the sample approximates to the fud-independent, $A_{\mathrm{o}} \approx A_{\mathrm{o}}^{\mathrm{EF}\left(F_{\mathrm{o}}\right)}$, the log likelihood of the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate (a) varies against the sum of the possible derived volumes or size scaled log possible derived volumes,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \\
& \quad-\sum_{T \in F_{\mathrm{o}}}\left(\left(\left|T_{F_{\mathrm{o}}}^{-1}\right|:\left|T_{F_{\mathrm{o}}}^{-1}\right|<z_{\mathrm{o}}\right)+\left(z_{\mathrm{o}} \ln \left|T_{F_{\mathrm{o}}}^{-1}\right|:\left|T_{F_{\mathrm{o}}}^{-1}\right| \geq z_{\mathrm{o}}\right)\right)
\end{aligned}
$$

(b) varies with the size scaled component size cardinality relative entropies,
$\ln \hat{Q}_{\mathrm{h}, \mathrm{d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \sum_{T \in F_{\mathrm{o}}}$ entropyRelative $\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{F_{\mathrm{o}}}\right)$
so (c) varies against the specialising fud substrate history coder space,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)
$$

and (d) varies against the specialising-canonical space difference,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) & \sim \\
& -\left(2 C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}^{V_{\mathrm{o}} \mathrm{~s}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)-C_{\mathrm{H}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)-C_{\mathrm{G}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right)
\end{aligned}
$$

where $F^{V}$ is the expansion that adds a unary transform in the remaining underlying variables, $F \cup\left\{\left\{(V \backslash \operatorname{und}(F))^{\mathrm{CS}}\right\}^{\mathrm{T}}\right\}$.

So the uniform possible log likelihood is maximised, in this case, when (a) the total possible derived volume is minimised, (b) the total derived entropy is minimised, (c) high size components are low cardinality components and low size components are high cardinality components for each transform, and (d) the total expected component entropy is maximised. It is also conjectured that, (i) the derived entropy decreases up the layers, (ii) the possible derived volume decreases up the layers, (iii) the expected component entropy increases up the layers, and (iv) the component size cardinality cross entropy increases up the layers.

Conjecture that, in the case of high component size cardinality relative entropies, the sum sensitivity of the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the specialising fud substrate history coder space,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{o}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)
$$

and so the sum sensitivity of the iso-fud conditional stuffed historical probability distribution varies against the log-likelihood of the iso-fud conditional stuffed historical probability distribution

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{o}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{o}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

Now consider the case where the model, $F_{\mathrm{o}}$, is unknown. The maximum likelihood estimate for the pair ( $\tilde{E}_{\mathrm{o}}, \tilde{F}_{\mathrm{o}}$ ) in the uniform possible case is

$$
\begin{aligned}
& \left(\tilde{E}_{\mathrm{o}}, \tilde{F}_{\mathrm{o}}\right) \in \operatorname{maxd}\left(\left\{\left((E, F), \hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right. \\
& \left.\left.\quad E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}, F \in \mathcal{F}_{U, V_{\mathrm{o}}}, \exists T \in F\left(W_{T}=W_{F}\right)\right\}\right)
\end{aligned}
$$

If there is a unique maximum for the distribution probability histogram, $\tilde{E}_{\mathrm{o}}$, this can be rewritten in terms of the fud-dependent,

$$
\begin{aligned}
& \tilde{F}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(F, \hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}\left(A_{\mathrm{o}}^{\mathrm{D}_{\mathrm{F}}(F)}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right. \\
& \\
& \left.\left.F \in \mathcal{F}_{U, V_{\mathrm{o}}}, \exists T \in F\left(W_{T}=W_{F}\right)\right\}\right)
\end{aligned}
$$

If the optimisation is restricted such that the sample is equal to the fudindependent, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}(F)} \Longrightarrow A_{\mathrm{o}}^{\mathrm{D}_{\mathrm{F}}(F)}=A_{\mathrm{o}}$, then the optimisation is

$$
\begin{aligned}
\tilde{F}_{\mathrm{o}} \in \operatorname{maxd}(\{(F, & \left.\hat{Q}_{\mathrm{m}, \mathrm{~d}, F, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): \\
& \left.\left.F \in \mathcal{F}_{U, V_{\mathrm{o}}}, \exists T \in F\left(W_{T}=W_{F}\right), A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}(F)}\right\}\right)
\end{aligned}
$$

In this case, all of the derived histogram sets are possible because the distribution equals the sample, so the optimisation is

$$
\begin{array}{r}
\tilde{F}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(F, \frac{1}{\left|\operatorname{ran}\left(D_{U, \mathrm{i}, F, z_{\mathrm{o}}}\right)\right|} \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in D_{U, \mathrm{i}, F, z_{\mathrm{o}}}^{-1}\left(D_{U, F, z_{\mathrm{o}}( }\left(A_{\mathrm{o}}\right)\right)} Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)(B)}\right):\right.\right. \\
\left.\left.F \in \mathcal{F}_{U, V_{\mathrm{o}}}, \exists T \in F\left(W_{T}=W_{F}\right), A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}}(F)\right\}\right)
\end{array}
$$

Now, the set of maximum likelihood estimates for the model, $\tilde{F}_{\mathrm{o}}$, is computable, if an approximation is used for the fud-independent, $A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}(F)}$,

$$
\begin{array}{r}
\tilde{F}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(F, \frac{1}{\left|\operatorname{ran}\left(D_{U, \mathrm{i}, F, z_{\mathrm{o}}}\right)\right|} \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in D_{U, \mathrm{i}, F, z_{\mathrm{o}}}^{-1}\left(D_{U, F, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)\right)} Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)(B)}\right):\right.\right. \\
\left.\left.F \in \mathcal{F}_{U, V_{\mathrm{o}}}, \exists T \in F\left(W_{T}=W_{F}\right), A_{\mathrm{o}}=Z_{1 /|F|} * \sum_{T \in F} A_{\mathrm{o}} * T_{F} * T_{F}^{\dagger}\right\}\right)
\end{array}
$$

In some cases the maximum likelihood estimate for the model is neither self nor unary, $\tilde{F}_{\mathrm{o}} \notin\left\{\left\{T_{\mathrm{s}}\right\},\left\{T_{\mathrm{u}}\right\}\right\}$.

In classical uniform possible functional definition set induction, where (i) the history probability function is uniform possible iso-fud historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, F_{\mathrm{o}}}$, given some unknown substrate fud in the sample variables $F_{\mathrm{o}} \in \mathcal{F}_{U, V_{\mathrm{o}}}$, such that there exists a top transform, $\exists T \in$ $F_{\mathrm{o}}\left(\operatorname{der}(T)=\operatorname{der}\left(F_{\mathrm{o}}\right)\right)$, if it is the case that (ii) the sample histogram equals the fud-independent, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}\left(F_{\mathrm{o}}\right)}$, then the maximum likelihood estimate of the distribution histogram, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the iso-fud conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, F_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, and, if it is also the case that (iii) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{0}$, and such that (iv) the scaled probability sample histogram is integral, $A_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the maximum likelihood estimate of the model, $\tilde{F}_{\mathrm{o}}$, in the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate of the distribution, $\tilde{E}_{\mathrm{o}}$, is

$$
\left.\left.\begin{array}{rl}
\tilde{F}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(F, \hat{Q}_{\mathrm{h}, \mathrm{~d}, F, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right. \\
& F \in \mathcal{F}_{U, V_{\mathrm{o}}}, \exists T \in F\left(W_{T}=W_{F}\right), A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}}(F)
\end{array}\right)\right)
$$

and in some cases the maximum likelihood estimate for the model, $\tilde{F}_{\mathrm{o}}$, is non-trivial,

$$
\tilde{F}_{\mathrm{o}} \notin\left\{\left\{T_{\mathrm{s}}\right\},\left\{T_{\mathrm{u}}\right\}\right\}
$$

In the case where the component size cardinality relative entropies are high,

$$
\forall T \in F_{\mathrm{o}}\left(\text { entropy } \operatorname{Cross}\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{F_{\mathrm{o}}}\right)>\ln \left|T_{F_{\mathrm{o}}}^{-1}\right|\right)
$$

the sum sensitivity of the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate of the distribution-model pair is less than or equal to the sum sensitivity of the stuffed historical probability distribution at the maximum likelihood estimate,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{F}_{\mathrm{o}}, U}\right.\right. & \left.\left.\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \\
\leq & \operatorname{sum}\left(\text { sensitivity }(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)
\end{aligned}
$$

In the case where the size is less than the volume, $z_{0}<v_{\mathrm{o}}$, the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate of the distribution, $\tilde{E}_{\mathrm{o}}$, is approximated

$$
\begin{aligned}
& \tilde{F}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(F, \hat{Q}_{\mathrm{h}, \mathrm{~d}, F, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right. \\
& \left.\left.\quad F \in \mathcal{F}_{U, V_{\mathrm{o}}}, \exists T \in F\left(W_{T}=W_{F}\right), A_{\mathrm{o}} \approx A_{\mathrm{o}}^{\mathrm{E}(F)}\right\}\right)
\end{aligned}
$$

In this case where the size is less than the volume, $z_{0}<v_{\mathrm{o}}$, the properties of the maximisation of the log likelihood, $\ln \hat{Q}_{\mathrm{m}, \mathrm{d}, F_{o}, U}\left(A_{\mathrm{o}}, z\right)\left(A_{\mathrm{o}}\right)$, are consistent with the properties of the minimisation of the sum sensitivity, $\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{d}, F_{o}, U}\left(A_{\mathrm{o}}, z\right)\right)\right)$. So conjecture that in classical uniform possible functional definition set induction, where the size is less than the volume, but the sample approximates to the fud-independent, and the relative entropies are high, the sum sensitivity varies against the log likelihood, and the optimisation tends to minimise the sensitivity to the distribution, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{F}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

Similarly, the query sensitivity to the distribution,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{F}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}}
$$

is also minimised by the optimisation of log-likelihood.

### 5.5.7 Uniform possible derived functional definition set decomposition induction

The last section extended the model from transforms to functional definition sets. Now extend further to functional definition set decompositions. This discussion is very similar to that of the previous section, except that now the fuds are contingent on the slice.

Given some non-empty known substrate fud decomposition, $D_{\mathrm{o}} \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}$, such that there exists a top transform for all of the fuds, $\forall F \in \operatorname{fuds}\left(D_{\mathrm{o}}\right) \exists T \in$ $F(\operatorname{der}(T)=\operatorname{der}(F))$, the component derived set of the distribution probability histogram is $\left\{\left(C,\left\{\hat{E}_{\mathrm{h}} * C * T_{F}: T \in F\right\}\right):(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right)\right\}$, where $\operatorname{cont}(D)=\operatorname{elements}(\operatorname{contingents}(D))$ and $T_{F}:=\operatorname{depends}(F, \operatorname{der}(T))^{\mathrm{T}}$. Consider the case where it is unknown if the given histogram, $A_{0}$, is a sample histogram drawn from the distribution histogram, $E_{\mathrm{h}}$, so, in some cases $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, D_{\mathrm{o}}}\left(H_{\mathrm{o}}\right)=0$. That is, it is known that some component derived set is necessary, $\exists B \in \mathcal{A}_{U, \mathrm{i}, V_{\mathrm{o}}, z_{\mathrm{o}}} \forall(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right) \forall T \in F\left(\hat{B} * C * T_{F}=\right.$ $\hat{E}_{\mathrm{h}} * C * T_{F}$ ), but not whether the given component derived set is necessary, $\forall(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right) \forall T \in F\left(\hat{A} * C * T_{F}=\hat{E}_{\mathrm{h}} * C * T_{F}\right)$. In the absence of further knowledge it is assumed that the given component derived set, $\left\{\hat{E}_{\mathrm{h}} * C * T_{F}:(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right), T \in F\right\}$ is at least possible and that the probability function of the component derived set is uniform. This relaxation of the constraint that the sample be necessarily drawn from the iso-fud-decomposition of the distribution to the constraint that the sample be possibly drawn from the iso-fud-decomposition of the distribution is equivalent to assuming that the sample is drawn from the uniform possible iso-fud-decomposition historically distributed history probability function $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, D_{\mathrm{o}}} \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}$, which is defined as the solution to

$$
\begin{aligned}
& P_{U, X, H_{\mathrm{h}, \mathrm{~d}, \mathrm{p}, D_{\mathrm{o}}}:=} \begin{array}{l}
\left(\bigcup \left\{\left\{\left(H, 1 / \sum\left(P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, D_{\mathrm{o}}}(G):\right.\right.\right.\right.\right. \\
G \subseteq H_{\mathrm{h}} \% V_{H},|G|=z_{H}, \forall(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right) \\
\left.\left.\forall T \in F\left(A_{G} * C * T_{F}=A_{H} * C * T_{F}\right)\right)\right): \\
\\
\left.\quad H \subseteq H_{\mathrm{h}} \% V_{H},|H|=z_{H}\right\}^{\wedge}: \\
\left.\left.V_{H} \subseteq V_{\mathrm{h}}, z_{H} \in\left\{1 \ldots z_{\mathrm{h}}\right\}\right\}\right)^{\wedge} \cup
\end{array} \\
& \left\{(H, 0): H \in \mathcal{H}_{U, X}, H \nsubseteq H_{\mathrm{h}} \% V_{H}\right\} \cup\{(\emptyset, 0)\}
\end{aligned}
$$

All iso-fud-decomposition subsets of the distribution history for a given set of variables and size are defined as equally probable,

$$
\begin{aligned}
& \forall V \subseteq V_{\mathrm{h}} \forall H, G \subseteq H_{\mathrm{h}} \% V \\
& \qquad\left(\begin{array}{l} 
\\
(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right) \forall T \in F\left(A_{G} * C * T_{F}=A_{H} * C * T_{F}\right) \Longrightarrow \\
\\
\left.\quad P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, D_{\mathrm{o}}}(G)=P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, D_{\mathrm{o}}}(H)\right)
\end{array}\right.
\end{aligned}
$$

The uniform possible iso-fud-decomposition historically distributed history probability function is such that given a drawn history $H \in \mathcal{H}_{U, X}$

$$
\begin{aligned}
& \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{o}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right)= \\
& \frac{\sum P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, D_{o}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}}{\sum P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, D_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, V_{G}=V_{H},|G|=z_{H}}
\end{aligned}
$$

The possible history probability function, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, D_{\mathrm{o}}}$, is related to the iso-fud-decomposition conditional historical distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, D_{o}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)$, in the same way as for the necessary case, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, D_{\mathrm{o}}}$, except that the normalising fraction is restored. In the case where all component derived sets are possible the normalising fraction is $1 /\left|\operatorname{ran}\left(D_{U, \mathrm{i}, D_{o}, \mathrm{~F}, z_{H}}\right)\right|$,

$$
\begin{aligned}
& \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{o}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right)= \\
& \quad \frac{1}{\left|\operatorname{ran}\left(D_{U, \mathrm{i}, D_{o}, \mathrm{~F}, z_{H}}\right)\right|} \frac{Q_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right)}{\sum_{B \in D_{U, i, D_{0}, \mathrm{~F}, z_{H}}^{-1}\left(D_{U, D_{\mathrm{o}}, \mathrm{~F}, z_{H}}\left(A_{H}\right)\right)} Q_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)(B)}
\end{aligned}
$$

Any historically drawn history is possible,

$$
\forall H \subseteq H_{\mathrm{h}} \% V_{H}\left(H \neq \emptyset \Longrightarrow P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, D_{\mathrm{o}}}(H)>0\right)
$$

but sometimes the probability is lower than in the necessary case,
$\forall H \subseteq H_{\mathrm{h}} \% V_{H}\left(P_{U, X, H_{\mathrm{h}}, \mathrm{d}, D_{\mathrm{o}}}(H)>0 \Longleftrightarrow P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, D_{\mathrm{o}}}(H) \leq P_{U, X, H_{\mathrm{h}}, \mathrm{d}, D_{\mathrm{o}}}(H)\right)$
The uniform possible log likelihood has similar properties to the necessary log likelihood.

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, D, U}(E, z)(A)= \\
& \quad \ln \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in D_{U, i, D, \mathrm{~F}, z}^{-1}\left(D_{U, D, \mathrm{~F}, z}(A)\right)} Q_{\mathrm{m}, U}(E, z)(B)}-\ln \left|\operatorname{ran}\left(D_{U, \mathrm{i}, D, \mathrm{~F}, z}\right)\right|
\end{aligned}
$$

In classical uniform possible functional definition set decomposition induction, where (i) the history probability function is uniform possible iso-fuddecomposition historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, D_{\mathrm{o}}}$, given some substrate fud in the sample variables $D_{\mathrm{o}} \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}$, such that there exists a
top transform for all of the fuds, $\forall F \in \operatorname{fuds}\left(D_{\mathrm{o}}\right) \exists T \in F(\operatorname{der}(T)=\operatorname{der}(F))$, if it is the case that (ii) the sample equals the fud-decomposition-independent, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}\left(D_{\mathrm{o}}\right)}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{O}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the iso-fud-decomposition conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, D_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, so, if it is also the case that (iii) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{0}$, and such that (iv) the scaled probability sample histogram is integral, $A_{0, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the log likelihood of the iso-fud-decomposition conditional stuffed historical probability distribution at the maximum likelihood estimate (a) varies against the sum of the possible derived volumes or size scaled log possible derived volumes of the slices

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \\
& -\sum_{(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right)} \sum_{T \in F}\left(\left(\left|T_{F}^{-1}\right|:\left|T_{F}^{-1}\right|<z_{A_{\mathrm{o}} * C}\right)+\right. \\
& \left.\quad\left(z_{A_{\mathrm{o}} * C} \ln \left|T_{F}^{-1}\right|:\left|T_{F}^{-1}\right| \geq z_{A_{\mathrm{o}} * C}\right)\right)
\end{aligned}
$$

and (b) with the sum of the size-volume scaled component size cardinality sum relative entropies for all slices,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \\
& \sum_{(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right)} \sum_{T \in F}\left(\left(z_{A_{\mathrm{o}} * C}+|C|\right) \times \operatorname{entropy}\left(A_{\mathrm{o}} * C * T_{F}+C * T_{F}\right)\right. \\
& \left.\quad-z_{A_{\mathrm{o}} * C} \times \operatorname{entropy}\left(A_{\mathrm{o}} * C * T_{F}\right)-|C| \times \operatorname{entropy}\left(C * T_{F}\right)\right)
\end{aligned}
$$

So the uniform possible log likelihood is maximised when (a) the total possible derived volume is minimised, (b) the sum of the derived entropy of all transforms for all slices is minimised, and (c) high size components are low cardinality components and low size components are high cardinality components for all transforms for all slices.

If, in addition, the component size cardinality relative entropies are high,

$$
\forall(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right) \forall T \in F\left(\text { entropy } \operatorname{Cross}\left(A_{\mathrm{o}} * C * T_{F}, C * T_{F}\right)>\ln \left|T_{F}^{-1}\right|\right)
$$

the sum sensitivity of the iso-fud-decomposition conditional stuffed historical probability distribution at the maximum likelihood estimate is less than or equal to the sum sensitivity of the stuffed historical probability distribution at the maximum likelihood estimate,

$$
\begin{aligned}
& \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \\
& \leq \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)
\end{aligned}
$$

The query sensitivity, $\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}}$, is also lower.
In the case where the size is greater than the volume, $z_{0}>v_{\mathrm{o}}$, the $\log$ likelihood of the iso-fud-decomposition conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the volume scaled component cardinality size relative entropies for all slices,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim
$$

In the case where the size is less than the volume, $z_{0}<v_{0}$, but the sample histogram approximates to the fud-decomposition-independent histogram, $A_{\mathrm{o}} \approx A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}\left(D_{\mathrm{o}}\right)}$, or spaceRelative $\left(A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}\left(D_{\mathrm{o}}\right)}\right)\left(A_{\mathrm{o}}\right) \approx 0$, the log likelihood of the iso-fud-decomposition conditional stuffed historical probability distribution at the maximum likelihood estimate (a) varies against the sum of the possible derived volumes or size scaled log possible derived volumes of the slices

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \\
& -\sum_{(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right)} \sum_{T \in F}\left(\left(\left|T_{F}^{-1}\right|:\left|T_{F}^{-1}\right|<z_{A_{\mathrm{o}} * C}\right)+\right. \\
& \left.\quad\left(z_{A_{\mathrm{o}} * C} \ln \left|T_{F}^{-1}\right|:\left|T_{F}^{-1}\right| \geq z_{A_{\mathrm{o}} * C}\right)\right)
\end{aligned}
$$

(b) varies with sum of the size scaled component size cardinality relative entropies of all transforms for all slices,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim
$$

so (c) varies against the specialising fud decomposition substrate history coder space,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D_{\mathrm{o}}^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)
$$

and (d) varies against the specialising-canonical space difference,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)( & \left(A_{\mathrm{o}}\right)
\end{aligned} \quad \sim
$$

where $D^{V}$ is the expansion that adds a unary transform in the remaining underlying variables to the leaf fuds in the decomposition tree such that the
fud of each path of the application tree has complete coverage of the substrate,

$$
\forall L \in \operatorname{paths}\left(D^{*}\right)\left(\bigcup_{(\cdot,(F, \cdot)) \in L} V_{F}=V\right)
$$

where $V_{F}=\operatorname{und}(F)$.
So the uniform possible log likelihood is maximised, in this case, when (a) the total possible derived volume is minimised, (b) the total derived entropy is minimised, (c) high size components are low cardinality components and low size components are high cardinality components for all transforms for all slices, and (d) the total expected component entropy is maximised. It is also conjectured that, for all fuds, (i) the derived entropy decreases up the layers, (ii) the possible derived volume decreases up the layers, (iii) the expected component entropy increases up the layers, and (iv) the component size cardinality cross entropy increases up the layers.

Conjecture that, in the case of high component size cardinality relative entropies, the sum sensitivity of the iso-fud-decomposition conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the specialising fud decomposition substrate history coder space,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim C_{\mathrm{G}, V_{o}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D_{\mathrm{o}}^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)
$$

and so the sum sensitivity of the iso-fud-decomposition conditional stuffed historical probability distribution varies against the log-likelihood of the iso-fud-decomposition conditional stuffed historical probability distribution

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

Now consider the case where the model, $D_{\mathrm{o}}$, is unknown. The maximum likelihood estimate for the pair $\left(\tilde{E}_{\mathrm{o}}, \tilde{D}_{\mathrm{o}}\right)$ in the uniform possible case is

$$
\begin{aligned}
&\left(\tilde{E}_{\mathrm{o}}, \tilde{D}_{\mathrm{o}}\right) \in \operatorname{maxd}( \left\{\left((E, D), \hat{Q}_{\mathrm{m}, \mathrm{~d}, D, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right. \\
& E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}, \\
&\left.\left.D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}, \forall F \in \operatorname{fuds}(D) \exists T \in F\left(W_{T}=W_{F}\right)\right\}\right)
\end{aligned}
$$

If there is a unique maximum for the distribution probability histogram, $\tilde{E}_{\mathrm{o}}$, this can be rewritten in terms of the fud-decomposition-dependent,

$$
\begin{aligned}
& \tilde{D}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(D, \hat{Q}_{\mathrm{m}, \mathrm{~d}, D, U}\left(A_{\mathrm{o}}^{\mathrm{D}_{\mathrm{D}, \mathrm{~F}}(D)}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right. \\
& \left.\left.\quad D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}, \forall F \in \operatorname{fuds}(D) \exists T \in F\left(W_{T}=W_{F}\right)\right\}\right)
\end{aligned}
$$

If the optimisation is restricted such that the sample is equal to the fud-decomposition-independent, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}(D)} \Longrightarrow A_{\mathrm{o}}^{\mathrm{D}_{\mathrm{D}, \mathrm{F}}(D)}=A_{\mathrm{o}}$, then the optimisation is

$$
\begin{aligned}
& \tilde{D}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(D, \hat{Q}_{\mathrm{m}, \mathrm{~d}, D, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right. \\
& D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}, \forall F \in \operatorname{fuds}(D) \exists T \in F\left(W_{T}=W_{F}\right), \\
& \left.\left.\quad A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{~F}}(D)}\right\}\right)
\end{aligned}
$$

In this case, all of the component derived sets are possible because the distribution equals the sample, so the optimisation is

$$
\begin{array}{r}
\tilde{D}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(D, \frac{1}{\left|\operatorname{ran}\left(D_{\left.U, \mathrm{i}, D, \mathrm{~F}, z_{\mathrm{o}}\right)}\right)\right|} \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in D_{U, \mathrm{i}, D, \mathrm{~F}, z_{\mathrm{o}}}^{-1}\left(D_{U, D, \mathrm{~F}, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)\right)} Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)(B)}\right):\right.\right. \\
D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}, \forall F \in \operatorname{fuds}(D) \exists T \in F\left(W_{T}=W_{F}\right), \\
\left.\left.A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{o}, \mathrm{~F}}(D)}\right\}\right)
\end{array}
$$

Now, the set of maximum likelihood estimates for the model, $\tilde{D}_{\mathrm{o}}$, is computable, if an approximation is used for the fud-decomposition-independent, $A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}(D)}$,
$\tilde{D}_{\mathrm{o}} \in$

$$
\begin{aligned}
\operatorname{maxd}\left(\left\{\left(D, \frac{1}{\mid \operatorname{ran}\left(D_{\left.U, \mathrm{i}, D, \mathrm{~F}, z_{\mathrm{o}}\right) \mid}\right)} \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in D_{U, i, D, \mathrm{~F}, z_{\mathrm{o}}}^{-1}\left(D_{U, D, \mathrm{~F}, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)\right)} Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)(B)}\right)\right.\right. \\
D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}, \forall F \in \operatorname{fuds}(D) \exists T \in F\left(W_{T}=W_{F}\right), \\
\left.\left.A_{\mathrm{o}}=Z_{z_{\mathrm{o}}} *\left(\sum_{(C, F) \in \operatorname{cont}(D)}\left(Z_{1 /|F|} * \sum_{T \in F} A_{\mathrm{o}} * C * T_{F} * T_{F}^{\dagger}\right)\right)\right\}\right)
\end{aligned}
$$

In some cases the maximum likelihood estimate for the model is neither self nor unary, $\tilde{D}_{\mathrm{o}} \notin\left\{\left\{\left(\left(\emptyset,\left\{T_{\mathrm{s}}\right\}\right), \emptyset\right)\right\},\left\{\left(\left(\emptyset,\left\{T_{\mathrm{u}}\right\}\right), \emptyset\right)\right\}\right\}$.

In classical uniform possible functional definition set decomposition induction, where (i) the history probability function is uniform possible iso-fuddecomposition historically distributed, $P=P_{U, X, H_{h}, \mathrm{~d}, \mathrm{p}, D_{\mathrm{o}}}$, given some unknown substrate fud decomposition in the sample variables $D_{\mathrm{o}} \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}$, such that there exists a top transform for all of the fuds, $\forall F \in \operatorname{fuds}\left(D_{\mathrm{o}}\right) \exists T \in$ $F(\operatorname{der}(T)=\operatorname{der}(F))$, if it is the case that (ii) the sample histogram equals the fud-decomposition-independent, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}\left(D_{\mathrm{o}}\right)}$, then the maximum likelihood estimate of the distribution histogram, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the iso-fud-decomposition conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, D_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, and, if it is also
the case that (iii) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{\mathrm{o}}$, and such that (iv) the scaled probability sample histogram is integral, $A_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the maximum likelihood estimate of the model, $\tilde{D}_{\mathrm{o}}$, in the iso-fud-decomposition conditional stuffed historical probability distribution at the maximum likelihood estimate of the distribution, $\tilde{E}_{\mathrm{o}}$, is

$$
\begin{aligned}
& \tilde{D}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(D, \hat{Q}_{\mathrm{h}, \mathrm{~d}, D, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right. \\
& D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}, \forall F \in \operatorname{fuds}(D) \exists T \in F\left(W_{T}=W_{F}\right), \\
& \left.\left.\quad A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}, \mathrm{~F}(D)}\right\}\right)
\end{aligned}
$$

and in some cases the maximum likelihood estimate for the model, $\tilde{D}_{\mathrm{o}}$, is non-trivial,

$$
\tilde{D}_{\mathrm{o}} \notin\left\{\left\{\left(\left(\emptyset,\left\{T_{\mathrm{s}}\right\}\right), \emptyset\right)\right\},\left\{\left(\left(\emptyset,\left\{T_{\mathrm{u}}\right\}\right), \emptyset\right)\right\}\right\}
$$

In the case where the component size cardinality relative entropies are high,

$$
\forall(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right) \forall T \in F\left(\text { entropy } \operatorname{Cross}\left(A_{\mathrm{o}} * C * T_{F}, C * T_{F}\right)>\ln \left|T_{F}^{-1}\right|\right)
$$

the sum sensitivity of the iso-fud-decomposition conditional stuffed historical probability distribution at the maximum likelihood estimate of the distributionmodel pair is less than or equal to the sum sensitivity of the stuffed historical probability distribution at the maximum likelihood estimate,

$$
\begin{aligned}
& \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{D}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \\
& \leq \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)
\end{aligned}
$$

In the case where the size is less than the volume, $z_{0}<v_{\mathrm{o}}$, the iso-fuddecomposition conditional stuffed historical probability distribution at the maximum likelihood estimate of the distribution, $\tilde{E}_{\mathrm{o}}$, is approximated

$$
\begin{aligned}
& \tilde{D}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(D, \hat{Q}_{\mathrm{h}, \mathrm{~d}, D, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right. \\
& D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}, \forall F \in \operatorname{fuds}(D) \exists T \in F\left(W_{T}=W_{F}\right), \\
&\left.\left.A_{\mathrm{o}} \approx A_{\mathrm{o}}^{\mathrm{E}, \mathrm{~F}(D)}\right\}\right)
\end{aligned}
$$

In this case where the size is less than the volume, $z_{0}<v_{0}$, the properties of the maximisation of the log likelihood, $\ln \hat{Q}_{\mathrm{m}, \mathrm{d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}}, z\right)\left(A_{\mathrm{o}}\right)$, are consistent with the properties of the minimisation of the sum sensitivity, $\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}}, z\right)\right)\right)$. So conjecture that in classical uniform possible functional definition set decomposition induction, where the size
is less than the volume, but the sample approximates to the fud-decompositionindependent, and the relative entropies are high, the sum sensitivity varies against the log likelihood, and the optimisation tends to minimise the sensitivity to the distribution, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{D}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

Similarly, the query sensitivity to the distribution,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{D}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}}
$$

is also minimised by the optimisation of log-likelihood.

### 5.5.8 Specialising induction

Although the maximum likelihood estimate for the model, $\tilde{T}_{\mathrm{o}}$, is computable for uniform possible derived induction, where the sample histogram is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, the computation is not tractable. The derived function, $D_{U, \mathrm{i}, T, z_{0}} \in \mathcal{A}_{U, \mathrm{i}, V_{o}, z_{0}}: \rightarrow \mathcal{A}_{U, \mathrm{i}, W_{,}, z_{0}}$, is intractable because its computation requires the computation of its domain of the substrate histograms, $\mathcal{A}_{U, \mathrm{i}, V_{0}, z_{0}}$. The substrate histograms have cardinality $\left|\mathcal{A}_{U, \mathrm{i}, V_{o}, z_{0}}\right|=$ $\left(z_{\mathrm{o}}+v_{\mathrm{o}}-1\right)!/\left(z_{\mathrm{o}}!\left(v_{\mathrm{o}}-1\right)!\right)$, which is exponential in the dimension, $\left|V_{\mathrm{o}}\right|$. In addition, in the case for uniform possible derived induction the computation of the set of substrate transforms, $\mathcal{T}_{U, V_{0}}$, is intractable. The cardinality of the substrate transforms is $\left|\mathcal{T}_{U, V_{0}}\right|=2^{\text {bell }\left(v_{o}\right)}$, which is factorial in the volume, $v_{0}$.

The discussion of specialising induction, below, considers this issue of intractability, firstly by constructing a somewhat artificial history probability function explicitly defined by specialising space, and then by showing how its log likelihood correlates to tractable induction. Whereas in uniform possible derived induction the natural log likelihood is merely anti-correlated to the specialising space, here in specialising induction the log likelihood is strictly proportional to the negative specialising space, whether natural or not. That is, the induction assumptions are amended by replacing the notion that histories are conditionally drawn from a distribution history, with a more explicit assertion of a degree of structure with respect to a specialising coder for arbitrary sample substrate variables and sample size.

Consider the specialising history probability function $P_{U, X, \mathrm{G}, T_{o}, \mathrm{H}} \in\left(\mathcal{H}_{U, X}: \rightarrow\right.$ $\left.\mathrm{Q}_{[0,1]}\right) \cap \mathcal{P}$ which is defined such that the probability of a history is inversely proportional to the bounding integer, for which the space is the logarithm,
of the integer encoding of the history in the specialising coder, given a known substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$,

$$
\begin{aligned}
& P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}:= \\
& \begin{array}{l}
\left(\bigcup \left\{\left\{\left(H, \exp \left(-C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)^{\mathrm{s}}(H)\right)\right):\right.\right.\right. \\
\\
H \in \mathcal{H}_{U, X}, \\
\left.\quad \operatorname{vars}(H)=V_{H},|H|=z_{H}\right\}^{\wedge}: \\
\left.\left.\quad V_{H} \subseteq \operatorname{vars}(U), z_{H} \in\{1 \ldots|X|\}\right\}\right)^{\wedge} \cup
\end{array}
\end{aligned}
$$

where the specialising derived substrate history coder is
$C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)=\operatorname{coderHistorySubstrateDerivedSpecialising}\left(U, X, T, D_{\mathrm{S}}, D_{\mathrm{X}}\right)$
and the expanded specialising derived history $\operatorname{coder} C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}(T) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$ expands the transform to the history variables, $V_{H}$, where the history variables is a superset of the underlying variables, $V=\operatorname{und}(T)$, and otherwise defaults to an index coder,

$$
\begin{aligned}
C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H)= & \left(C_{\mathrm{G}, V_{H}, \mathrm{~T}, \mathrm{H}}\left(T^{\mathrm{P} V_{H} \mathrm{~T}}\right)^{\mathrm{s}}(H)+s_{\left|V_{H}\right|}: V_{H} \supseteq V\right)+ \\
& \left(C_{\mathrm{H}}^{\mathrm{s}}(H): V_{H} \nsupseteq V\right)
\end{aligned}
$$

where $s_{n}=\operatorname{spaceVariables}(U)(n)$.
All non-empty histories are possible in specialising induction, $\forall H \in \mathcal{H}_{U, X} \backslash$ $\{\emptyset\}\left(P_{U, X, \mathrm{G}, T_{\circ}, \mathrm{H}}(H)>0\right)$.

All histories having the same specialising space for a given set of variables and size are defined as equally probable,

$$
\begin{aligned}
& \forall H, G \in \mathcal{H}_{U, V, z, X} \\
& \qquad\left(C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)^{\mathrm{s}}(G)=C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)^{\mathrm{s}}(H) \Longrightarrow P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}(G)=P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}(H)\right)
\end{aligned}
$$

The specialising history probability function, $P_{U, X, \mathrm{G}, T_{\circ}, \mathrm{H}}$, may be compared to a probability function $P \in \mathcal{P}$ for which there exists an entropy coder $C \in$ $\operatorname{coders}(Y)$. Entropy coders need no normalisation, $\forall x \in Y\left(C^{\mathrm{s}}(x)=\ln 1 / P_{x}\right)$ or $\forall x \in Y\left(P_{x}=\exp \left(-C^{\mathrm{s}}(x)\right)\right)$. The expected space of an entropy coder is the entropy, expected $(P)\left(C^{\mathrm{s}}\right)=\operatorname{entropy}(P)$, so a derived history coder $C \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$ that is also an entropy coder is maximally compressing, structure $(U, X)(P, C)=1$. The specialising history probability function, $P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}$, may have less than maximum degree of structure because (i) histories having variables which are not a superset of the underlying variables,
$V_{\mathrm{o}}$, of the given transform, $T_{\mathrm{o}}$, are encoded in a canonical coder, and (ii) there is a normalisation by variables and size, $\left(V_{H}, z_{H}\right)$.

In specialising induction there is no distribution histogram, so the drawn history is parameterised only by substrate variables and size, $\left(V_{H}, z_{H}\right)$. Nor is any sample constrained to equal its naturalisation, $A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$. If a history is possible in uniform possible derived induction, then it is possible in specialising induction,

$$
\forall H \in \mathcal{H}_{U, X}\left(P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, T_{\mathrm{o}}}(H)>0 \Longrightarrow P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}(H)>0\right)
$$

The specialising space is the same for all members of an iso-derived, $\forall B \in$ $D_{U, \mathbf{i}, T, z}^{-1}(A * T)\left(C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H_{B}\right)=C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H_{A}\right)\right)$, so all iso-derived subsets of the distribution history for a given set of variables and size are not only equally iso-derived probable,

$$
\begin{aligned}
& \forall V \subseteq V_{\mathrm{h}} \forall H, G \subseteq H_{\mathrm{h}} \% V \\
& \quad\left(A_{G} * T_{\mathrm{o}}=A_{H} * T_{\mathrm{o}} \Longrightarrow P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, T_{\mathrm{o}}}(G)=P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, T_{\mathrm{o}}}(H)\right)
\end{aligned}
$$

but also equally specialising probable,

$$
\begin{aligned}
& \forall V \subseteq V_{\mathrm{h}} \forall H, G \subseteq H_{\mathrm{h}} \% V \\
& \quad\left(A_{G} * T_{\mathrm{o}}=A_{H} * T_{\mathrm{o}} \Longrightarrow P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}(G)=P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}(H)\right)
\end{aligned}
$$

Given a history $H \in \mathcal{H}_{U, X}$, such that $H \neq \emptyset$, the specialised historical probability of histogram $A_{H}=\operatorname{histogram}(H)+V_{H}^{\mathrm{CZ}} \in \mathcal{A}_{U, \mathrm{i}, V_{H}, z_{H}}$ is

$$
\hat{Q}_{\mathrm{G}, T_{\circ}, \mathrm{H}, U}\left(z_{H}\right)\left(A_{H}\right) \propto \sum\left(P_{U, X, \mathrm{G}, T_{o}, \mathrm{H}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}\right)
$$

where the specialising probability distribution is defined

$$
\begin{aligned}
& \hat{Q}_{\mathrm{G}, T, \mathrm{H}, U}(z):= \\
& \quad\left\{\left(A, \frac{z!}{\prod_{S \in A^{\mathrm{Fs}}} A_{S}!} \times \exp \left(-C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H_{A}\right)\right)\right): A \in \mathcal{A}_{U, i, \mathrm{i}, z, z}\right\}^{\wedge}
\end{aligned}
$$

where $V=\operatorname{und}(T)$ and $H_{A}=\operatorname{history}(A)$.
The log likelihood is proportional to the classification space of the underlying histogram less the specialising space of the corresponding history,

$$
\ln \hat{Q}_{\mathrm{G}, T, \mathrm{H}, U}(z)(A) \propto \operatorname{spaceClassification}(A)-\operatorname{space}\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)\right)\left(H_{A}\right)
$$

The space of the specialising coder is

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)\right)(H)= & \operatorname{spaceIds}(|X|,|H|)+ \\
& \text { spaceCountsDerived }(U)(A, T)+ \\
& \text { spaceClassification }(A * T)+ \\
& \text { spaceEventsPartition }(A, T) \\
= & \operatorname{spaceIds}(|X|,|H|)+ \\
& \ln \frac{\left(z+w^{\prime}-1\right)!}{z!\left(w^{\prime}-1\right)!}+ \\
& \ln z!-\sum_{R \in(A * T)^{\mathrm{s}}} \ln (A * T)_{R}!+ \\
& \sum_{(R, C) \in T^{-1}}(A * T)_{R} \ln |C|
\end{aligned}
$$

The space of the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)$, varies (i) with the possible derived volume, $w^{\prime}$, where the possible derived volume is less than the size, $w^{\prime}<z$, otherwise with the size scaled log possible derived volume, $z \ln w^{\prime}$, and (ii) against the size scaled component size cardinality relative entropy,

$$
\begin{aligned}
C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H) & \sim \\
& \left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right) \\
- & z \times \operatorname{entropyRelative}\left(A * T, V^{\mathrm{C}} * T\right)
\end{aligned}
$$

The specialising-canonical space difference, $2 C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)-$ $C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, varies (i) with twice the possible derived volume, $2 w^{\prime}$, where $w^{\prime}<z$, otherwise with twice the size scaled $\log$ possible derived volume, $2 z \ln w^{\prime}$, (ii) with the size scaled derived entropy, (iii) against twice the size scaled component size cardinality cross entropy and (iv) against the size scaled size expected component entropy,

$$
\begin{aligned}
2 C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}} & (H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H) \sim \\
& 2\left(\left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right)\right) \\
& +z \times \operatorname{entropy}(A * T) \\
& -2 z \times \operatorname{entropyCross}\left(A * T, V^{\mathrm{C}} * T\right) \\
& -z \times \text { entropyComponent }(A, T)
\end{aligned}
$$

The canonical term, $C_{\mathrm{H}, V}^{\mathrm{s}}(H)+C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, is independent of the model, $T$, so properties of the specialising-canonical space difference, $2 C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H)$ -
$C_{\mathrm{H}, V}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, are also properties of the specialising space, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H)$.
The specialising log likelihood varies (i) against twice the possible derived volume, $2 w^{\prime}$, where $w^{\prime}<z$, otherwise against twice the size scaled log possible derived volume, $2 z \ln w^{\prime}$, (ii) with the size scaled underlying entropy, (iii) against the size scaled derived entropy, (iv) with twice the size scaled component size cardinality cross entropy and (v) with the size scaled size expected component entropy,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{G}, T, \mathrm{H}, U}(z) & (A) \sim \\
& -2\left(\left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right)\right) \\
& +z \times \operatorname{entropy}(A) \\
& -z \times \operatorname{entropy}(A * T) \\
& +2 z \times \operatorname{entropy} \operatorname{Cross}\left(A * T, V^{\mathrm{C}} * T\right) \\
& +z \times \operatorname{entropyComponent}(A, T)
\end{aligned}
$$

Let $H_{\mathrm{o}}$ be a sample history of known size $z_{\mathrm{o}}=\left|H_{\mathrm{o}}\right|>0$ in the known sample variables, $V_{\mathrm{o}}$, which has a known histogram $A_{\mathrm{o}}=\operatorname{histogram}\left(H_{\mathrm{o}}\right)+V_{\mathrm{o}}^{\mathrm{CZ}} \in$ $\mathcal{A}_{U, \mathrm{i}, V_{o}, z_{0}}$. In classical specialising induction, where the history probability function is the specialising history probability function, $P=P_{U, X, \mathrm{G}, T_{o}, \mathrm{H}}$, given some substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, the log likelihood of the specialising probability distribution (a) varies with the size scaled underlying entropy,

$$
\ln \hat{Q}_{\mathrm{G}, T_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}}\right)
$$

(b) varies against the possible derived volume where $w_{\mathrm{o}}^{\prime}<z_{\mathrm{o}}$, otherwise against the size scaled $\log$ possible derived volume, $z_{0} \ln w_{o}^{\prime}$

$$
\ln \hat{Q}_{\mathrm{G}, T_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\left(\left(w_{\mathrm{o}}^{\prime}: w_{\mathrm{o}}^{\prime}<z_{\mathrm{o}}\right)+\left(z_{\mathrm{o}} \ln w_{\mathrm{o}}^{\prime}: w_{\mathrm{o}}^{\prime} \geq z_{\mathrm{o}}\right)\right)
$$

(c) varies against the size scaled derived entropy

$$
\ln \hat{Q}_{\mathrm{G}, T_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

(d) varies with the size scaled component size cardinality cross entropy

$$
\ln \hat{Q}_{\mathrm{G}, T_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \text { entropy } \operatorname{Cross}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)
$$

and (e) varies with the size scaled size expected component entropy,

$$
\ln \hat{Q}_{\mathrm{G}, T_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \text { entropyComponent }\left(A_{\mathrm{o}}, T_{\mathrm{o}}\right)
$$

So the specialising log likelihood is maximised when (a) the possible derived volume is minimised, (b) the underlying entropy is maximised, (c) the derived entropy is minimised, (d) high size components are low cardinality components and low size components are high cardinality components, and (e) the expected component entropy is maximised.

In the case where the model is unary, $T_{\mathrm{o}}=T_{\mathrm{u}}$, (i) the derived entropy is zero, entropy $\left(A_{\mathrm{o}} * T_{\mathrm{u}}\right)=0$, (ii) the cross entropy is zero, entropy $\operatorname{Cross}\left(A_{\mathrm{o}} *\right.$ $\left.T_{\mathrm{u}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{u}}\right)=0$, so (iii) the relative entropy is zero. The size expected component entropy equals the underlying entropy. The log likelihood of the specialising probability distribution only varies with the size scaled underlying entropy,

$$
\ln \hat{Q}_{\mathrm{G}, T_{\mathrm{u}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}}\right)
$$

In the case where the model is self, $T_{\mathrm{o}}=T_{\mathrm{s}}$, (i) the derived entropy equals the underlying entropy, entropy $\left(A_{\mathrm{o}} * T_{\mathrm{s}}\right)=\operatorname{entropy}\left(A_{\mathrm{o}}\right)$, (ii) the cross entropy equals the volume space, entropy $\operatorname{Cross}\left(A_{\mathrm{o}} * T_{\mathrm{s}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{s}}\right)=\ln v_{\mathrm{o}}$, so (iii) the relative entropy varies against the underlying entropy. The size expected component entropy is zero. The log likelihood of the specialising probability distribution only varies against the underlying volume where $v_{0}<z_{0}$, otherwise against the size scaled $\log$ underlying volume, $z_{0} \ln v_{\mathrm{o}}$

$$
\ln \hat{Q}_{\mathrm{G}, T_{\mathrm{s}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\left(\left(v_{\mathrm{o}}: v_{\mathrm{o}}<z_{\mathrm{o}}\right)+\left(z_{\mathrm{o}} \ln v_{\mathrm{o}}: v_{\mathrm{o}} \geq z_{\mathrm{o}}\right)\right)
$$

Although the specialising history probability function, $P_{U, X, \mathrm{G}, T_{o}, \mathrm{H}}$, is not derived from a conditional draw from a distribution history, it does have a physical analogy in isolated thermodynamic systems.

Let $Y \subset \mathcal{X}$ be a set of unweighted micro-states. Consider a system of $n$ distinguishable particles each in a micro-state. The states of the system is the set of micro-state functions of particle identifier, $\{1 \ldots n\}: \rightarrow Y$. Each state implies a distribution of particles over micro-states,

$$
I=\left\{\left(R,\left\{(x,|C|):(x, C) \in R^{-1}\right\}\right): R \in\{1 \ldots n\}: \rightarrow Y\right\}
$$

so the cardinality of states for each distribution is

$$
W=\left\{(N,|D|):(N, D) \in I^{-1}\right\}=\left\{\left(N, \frac{n!}{\prod_{(x,) \in N} N_{x}!}\right):(N, \cdot) \in I^{-1}\right\}
$$

Let $E$ be an energy valued function of micro-state, $E \in Y: \rightarrow \mathbf{R}_{\geq 0}$. Consider the subset of the states that have total energy $\epsilon$,

$$
\left\{R: R \in\{1 \ldots n\}: \rightarrow Y, \sum_{(\cdot, x) \in R} E_{x}=\epsilon\right\}
$$

If a state is chosen at random from this subset, the modal distribution $N_{n, E, \epsilon}$ has the greatest cardinality,

$$
\left.\left.\begin{array}{rl}
N_{n, E, \epsilon} \in \operatorname{maxd}\left(\left\{\left(N, \frac{n!}{\prod_{(x,) \in N} N_{x}!}\right): N \in Y \rightarrow\{1 \ldots n\},\right.\right. \\
& \sum_{(x,) \in N} N_{x}=n,
\end{array} \sum_{(x,) \in N} N_{x} E_{x}=\epsilon\right\}\right), ~ l
$$

The states of the modal distribution, $I^{-1}\left(N_{n, E, \epsilon}\right) \subseteq\{1 \ldots n\}: \rightarrow Y$, are said to be at thermodynamic equilibrium. The thermodynamic entropy of these states is $S_{n, E, \epsilon}=k \ln W\left(N_{n, E, \epsilon}\right)$, where $k$ is the Boltzmann constant. The logarithm of the multinomial coefficient approximates to the scaled entropy, so the modal distribution probability function $P_{n, E, \epsilon}$ is

$$
\begin{aligned}
P_{n, E, \epsilon} \in \operatorname{maxd}\left(\left\{(P, \operatorname{entropy}(P)): P \in Y: \rightarrow \mathbf{R}_{[0,1]},\right.\right. & \sum_{x \in Y} P_{x}=1, \\
& \left.\left.n \sum_{x \in Y} P_{x} E_{x}=\epsilon\right\}\right)
\end{aligned}
$$

The solution for this probability function is the Boltzmann distribution,

$$
\begin{aligned}
P_{n, E, \epsilon} & =\left\{\left(x, \frac{\exp \left(-E_{x} / k \tau_{n, E, \epsilon}\right)}{\sum_{y \in Y} \exp \left(-E_{y} / k \tau_{n, E, \epsilon}\right)}\right): x \in Y\right\} \\
& =\left\{\left(x, \exp \left(-E_{x} / k \tau_{n, E, \epsilon}\right)\right): x \in Y\right\}^{\wedge}
\end{aligned}
$$

where $\tau_{n, E, \epsilon}$ is the temperature. The inverted temperature is the sensitivity of the equilibrium entropy to energy, $1 / \tau_{n, E, \epsilon}=\partial S_{n, E, \epsilon} / \partial \epsilon$. The thermodynamic entropy at equilibrium varies with the probability distribution entropy, $S_{n, E, \epsilon} \sim n k \times$ entropy $\left(P_{n, E, \epsilon}\right)$. The Boltzmann distribution is the solution that maximises the entropy given the energy.

Conversely, let the distribution probability function $P_{n, s, E}$ be the probability function that minimises the energy given the entropy,

$$
\begin{aligned}
P_{n, s, E} \in \operatorname{mind}\left(\left\{\left(P, \sum_{x \in Y} P_{x} E_{x}\right): P \in Y: \rightarrow \mathbf{R}_{[0,1]},\right.\right. & \sum_{x \in Y} P_{x}=1, \\
& n k \times \operatorname{entropy}(P)=s\})
\end{aligned}
$$

Now the temperature is the sensitivity of the equilibrium energy to entropy, $\tau_{n, s, E}=\partial \epsilon_{n, s, E} / \partial s$. In the case where the temperature is positive, so that the energy is monotonic with respect to entropy at equilibrium, these optimisations intersect, $P_{n, s, E}=P_{n, E, \epsilon}$, where $s=\operatorname{entropy}\left(P_{n, E, \epsilon}\right)$. That is, the

Boltzmann distribution is also the solution that minimises the energy given the entropy.

Together the Boltzmann distribution is the solution that minimises the ratio of (i) the energy to (ii) the temperature times the entropy at equilibrium,

$$
\frac{\epsilon}{\tau_{n, E, \epsilon} \times S_{n, E, \epsilon}}=\frac{\epsilon_{n, s, E}}{\tau_{n, s, E} \times s}
$$

Consider the probability of a thermodynamic particle being in micro-state $x_{2}$ given it is in either micro-state $x_{1}$ or $x_{2}$,

$$
\frac{P_{n, E, \epsilon}\left(x_{2}\right)}{P_{n, E, \epsilon}\left(x_{1}\right)+P_{n, E, \epsilon}\left(x_{2}\right)}=\frac{1}{1+\exp \left(\left(E_{x_{2}}-E_{x_{1}}\right) / k \tau_{n, E, \epsilon}\right)}
$$

As the temperature increases, the probability that the particle will be in the higher energy micro-state increases to a half. So both the entropy at equilibrium, $S_{n, E, \epsilon}$, and the energy at equilibrium, $\epsilon_{n, s, E}$, vary with temperature, $\tau_{n, E, \epsilon}=\tau_{n, s, E}$.

Consider treating the micro-state energy divided by the Boltzmann constant, $E_{x} / k$, as a continuous random variable. Let $P_{n, E, \epsilon, \lambda}=\{(u, \lambda \exp (-\lambda u)): u \in$ $\left.\mathbf{R}_{\geq 0}\right\} \in \mathbf{R}_{\geq 0}: \rightarrow \mathbf{R}_{\geq 0}$ be the exponential distribution parameterised only by $\lambda$ that is the nearest fit to the Boltzmann distribution, $\forall x \in Y\left(P_{n, E, \epsilon, \lambda}\left(E_{x} / k\right) \approx\right.$ $\left.P_{n, E, \epsilon}(x)\right)$. That is,

$$
\forall x \in Y\left(\lambda \exp \left(-\lambda E_{x} / k\right) \approx \frac{\exp \left(-E_{x} / k \tau_{n, E, \epsilon}\right)}{\sum_{y \in Y} \exp \left(-E_{y} / k \tau_{n, E, \epsilon}\right)}\right)
$$

For higher temperatures, $1 / \lambda$ is between $\sum_{y \in Y} \exp \left(-E_{y} / k \tau_{n, E, \epsilon}\right)$ and $\tau_{n, E, \epsilon}$. The variance of the exponential distribution, $P_{n, E, \epsilon, \lambda}$, is $1 / \lambda^{2}$. Let the corresponding likelihood function be $L_{n, E, \epsilon}(u)=\left\{(\lambda, \lambda \exp (-\lambda u)): \lambda \in \mathbf{R}_{\geq 0}\right\} \in$ $\mathbf{R}_{\geq 0}: \rightarrow \mathbf{R}_{\geq 0}$. The exponential distribution is not centrally distributed, so the curvature of the likelihood function at the mode, $\partial^{2}\left(L_{n, E, \epsilon}(0)\right)(\lambda)$, is not negative, and the Fisher information is not a measure of the sensitivity to parameter. Instead its sensitivity to parameter may be approximated by the negative gradient of the likelihood function at the mode, $-\partial\left(L_{n, E, \epsilon}(0)\right)(\lambda)=\lambda^{2}-1$, which varies oppositely to the variance. That is, the sensitivity to parameter varies against up to the temperature squared,

$$
\begin{aligned}
-\partial\left(L_{n, E, \epsilon}(0)\right)(\lambda) & =\lambda^{2}-1 \\
& \sim 1 / \tau_{n, E, \epsilon}^{2}
\end{aligned}
$$

Given a set of variables $V=\operatorname{und}(T)$ and a size $z$, the specialising history probability function $P_{U, X, \mathrm{G}, T, \mathrm{H}, z}$ is defined

$$
P_{U, X, \mathrm{G}, T, \mathrm{H}, z}:=\left\{\left(H, \exp \left(-C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H)\right)\right): H \in \mathcal{H}_{U, V, z, X}\right\}^{\wedge}
$$

where $\mathcal{H}_{U, V, z, X}=\left\{H: H \in \mathcal{H}_{U, X}, \operatorname{vars}(H)=V,|H|=z\right\}$.
Mapping the specialising history probability function, $P_{U, X, \mathrm{G}, T, \mathrm{H}, z}$, to the Boltzmann distribution, $P_{n, E, \epsilon}$, implies that the energy of the micro-state, $E_{x}$, is proportional to the specialising space of the history, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H)$. The thermodynamic energy $\epsilon_{n, U, X, T, z}$ is proportional to the thermodynamic temperature $\tau_{n, U, X, T, z}$ times the expected specialising space,

$$
\epsilon_{n, U, X, T, z}=n k \times \tau_{n, U, X, T, z} \times \operatorname{expected}\left(P_{U, X, \mathrm{G}, T, \mathrm{H}, z}\right)\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\right)
$$

The thermodynamic entropy at equilibrium $S_{n, U, X, T, z}$ is proportional to the entropy of the specialising history probability function,

$$
S_{n, U, X, T, z} \sim n k \times \operatorname{entropy}\left(P_{U, X, \mathrm{G}, T, \mathrm{H}, z}\right)
$$

The specialising history probability function is such that the thermodynamic entropy, $S_{n, U, X, T, z}$, is maximised for given thermodynamic energy, $\epsilon_{n, U, X, T, z}$,

$$
\begin{aligned}
& P_{U, X, \mathrm{G}, T, \mathrm{H}, z} \in \\
& \quad \operatorname{maxd}\left(\left\{(P, n k \times \operatorname{entropy}(P)): P \in\left(\mathcal{H}_{U, V, z, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P},\right.\right. \\
& \left.\left.\quad n k \tau_{n, U, X, T, z} \times \operatorname{expected}(P)\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\right)=\epsilon_{n, U, X, T, z}\right\}\right)
\end{aligned}
$$

and also such that the thermodynamic energy, $\epsilon_{n, U, X, T, z}$, is minimised for given thermodynamic entropy, $S_{n, U, X, T, z}$,

$$
\begin{aligned}
& P_{U, X, \mathrm{G}, T, \mathrm{H}, z} \in \\
& \quad \operatorname{mind}\left(\left\{\left(P, n k \tau_{n, U, X, T, z} \times \operatorname{expected}(P)\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\right)\right):\right.\right. \\
& \left.\left.\quad P \in\left(\mathcal{H}_{U, V, z, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}, n k \times \operatorname{entropy}(P)=S_{n, U, X, T, z}\right\}\right)
\end{aligned}
$$

That is, specialising induction is balanced such that the total specialising space is minimised while the specialising entropy is maximised.

Physical thermodynamic systems usually define a topology or measure on the states of the system implied by the interactions between particles that conserve energy, so that dynamic processes starting in low entropy states generally evolve towards neighbouring high entropy states. Specialising induction, however, does not have parallels for these physical properties.

Note that, conversely, the mapping of the energy of the micro-state, $E_{x}$, to the specialising space of the history, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H)$, suggests that the micro-state energy, $E_{x}$, of any thermodynamical system can be viewed as the logarithm of the bounding integer of the integer encoding of the microstate in some coder $C \in \operatorname{coders}(Y)$.

While classical specialising induction, $P=P_{U, X, \mathrm{G}, T_{0}, \mathrm{H}}$, is completely defined given a system, $(U, X)$, and a model, $T_{\mathrm{o}}$, the definition of classical derived induction, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{o}}$, also requires a distribution history, $H_{\mathrm{h}} \in \mathcal{H}_{U, X}$. In derived induction, the sample history is drawn from the distribution history,

$$
H_{\mathrm{o}} \in\left\{H: H \in \mathrm{P}\left(H_{\mathrm{h}} \% V_{\mathrm{o}}\right),|H|=z_{\mathrm{o}}, \hat{A}_{H} * T_{\mathrm{o}}=\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right\}
$$

An analogy to the distribution history, $H_{\mathrm{h}}$, is implied by specialising induction. Let $R_{\mathrm{G}, \mathrm{H}}$ be a thermodynamic state, $R_{\mathrm{G}, \mathrm{H}} \in\{1 \ldots n\}: \rightarrow\left(\mathcal{H}_{U, X} \backslash\{\emptyset\}\right)$. The thermodynamic state, $R_{\mathrm{G}, \mathrm{H}}$, is at equilibrium for arbitrary draw, $\left(V_{\mathrm{o}}, z_{\mathrm{o}}\right)$, so $\left\{(H,|C| / n):(H, C) \in R_{\mathrm{G}, \mathrm{H}}^{-1}\right\}=P_{U, X, \mathrm{G}, T_{\mathrm{o}}} \backslash\{(\emptyset, 0)\}$. Now the sample history is the history of a particle in the thermodynamic state,

$$
H_{\mathrm{o}} \in\left\{H:(\cdot, H) \in R_{\mathrm{G}, \mathrm{H}}, V_{H}=V_{\mathrm{o}},|H|=z_{\mathrm{o}}\right\}
$$

The ratio of the thermodynamic energy to the thermodynamic temperature times the thermodynamic entropy at equilibrium approximates to the ratio of the expected specialising space to the specialising entropy,

$$
\frac{\epsilon_{n, U, X, T, z}}{\tau_{n, U, X, T, z} \times S_{n, U, X, T, z}} \sim \frac{\operatorname{expected}\left(P_{U, X, \mathrm{G}, T, \mathrm{H}, z}\right)\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\right)}{\operatorname{entropy}\left(P_{U, X, \mathrm{G}, T, \mathrm{H}, z}\right)}
$$

This ratio is minimised at equilibrium. As the ratio tends to one, the specialising coder tends to an entropy coder and so the degree of structure tends to one. The specialising structure over all variables and sizes varies (i) against thermodynamic energy, (ii) with thermodynamic temperature and (iii) with thermodynamic entropy,

$$
\begin{aligned}
& \text { structure }(U, X)\left(P_{U, X, \mathrm{G}, T, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}(T)\right) \\
& :=\frac{\operatorname{canonical}(U, X)\left(P_{U, X, \mathrm{G}, T, \mathrm{H}}\right)-\operatorname{expected}\left(P_{U, X, \mathrm{G}, T, \mathrm{H}}\right)\left(C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\right)}{\operatorname{canonical}(U, X)\left(P_{U, X, \mathrm{G}, T, \mathrm{H}}\right)-\operatorname{entropy}\left(P_{U, X, \mathrm{G}, T, \mathrm{H}}\right)} \\
& \sim \frac{\operatorname{canonical}(U, X)\left(P_{U, X, \mathrm{G}, T, \mathrm{H}}\right)-\epsilon_{n, U, X, T} /\left(n k \times \tau_{n, U, X, T}\right)}{\operatorname{canonical}(U, X)\left(P_{U, X, \mathrm{G}, T, \mathrm{H}}\right)-S_{n, U, X, T} /(n k)}
\end{aligned}
$$

In the case where the model is unary, $T_{\mathrm{o}}=T_{\mathrm{u}}$, the expanded specialising derived substrate history space equals the index space, $C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}\left(T_{\mathrm{u}}\right)^{\mathrm{s}}(H)=$
$C_{\mathrm{H}}^{\mathrm{s}}(H)$, so the degree of structure is zero or negative,

$$
\operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, T_{\mathrm{u}}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{u}}\right)\right) \leq 0
$$

In the case where the model is self, $T_{\mathrm{o}}=T_{\mathrm{s}}$, the expanded specialising derived substrate history space is at least the index space or the classification space, $C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}\left(T_{\mathrm{s}}\right)^{\mathrm{s}}(H) \geq \operatorname{minimum}\left(C_{\mathrm{H}}^{\mathrm{s}}(H), C_{\mathrm{G}}^{\mathrm{s}}(H)\right)$, so the degree of structure is zero or negative,

$$
\text { structure }(U, X)\left(P_{U, X, \mathrm{G}, T_{\mathrm{s}}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{s}}\right)\right) \leq 0
$$

The specialising history probability function, $P_{U, X, \mathrm{G}, T_{\circ}, \mathrm{H}}$, is the history probability function $P$ that maximises the degree of structure with respect to the expanded specialising derived history coder, $C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)$, given arbitrary draw, $\left(V_{H}, z_{H}\right)$,

$$
\begin{aligned}
& P_{U, X, \mathrm{G}, T_{o}, \mathrm{H}} \in \\
& \operatorname{maxd}\left(\left\{\left(P, \text { structure }(U, X)\left(P, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)\right):\right.\right. \\
& \quad P \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}, \\
& \quad \mid\left\{\left(\sum P_{H}: H \in \mathcal{H}_{U, X}, \operatorname{vars}(H)=V_{H},|H|=z_{H}\right):\right. \\
& \left.\quad V_{H} \subseteq \operatorname{vars}(U), z_{H} \in\{1 \ldots|X|\}\right\} \mid=1,
\end{aligned}
$$

The model, $T$, may be mapped to the continuous parameter of temperature, $\tau_{n, U, X, T}$, by choosing the micro-states such that the energy divided by the Boltzmann constant, $E_{x} / k$, approximates to the canonical space,

$$
\forall H \in \mathcal{H}_{U, V, z, X}\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H) \approx \operatorname{minimum}\left(C_{\mathrm{H}, V}^{\mathrm{s}}, C_{\mathrm{G}, V}^{\mathrm{s}}\right)(H) / \tau_{n, U, X, T, z}\right)
$$

Insofar as the approximation holds, the micro-states do not depend on the model, $T$, and so all of the dependency on model is encapsulated by the temperature, $\tau_{n, U, X, T}$. Under this mapping, the temperature is the ratio of the canonical space to the expected specialising space

$$
\tau_{n, U, X, T}=\frac{\operatorname{canonical}(U, X)\left(P_{U, X, \mathrm{G}, T, \mathrm{H}}\right)}{\operatorname{expected}\left(P_{U, X, \mathrm{G}, T, \mathrm{H}}\right)\left(C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\right)}
$$

and the thermodynamic energy $\epsilon_{n, U, X, T}$ is proportional to the canonical space,

$$
\epsilon_{n, U, X, T}=n k \times \operatorname{canonical}(U, X)\left(P_{U, X, \mathrm{G}, T, \mathrm{H}}\right)
$$

Given a modal history $H \in \operatorname{maxd}\left(P_{U, X, \mathrm{G}, T, \mathrm{H}, z}\right)$, the temperature varies with the component size cardinality relative entropy,

$$
\tau_{n, U, X, T, z} \sim \text { entropyRelative }\left(A_{H} * T, V^{\mathrm{C}} * T\right)
$$

That is, at high temperatures the modal history, $H$, is such that high size components are low cardinality components and low size components are high cardinality components.

Formally, under the mapping such that the thermodynamic energy is proportional to the canonical space,

$$
\epsilon_{n, U, X, T_{o}}=n k \times \operatorname{canonical}(U, X)\left(P_{U, X, \mathrm{G}, T_{o}, \mathrm{H}}\right)
$$

the specialising structure varies principally with thermodynamic temperature,

$$
\operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right) \sim \tau_{n, U, X, T_{\mathrm{o}}}
$$

The exponential distribution function, continuously parameterised only by $\lambda_{0}$, which is the best fit to the Boltzmann distribution is

$$
P_{n, U, X, T_{o}, \lambda_{o}}=\left\{\left(u, \lambda_{o} \exp \left(-\lambda_{o} u\right)\right): u \in \mathbf{R}_{\geq 0}\right\} \in \mathbf{R}_{\geq 0}: \rightarrow \mathbf{R}_{\geq 0}
$$

Its corresponding likelihood function at the mode is $L_{n, U, X, T_{\circ}}(0) \in \mathbf{R}_{\geq 0}: \rightarrow$ $\mathbf{R}_{>0}$. The sensitivity to parameter is defined as the negative gradient of the likelihood function at the mode, $-\partial\left(L_{n, U, X, T_{\mathrm{o}}}(0)\right)\left(\lambda_{\mathrm{o}}\right)=\lambda_{\mathrm{o}}^{2}-1$, which varies against up to the temperature squared, $-\partial\left(L_{n, U, X, T_{o}}(0)\right)\left(\lambda_{\circ}\right) \sim 1 / \tau_{n, U, X, T_{o}}^{2}$. The specialising structure varies with thermodynamic temperature,

$$
\operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, T_{o}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right) \sim \tau_{n, U, X, T_{\mathrm{o}}}
$$

so the sensitivity to parameter varies against the specialising structure,

$$
-\partial\left(L_{n, U, X, T_{\mathrm{o}}}(0)\right)\left(\lambda_{\mathrm{o}}\right) \sim-\operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)
$$

Although the specialising entropy, entropy $\left(P_{U, X, \mathrm{G}, T, \mathrm{H}}\right)$, is maximised and the expected specialising space, expected $\left(P_{U, X, \mathrm{G}, T, \mathrm{H}}\right)\left(C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}(T)^{\mathrm{s}}\right)$, is minimised but sometimes not minimal, the modal specialising space, $C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}(T)^{\mathrm{s}}(H)$, of a modal history $H \in \operatorname{maxd}\left(P_{U, X, \mathrm{G}, T, \mathrm{H}}\right)$, is always minimal.

At high thermodynamic temperatures the sensitivity of thermodynamic entropy to thermodynamic energy is low, $1 / \tau_{n, U, X, T}=\partial S_{n, U, X, T} / \partial \epsilon_{n, U, X, T} \approx 0$, and the degree of structure varies proportionately against the expected specialising space,

```
structure(U,X)(P
```

Let $H$ be a modal history, $H \in \operatorname{maxd}\left(P_{U, X, \mathrm{G}, T, \mathrm{H}}\right)$. At high thermodynamic temperatures, as the mean specialising space, $\operatorname{expected}\left(P_{U, X, \mathrm{G}, T, \mathrm{H}}\right)\left(C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}(T)^{\mathrm{s}}\right)$,
decreases to the modal specialising space, $C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}(T)^{\mathrm{s}}(H)$, the degree of structure tends to maximal, structure $(U, X)\left(P_{U, X, \mathrm{G}, T, \mathrm{H}}, C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}(T)\right) \approx 1$. Conjecture that as the mean specialising space decreases, for constant specialising entropy, the logarithm of the modal probability, or log likelihood, increases,

$$
\ln P_{U, X, \mathrm{G}, T, \mathrm{H}}(H) \sim-\operatorname{expected}\left(P_{U, X, \mathrm{G}, T, \mathrm{H}}\right)\left(C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\right)
$$

so

$$
\ln P_{U, X, \mathrm{G}, T, \mathrm{H}}(H) \sim \operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, T, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}(T)\right)
$$

Conjecture further that this correlation is always positive regardless of thermodynamic temperature. Formally, in classical specialising induction, where (i) the history probability function is the specialising history probability function, $P=P_{U, X, \mathrm{G}, T_{o}, \mathrm{H}}$, given some substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, and (ii) the sample history is modal, $H_{\mathrm{o}} \in \operatorname{maxd}\left(P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}\right)$, the log likelihood of the specialising probability distribution varies with the degree of structure,

$$
\ln \hat{Q}_{\mathrm{G}, T_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)
$$

Note that the degree of structure is a property only of the system and model, not of the sample. The sample is itself implied by the system and model because it is modal.

In the case where the model, $T_{\mathrm{o}}$, is known, 'likelihood' is an abuse of terminology because there is no distribution histogram nor other unknown parameterisation of the probability function, $\hat{Q}_{\mathrm{G}, T_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right) \in \mathcal{P}$.

In the case, however, where the model, $T_{\mathrm{o}}$, is unknown, the maximum likelihood estimate $\tilde{T}_{\mathrm{o}}$ can be defined as an optimisation of the specialising probability given the sample,

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{G}, T, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

That is, the probability function is now parameterised by the unknown model, $T_{\mathrm{o}}$, so a model is the argument to the corresponding likelihood function parameterised by the sample histogram, $A_{0}$.

In specialising induction, which is such that the history probability function is $P=P_{U, X, \mathrm{G}, T_{o}, \mathrm{H}}$, given some unknown substrate transform $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{o}}$, the maximum likelihood estimate of the model, $\tilde{T}_{\mathrm{o}}$, occurs at the minimisation of the specialising space of the sample history,

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{mind}\left(\left\{\left(T, C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

The maximum likelihood estimate for the model, $\tilde{T}_{\mathrm{o}}$, is non-trivial, $\tilde{T}_{\mathrm{o}} \notin$ $\left\{T_{\mathrm{s}}, T_{\mathrm{u}}\right\}$, if there exists a model for which the specialising derived substrate history space is less than either the index space or the classification space, $C_{\mathrm{G}, \mathrm{V}_{\mathrm{o}}, \mathrm{T}, \mathrm{H}}\left(\tilde{T}_{\mathrm{o}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)<\operatorname{minimum}\left(C_{\mathrm{H}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right), C_{\mathrm{G}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right)$. This the case if the degree of structure is greater than zero,

$$
\operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(\tilde{T}_{\mathrm{o}}\right)\right)>0
$$

and the component size cardinality relative entropy of the modal sample is greater than zero,

$$
\text { entropyRelative }\left(A_{\mathrm{o}} * \tilde{T}_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * \tilde{T}_{\mathrm{o}}\right)>0
$$

An example of a non-trivial model is where the histogram is sparse, $\operatorname{trim}\left(A_{\circ}\right)=$ $A_{\mathrm{o}}^{\mathrm{F}}$ or $A_{\mathrm{o}} * A_{\mathrm{o}}^{\mathrm{F}}=A_{\mathrm{o}}^{\mathrm{F}}$. In this case, the under-fitted effective binary transform is the solution to the optimisation,

$$
A_{\mathrm{o}} * A_{\mathrm{o}}^{\mathrm{F}}=A_{\mathrm{o}}^{\mathrm{F}} \Longrightarrow \tilde{T}_{\mathrm{o}}=\left\{A_{\mathrm{o}}^{\mathrm{FS}}, V_{\mathrm{o}}^{\mathrm{CS}} \backslash A_{\mathrm{o}}^{\mathrm{FS}}\right\}^{\mathrm{T}}
$$

The effective binary transform has a component for effective states, $A_{\mathrm{o}}^{\mathrm{FS}}$, and a remainder component for the ineffective states, $V_{\mathrm{o}}^{\mathrm{CS}} \backslash A_{\mathrm{o}}^{\mathrm{FS}}$. The derived volume is 2 .

The sensitivity to model is defined as the negative logarithm of the cardinality of the maximum likelihood estimate models,

$$
-\ln \left|\max \left(\left\{\left(T, \hat{Q}_{\mathrm{G}, T, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{o}}\right\}\right)\right|
$$

Conjecture that the cardinality of the modes varies against the negative gradient of the likelihood function of the singly parameterised exponential function fitted to the Boltzmann distribution, so the sensitivity to model varies with the negative gradient,

$$
-\ln \left|\max \left(\left\{\left(T, \hat{Q}_{\mathrm{G}, T, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{o}}\right\}\right)\right| \sim-\partial\left(L_{n, U, X, T_{\mathrm{o}}}(0)\right)\left(\lambda_{\mathrm{o}}\right)
$$

Hence, given the canonical mapping, the sensitivity to model varies against the specialising structure,

$$
\begin{aligned}
-\ln \mid \max \left(\left\{\left(T, \hat{Q}_{\mathrm{G}, T, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right. & \left.\left.: T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right) \mid \sim \\
& -\operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)
\end{aligned}
$$

As shown above, the degree of structure varies with the log likelihood of the specialising probability distribution,

$$
\operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right) \sim \ln \hat{Q}_{\mathrm{G}, T_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

and so the sensitivity to model varies against the log likelihood,
$-\ln \left|\max \left(\left\{\left(T, \hat{Q}_{\mathrm{G}, T, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)\right| \sim-\ln \hat{Q}_{\mathrm{G}, T_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$
That is, maximisation of the log likelihood also tends to minimise the sensitivity to model.

In the cases where there exists a modal transform which is either self or unary, $\tilde{T}_{\mathrm{o}} \in\left\{T_{\mathrm{s}}, T_{\mathrm{u}}\right\}$, the degree of structure is negative and the modal specialising space is high, $C_{\mathrm{G}, \mathrm{V}_{\mathrm{o}}, \mathrm{T}, \mathrm{H}}\left(\tilde{T}_{\mathrm{o}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right) \geq \operatorname{minimum}\left(C_{\mathrm{H}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right), C_{\mathrm{G}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right)$, so the log likelihood is low and the sensitivity to model is high. All transforms must have at least canonical space, $\forall T \in \mathcal{T}_{U, V_{\mathrm{o}}}\left(C_{\mathrm{G}, \mathrm{V}_{\mathrm{o}}, \mathrm{T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H_{\mathrm{o}}\right) \geq\right.$ $\left.C_{\mathrm{G}, \mathrm{V}_{\mathrm{o}}, \mathrm{T}, \mathrm{H}}\left(\tilde{T}_{\mathrm{o}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right)$.

The conclusion that the sensitivity to model varies against the log likelihood is rather counter-intuitive but has other evidence that is more direct than the analysis of parameterisation above. Consider a pair of modal transforms $T, T^{\prime} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{G}, T, \mathrm{H}, U}(z)(A)\right): T \in \mathcal{T}_{U, V}\right\}\right)$. The two transforms are equal except that a sub-component $C_{1}^{\prime} \subset C_{1}$ is transferred from component $C_{1}$ to $C_{2}$ such that (i) the derived counts are unchanged, $\left(A * T^{\prime}\right)_{R_{1}}=$ $(A * T)_{R_{2}}$, and $\left(A * T^{\prime}\right)_{R_{2}}=(A * T)_{R_{1}}$, (ii) the cartesian derived counts are unchanged, $\left(V^{\mathrm{C}} * T^{\prime}\right)_{R_{1}}=\left(V^{\mathrm{C}} * T\right)_{R_{2}}$, and $\left(V^{\mathrm{C}} * T^{\prime}\right)_{R_{2}}=\left(V^{\mathrm{C}} * T\right)_{R_{1}}$, and (iii) the other components are unchanged, $\operatorname{ran}\left(\left(T^{\prime}\right)^{-1}\right) \backslash\left\{C_{1}, C_{2}\right\}=\operatorname{ran}\left(T^{-1}\right) \backslash$ $\left\{C_{1}, C_{2}\right\}$, where $\left(R_{1}, C_{1}\right),\left(R_{2}, C_{2}\right) \in T^{-1}$ and $\left(R_{1}, C_{1} \backslash C_{1}^{\prime}\right),\left(R_{2}, C_{2} \cup C_{1}^{\prime}\right) \in$ $\left(T^{\prime}\right)^{-1}$. In this case, the specialising spaces are equal, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(T^{\prime}\right)^{\mathrm{s}}(H)=$ $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}(H)$. The cardinality of these pairs with respect to transform $T$ is the cardinality of

$$
\begin{aligned}
& \left\{\left(C_{1}, C_{2}, C_{1}^{\prime}\right):\left(R_{1}, C_{1}\right),\left(R_{2}, C_{2}\right) \in T^{-1},\right. \\
& R_{1} \neq R_{2}, C_{1}^{\prime} \subset C_{1}, 0<\left|C_{1}^{\prime}\right|<\left|C_{1}\right|, \\
& \\
& (A * T)_{R_{1}}=(A * T)_{R_{2}}+\operatorname{size}\left(A * C_{1}^{\prime}\right), \\
& \\
& \left.\left(V^{\mathrm{C}} * T\right)_{R_{1}}=\left(V^{\mathrm{C}} * T\right)_{R_{2}}+\left|C_{1}^{\prime}\right|\right\}
\end{aligned}
$$

which is the intersection,

$$
\begin{aligned}
& \left\{\left(C_{1}, C_{2}, C_{1}^{\prime}\right):\left(R_{1}, C_{1}\right),\left(R_{2}, C_{2}\right) \in T^{-1},\right. \\
& R_{1} \neq R_{2}, C_{1}^{\prime} \subset C_{1}, 0<\left|C_{1}^{\prime}\right|<\left|C_{1}\right|, \\
& \left.(A * T)_{R_{1}}=(A * T)_{R_{2}}+\operatorname{size}\left(A * C_{1}^{\prime}\right)\right\} \\
& \cap\left\{\left(C_{1}, C_{2}, C_{1}^{\prime}\right):\left(R_{1}, C_{1}\right),\left(R_{2}, C_{2}\right) \in T^{-1},\right. \\
& R_{1} \neq R_{2}, C_{1}^{\prime} \subset C_{1}, 0<\left|C_{1}^{\prime}\right|<\left|C_{1}\right|, \\
& \left.\quad\left(V^{\mathrm{C}} * T\right)_{R_{1}}=\left(V^{\mathrm{C}} * T\right)_{R_{2}}+\left|C_{1}^{\prime}\right|\right\}
\end{aligned}
$$

The logarithm of the cardinality of the derived term of the intersection varies against the derived entropy,

$$
\ln \left|\left\{(A * T)_{R_{1}}-(A * T)_{R_{2}}:\left(R_{1}, \cdot\right),\left(R_{2}, \cdot\right) \in T^{-1}\right\}\right| \sim-\operatorname{entropy}(A * T)
$$

and the logarithm of the cardinality of the cartesian derived term of the intersection varies against the cartesian derived entropy,
$\left.\ln \mid\left\{V^{\mathrm{C}} * T\right)_{R_{1}}-\left(V^{\mathrm{C}} * T\right)_{R_{2}}:\left(R_{1}, \cdot\right),\left(R_{2}, \cdot\right) \in T^{-1}\right\} \mid \sim-\operatorname{entropy}\left(V^{\mathrm{C}} * T\right)$
Given the derived entropy and cartesian derived entropy, the cardinality of the intersection decreases as the correlation between the sub-component size, $\operatorname{size}\left(A * C_{1}^{\prime}\right)$, and the sub-component cardinality, $\left|C_{1}^{\prime}\right|$, increases. That is, the intersection is more constrained when the sub-component size and cardinality are synchronised, so the logarithm of the cardinality of the intersection varies with the cross entropy, entropy $\left(A * T+V^{\mathrm{C}} * T\right)$. Overall, the logarithm of the cardinality of these pairs varies with the size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
& \ln \mid\left\{\left(C_{1}, C_{2}, C_{1}^{\prime}\right):\left(R_{1}, C_{1}\right),\left(R_{2}, C_{2}\right) \in T^{-1},\right. \\
& R_{1} \neq R_{2}, C_{1}^{\prime} \subset C_{1}, 0<\left|C_{1}^{\prime}\right|<\left|C_{1}\right|, \\
& \quad(A * T)_{R_{1}}=(A * T)_{R_{2}}+\operatorname{size}\left(A * C_{1}^{\prime}\right), \\
& \left.\quad\left(V^{\mathrm{C}} * T\right)_{R_{1}}=\left(V^{\mathrm{C}} * T\right)_{R_{2}}+\left|C_{1}^{\prime}\right|\right\} \mid \\
& \sim \quad(z+v) \times \operatorname{entropy}\left(A * T+V^{\mathrm{C}} * T\right) \\
& -z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)
\end{aligned}
$$

Hence the sensitivity to model varies against the size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
& -\ln \left|\max \left(\left\{\left(T, \hat{Q}_{\mathrm{G}, T, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)\right| \sim \\
& \quad-\left(\left(z_{\mathrm{o}}+v_{\mathrm{o}}\right) \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{\mathrm{o}}+V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)\right. \\
& \\
& \left.\quad-z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)-v_{\mathrm{o}} \times \operatorname{entropy}\left(V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)\right)
\end{aligned}
$$

The size scaled component size cardinality relative entropy approximates to the size-volume scaled component size cardinality sum relative entropy, especially where the size is less than the volume, $z_{\mathrm{o}}<v_{\mathrm{o}}$,

$$
\begin{aligned}
& z_{\mathrm{o}} \times \text { entropyRelative }\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right) \approx \\
& \left(z_{\mathrm{o}}+v_{\mathrm{o}}\right) \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{\mathrm{o}}+V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right) \\
& \\
& \quad-z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)-v_{\mathrm{o}} \times \operatorname{entropy}\left(V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)
\end{aligned}
$$

but the log-likelihood varies with the size scaled component size cardinality relative entropy,

$$
\ln \hat{Q}_{\mathrm{G}, T_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \text { entropyRelative }\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)
$$

so, again, the sensitivity to model varies against the log likelihood,
$-\ln \left|\max \left(\left\{\left(T, \hat{Q}_{\mathrm{G}, T, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)\right| \sim-\ln \hat{Q}_{\mathrm{G}, T_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$
It is shown above in classical uniform possible modelled induction, where the history probability function is uniform possible iso-derived historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, T_{o}}$, that, in the case where the size is less than the volume, $z_{\mathrm{o}}<v_{\mathrm{o}}$, but the sample approximates to the naturalisation, $A_{\mathrm{o}} \approx$ $A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, the log likelihood of the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate (a) varies against the possible derived volume, $w_{\mathrm{o}}^{\prime}$, where the possible derived volume is less than the size, $w_{\mathrm{o}}^{\prime}<z_{0}$, otherwise against the size scaled log possible derived volume, $z_{0} \ln w_{\mathrm{o}}^{\prime}$,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\left(\left(w_{\mathrm{o}}^{\prime}: w_{\mathrm{o}}^{\prime}<z_{\mathrm{o}}\right)+\left(z_{\mathrm{o}} \ln w_{\mathrm{o}}^{\prime}: w^{\prime} \geq z_{\mathrm{o}}\right)\right)
$$

(b) varies with the size scaled component size cardinality relative entropy,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \text { entropyRelative }\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)
$$

so (c) varies against the specialising derived substrate history coder space,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\operatorname{space}\left(C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)\left(H_{\mathrm{o}}\right)
$$

In classical specialising induction, where the history probability function is the specialising history probability function, $P=P_{U, X, \mathrm{G}, T_{o}, \mathrm{H}}$, the specialising history probability function is specifically defined such that the log likelihood of the specialising probability distribution is proportional to the classification space of the underlying histogram less the specialising space of the corresponding history,
$\ln \hat{Q}_{\mathrm{G}, T_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \propto \operatorname{spaceClassification}\left(A_{\mathrm{o}}\right)-\operatorname{space}\left(C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)\left(H_{\mathrm{o}}\right)$
All iso-derived subsets of the distribution history for a given set of variables and size are defined as equally iso-derived conditional probable, and, because the specialising space is the same for all members of an iso-derived, all isoderived subsets of the distribution history for a given set of variables and size are also equally specialising probable,

$$
\begin{aligned}
& \forall V \subseteq V_{\mathrm{h}} \forall H, G \subseteq H_{\mathrm{h}} \% V \\
& \quad\left(A_{G} * T_{\mathrm{o}}=A_{H} * T_{\mathrm{o}} \Longrightarrow P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}(G)=P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}(H)\right)
\end{aligned}
$$

Therefore, in the near-natural case, insofar as the uniform possible iso-derived history probability function approximates to the specialising history probability function, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, T_{\mathrm{o}}} \approx P_{U, X, \mathrm{G}, T_{o}, \mathrm{H}}$, conjecture that (a) the log likelihood of the iso-derived conditional stuffed historical probability distribution varies with the log likelihood of the specialising probability distribution,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \ln \hat{Q}_{\mathrm{G}, T_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

and (b) the degree of structure of the uniform possible iso-derived history probability function with respect to the specialising coder varies with specialising degree of structure,

$$
\begin{aligned}
& \operatorname{structure}(U, X)( P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, T_{\mathrm{o}}}, \\
&\left.C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right) \sim \\
& \quad \operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)
\end{aligned}
$$

So conjecture that, in the case where the sample history is modal, $H_{o} \in$ $\operatorname{maxd}\left(P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, T_{\mathrm{o}}}\right)$, the log-likelihood of the iso-derived conditional stuffed historical probability distribution also varies with its degree of structure,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{structure}(U, X)\left(P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, T_{\mathrm{o}}}, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)
$$

In other words, when the iso-derived log-likelihood is high, the expected space of the specialising coder is low and so the compression of the coder with respect to the iso-derived historically distributed history probability function is high.

Further, conjecture that the sensitivity to model also varies against the log likelihood,
$-\ln \left|\max \left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{d}, T, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}} \approx A_{\mathrm{o}} * T * T^{\dagger}\right\}\right)\right| \sim$

$$
-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

In the case where the relative entropy is high, entropy $\operatorname{Cross}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)>$ $\ln \left|T_{\mathrm{o}}^{-1}\right|$, the sum sensitivity varies against the log likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

So in this case, in classical uniform possible modelled induction, both (a) the sensitivity to distribution histogram,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)
$$

and (b) the sensitivity to model,
$-\ln \left|\max \left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{d}, T, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}} \approx A_{\mathrm{o}} * T * T^{\dagger}\right\}\right)\right|$
vary against the log-likelihood. That is, in classical modelled induction in some circumstances, the optimisation of the log-likelihood tends to minimise the sensitivity to parameter.

### 5.5.9 Specialising functional definition set induction

Again, consider extending the model for specialising induction from transforms to functional definition sets.

Consider the specialising functional definition set history probability function $P_{U, X, \mathrm{G}, F_{o}, \mathrm{H}} \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}$ which is defined such that the probability of a history is inversely proportional to the bounding integer, for which the space is the logarithm, of the integer encoding of the history in the specialising fud coder, given a non-empty known substrate fud in the sample variables $F_{\mathrm{o}} \in \mathcal{F}_{U, V_{\mathrm{o}}} \backslash\{\emptyset\}$,

$$
\begin{aligned}
& P_{U, X, \mathrm{G}, F_{o}, \mathrm{H}}:= \\
& \quad \begin{array}{l}
\left(\bigcup \left\{\left\{\left(H, \exp \left(-C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}\right)^{\mathrm{s}}(H)\right)\right):\right.\right.\right. \\
\\
\left.\qquad H \in \mathcal{H}_{U, X}, \operatorname{vars}(H)=V_{H},|H|=z_{H}\right\}^{\wedge}: \\
\left.\left.\quad V_{H} \subseteq \operatorname{vars}(U), z_{H} \in\{1 \ldots|X|\}\right\}\right)^{\wedge} \cup
\end{array}
\end{aligned}
$$

where the specialising fud substrate history coder is

$$
C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)=\text { coderHistorySubstrateFudSpecialising }\left(U, X, F, D_{\mathrm{S}}, D_{\mathrm{X}}\right)
$$

and the expanded specialising fud history coder $C_{\mathrm{G}, \mathrm{F}, \mathrm{H}}(F) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$ is derived from the specialising fud substrate history coder, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}$,

$$
\begin{aligned}
C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)= & \left(C_{\mathrm{G}, V_{H}, \mathrm{~F}, \mathrm{H}}\left(F^{V_{H}}\right)^{\mathrm{s}}(H)+s_{\left|V_{H}\right|}: V_{H} \supseteq V\right)+ \\
& \left(C_{\mathrm{H}}^{\mathrm{s}}(H): V_{H} \nsupseteq V\right)
\end{aligned}
$$

where $F^{V}$ is the expansion that adds a unary transform in the remaining underlying variables, $F \cup\left\{\left\{(V \backslash \operatorname{und}(F))^{\mathrm{CS}}\right\}^{\mathrm{T}}\right\}$, and $s_{n}=\operatorname{spaceVariables}(U)(n)$.

All non-empty histories are possible in specialising fud induction, $\forall H \in$ $\mathcal{H}_{U, X} \backslash\{\emptyset\}\left(P_{U, X, \mathrm{G}, F_{o}, \mathrm{H}}(H)>0\right)$.

All histories having the same specialising space for a given set of variables and size are defined as equally probable,

$$
\begin{aligned}
& \forall H, G \in \mathcal{H}_{U, V, z, X} \\
& \qquad\left(C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}\right)^{\mathrm{s}}(G)=C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}\right)^{\mathrm{s}}(H) \Longrightarrow P_{U, X, \mathrm{G}, F_{\mathrm{o}}, \mathrm{H}}(G)=P_{U, X, \mathrm{G}, F_{\mathrm{o}}, \mathrm{H}}(H)\right)
\end{aligned}
$$

In specialising fud induction there is no distribution histogram, so the drawn history is parameterised only by substrate variables and size, $\left(V_{H}, z_{H}\right)$. Nor
is any sample constrained to equal its fud-independent, $A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}\left(F_{\mathrm{o}}\right)}$. If a history is possible in uniform possible fud induction, then it is possible in specialising fud induction,

$$
\forall H \in \mathcal{H}_{U, X}\left(P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, F_{o}}(H)>0 \Longrightarrow P_{U, X, \mathrm{G}, F_{o}, \mathrm{H}}(H)>0\right)
$$

The specialising space is the same for all members of an iso-fud, $\forall B \in$ $D_{U, \mathrm{i}, F, z}^{-1}\left(D_{U, F, z}(A)\right)\left(C_{\mathrm{G}, \mathrm{F}, \mathrm{H}}(F)^{\mathrm{s}}\left(H_{B}\right)=C_{\mathrm{G}, \mathrm{F}, \mathrm{H}}(F)^{\mathrm{s}}\left(H_{A}\right)\right)$, so all iso-fud subsets of the distribution history for a given set of variables and size are not only equally iso-fud probable,
$\forall V \subseteq V_{\mathrm{h}} \forall H, G \subseteq H_{\mathrm{h}} \% V$
$\left(\forall T \in F_{\mathrm{o}}\left(A_{G} * T_{F_{\mathrm{o}}}=A_{H} * T_{F_{\mathrm{o}}}\right) \Longrightarrow P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, F_{\mathrm{o}}}(G)=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, F_{\mathrm{o}}}(H)\right)$
but also equally specialising probable,

$$
\begin{aligned}
& \forall V \subseteq V_{\mathrm{h}} \forall H, G \subseteq H_{\mathrm{h}} \% V \\
& \quad\left(\forall T \in F_{\mathrm{o}}\left(A_{G} * T_{F_{\mathrm{o}}}=A_{H} * T_{F_{\mathrm{o}}}\right) \Longrightarrow P_{U, X, \mathrm{G}, F_{\mathrm{o}}, \mathrm{H}}(G)=P_{U, X, \mathrm{G}, F_{\mathrm{o}}, \mathrm{H}}(H)\right)
\end{aligned}
$$

where $T_{F}:=\operatorname{depends}(F, \operatorname{der}(T))^{\mathrm{T}}$.
Given a history $H \in \mathcal{H}_{U, X}$, such that $H \neq \emptyset$, the specialised historical probability of histogram $A_{H}=\operatorname{histogram}(H)+V_{H}^{\mathrm{CZ}} \in \mathcal{A}_{U, \mathrm{i}, V_{H}, z_{H}}$ is

$$
\hat{Q}_{\mathrm{G}, F_{o}, \mathrm{H}, U}\left(z_{H}\right)\left(A_{H}\right) \propto \sum\left(P_{U, X, \mathrm{G}, F_{o}, \mathrm{H}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}\right)
$$

where the specialising fud probability distribution is defined

$$
\begin{aligned}
& \hat{Q}_{\mathrm{G}, F, \mathrm{H}, U}(z):= \\
& \qquad\left\{\left(A, \frac{z!}{\prod_{S \in A^{\mathrm{FS}}} A_{S}!} \times \exp \left(-C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}\left(H_{A}\right)\right)\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}^{\wedge}
\end{aligned}
$$

where $V=\operatorname{und}(F)$ and $H_{A}=\operatorname{history}(A)$.
The log likelihood is proportional to the classification space of the underlying histogram less the specialising space of the corresponding history,

$$
\ln \hat{Q}_{\mathrm{G}, F, \mathrm{H}, U}(z)(A) \propto \operatorname{spaceClassification}(A)-\operatorname{space}\left(C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)\right)\left(H_{A}\right)
$$

In the law-like case where the fud has a top transform, $\exists T \in F\left(W_{T}=\right.$ $\operatorname{der}(F))$, the space of the specialising coder is

$$
\begin{aligned}
& \operatorname{space}\left(C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)\right)(H)= \\
& \text { spaceIds }(|X|,|H|)+ \\
& \operatorname{spaceCountsDerived}(U)\left(A, F^{\mathrm{T}}\right)+ \\
& \text { spaceClassification }\left(A * F^{\mathrm{T}}\right)+ \\
& \sum_{T \in F} \operatorname{spaceEventsPartition}\left(A * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}, T\right)
\end{aligned}
$$

where $V_{T}=\operatorname{und}(T), W_{T}=\operatorname{der}(T)$, and dep $=$ depends.
The space of the specialising fud substrate history coder, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)$, varies (i) with the possible fud derived volume, $w^{\prime}=\left|\left(F^{\mathrm{T}}\right)^{-1}\right|$, or the size scaled log possible fud derived volume, $z \ln w^{\prime}$, (ii) with the size scaled fud transform derived entropy and (iii) against the sum of the size scaled component size cardinality cross entropies of the transforms of the fud,

$$
\begin{aligned}
C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}} & (H) \sim \\
& \left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right) \\
+ & z \times \operatorname{entropy}\left(A * F^{\mathrm{T}}\right) \\
- & z \times \sum_{T \in F} \operatorname{entropyCross}\left(A * T_{F}, V_{T}^{\mathrm{C}} * T\right)
\end{aligned}
$$

The specialising-canonical space difference, $2 C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)-$ $C_{\mathrm{G}, V}^{\mathrm{s}}(H)$, varies (i) with twice the total possible derived volume or twice the total size scaled log possible derived volume, (ii) with the sum of the size scaled derived entropies, (iii) against twice the sum of the size scaled component size cardinality cross entropies and (iv) against the sum of the size scaled size expected component entropies,

$$
\begin{aligned}
& 2 C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)-C_{\mathrm{H}, V}^{\mathrm{s}}(H)-C_{\mathrm{G}, V}^{\mathrm{s}}(H) \sim \\
& \sum_{T \in F} 2\left(\left(w_{T}^{\prime}: w_{T}^{\prime}<z\right)+\left(z \ln w_{T}^{\prime}: w_{T}^{\prime} \geq z\right)\right) \\
&+ \sum_{T \in F} z \times \operatorname{entropy}\left(A * T_{F}\right) \\
&- \sum_{T \in F} 2 z \times \operatorname{entropyCross}\left(A * T_{F}, V_{T}^{\mathrm{C}} * T\right) \\
&- \sum_{T \in F} z \times \operatorname{entropyComponent}\left(A * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}, T\right)
\end{aligned}
$$

where $w_{T}^{\prime}=\left|T^{-1}\right|$, and $T_{F}=\operatorname{depends}\left(F, W_{T}\right)^{\mathrm{T}}$.
The specialising log likelihood varies (a) with the size scaled underlying en-
tropy and (b) against the specialising-canonical space difference,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{G}, F, \mathrm{H}, U}(z)(A) \sim \\
&-\sum_{T \in F} 2\left(\left(w_{T}^{\prime}: w_{T}^{\prime}<z\right)+\left(z \ln w_{T}^{\prime}: w_{T}^{\prime} \geq z\right)\right) \\
&+z \times \operatorname{entropy}(A) \\
&-\sum_{T \in F} z \times \operatorname{entropy}\left(A * T_{F}\right) \\
&+\sum_{T \in F} 2 z \times \operatorname{entropyCross}\left(A * T_{F}, V_{T}^{\mathrm{C}} * T\right) \\
&+\sum_{T \in F} z \times \operatorname{entropyComponent}\left(A * \operatorname{dep}\left(F, V_{T}\right)^{\mathrm{T}}, T\right)
\end{aligned}
$$

Let $H_{\mathrm{o}}$ be a sample history of known size $z_{\mathrm{o}}=\left|H_{\mathrm{o}}\right|>0$ in the known sample variables, $V_{\mathrm{o}}$, which has a known histogram $A_{\mathrm{o}}=\operatorname{histogram}\left(H_{\mathrm{o}}\right)+V_{\mathrm{o}}^{\mathrm{CZ}} \in$ $\mathcal{A}_{U, \mathrm{i}, V_{o}, z_{0}}$. In classical specialising fud induction, where the history probability function is the specialising fud history probability function, $P=P_{U, X, \mathrm{G}, F_{0}, \mathrm{H}}$, given some substrate fud in the sample variables $F_{\mathrm{o}} \in \mathcal{F}_{U, V_{0}}$, the log likelihood of the specialising fud probability distribution (a) varies with the size scaled underlying entropy,

$$
\ln \hat{Q}_{\mathrm{G}, F_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \text { entropy }\left(A_{\mathrm{o}}\right)
$$

(b) varies against the total possible derived volume or size scaled log possible derived volume,
$\ln \hat{Q}_{\mathrm{G}, F_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\sum_{T \in F_{\mathrm{o}}}\left(\left(w_{T}^{\prime}: w_{T}^{\prime}<z_{\mathrm{o}}\right)+\left(z_{\mathrm{o}} \ln w_{T}^{\prime}: w_{T}^{\prime} \geq z_{\mathrm{o}}\right)\right)$
(c) varies against the total size scaled derived entropy

$$
\ln \hat{Q}_{\mathrm{G}, F_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-z_{\mathrm{o}} \times \sum_{T \in F_{\mathrm{o}}} \text { entropy }\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}\right)
$$

(d) varies with the total size scaled component size cardinality cross entropy

$$
\ln \hat{Q}_{\mathrm{G}, F_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \sum_{T \in F_{\mathrm{o}}} \text { entropyCross }\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}, V_{T}^{\mathrm{C}} * T\right)
$$

and (e) varies with the total size scaled size expected component entropy,
$\ln \hat{Q}_{\mathrm{G}, F_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \sum_{T \in F_{\mathrm{o}}}$ entropyComponent $\left(A_{\mathrm{o}} * \operatorname{dep}\left(F_{\mathrm{o}}, V_{T}\right)^{\mathrm{T}}, T\right)$

So the specialising log likelihood is maximised when (a) the total possible derived volume is minimised, (b) the underlying entropy is maximised, (c) the total derived entropy is minimised, (d) high size components are low cardinality components and low size components are high cardinality components for each transform, and (e) the total expected component entropy is maximised. It is also conjectured that, (i) the derived entropy decreases up the layers, (ii) the possible derived volume decreases up the layers, (iii) the expected component entropy increases up the layers, and (iv) the component size cardinality cross entropy increases up the layers.

The ratio of the expected specialising space to the specialising entropy,

$$
\frac{\operatorname{expected}\left(P_{U, X, \mathrm{G}, F, \mathrm{H}, z}\right)\left(C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}\right)}{\operatorname{entropy}\left(P_{U, X, \mathrm{G}, F, \mathrm{H}, z}\right)}
$$

is minimised at equilibrium. As the ratio tends to one, the specialising coder tends to an entropy coder and so the degree of structure tends to one,

$$
\begin{aligned}
& \text { structure }(U, X)\left(P_{U, X, \mathrm{G}, F, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}(F)\right) \\
& :=\frac{\operatorname{canonical}(U, X)\left(P_{U, X, \mathrm{G}, F, \mathrm{H}}\right)-\operatorname{expected}\left(P_{U, X, \mathrm{G}, F, \mathrm{H}}\right)\left(C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}\right)}{\operatorname{canonical}(U, X)\left(P_{U, X, \mathrm{G}, F, \mathrm{H}}\right)-\operatorname{entropy}\left(P_{U, X, \mathrm{G}, F, \mathrm{H}}\right)}
\end{aligned}
$$

The specialising fud history probability function, $P_{U, X, \mathrm{G}, F_{0}, \mathrm{H}}$, is the history probability function $P$ that maximises the degree of structure with respect to the expanded specialising fud history coder, $C_{\mathrm{G}, \mathrm{F}, \mathrm{H}}\left(F_{\mathrm{o}}\right)$, given arbitrary draw, $\left(V_{H}, z_{H}\right)$,

$$
\begin{aligned}
& P_{U, X, \mathrm{G}, F_{o}, \mathrm{H}} \in \\
& \operatorname{maxd}\left(\left\{\left(P, \text { structure }(U, X)\left(P, C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}\right)\right)\right):\right.\right. \\
& \quad P \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}, \\
& \quad \mid\left\{\left(\sum P_{H}: H \in \mathcal{H}_{U, X}, \operatorname{vars}(H)=V_{H},|H|=z_{H}\right):\right. \\
& \left.\quad V_{H} \subseteq \operatorname{vars}(U), z_{H} \in\{1 \ldots|X|\}\right\} \mid=1,
\end{aligned}
$$

Although the specialising entropy, entropy $\left(P_{U, X, \mathrm{G}, F, \mathrm{H}}\right)$, is maximised and the expected specialising space, expected $\left(P_{U, X, \mathrm{G}, F, \mathrm{H}}\right)\left(C_{\mathrm{G}, \mathrm{F}, \mathrm{H}}(F)^{\mathrm{s}}\right)$, is minimised but sometimes not minimal, the modal specialising space, $C_{\mathrm{G}, \mathrm{F}, \mathrm{H}}(F)^{\mathrm{s}}(H)$, of a modal history $H \in \operatorname{maxd}\left(P_{U, X, \mathrm{G}, F, \mathrm{H}}\right)$, is always minimal. The degree of structure varies proportionately against the expected specialising space,

$$
\operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, F, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}(F)\right) \sim-\operatorname{expected}\left(P_{U, X, \mathrm{G}, F, \mathrm{H}}\right)\left(C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}\right)
$$

Conjecture that as the mean specialising space decreases, the log likelihood increases. So, in classical specialising fud induction, where (i) the history probability function is the specialising fud history probability function, $P=$ $P_{U, X, \mathrm{G}, F_{0}, \mathrm{H}}$, given some substrate fud in the sample variables $F_{\mathrm{o}} \in \mathcal{F}_{U, V_{o}}$, and (ii) the sample history is modal, $H_{\mathrm{o}} \in \operatorname{maxd}\left(P_{U, X, \mathrm{G}, F_{\mathrm{F}}, \mathrm{H}}\right)$, the log likelihood of the specialising fud probability distribution varies with the degree of structure,

$$
\ln \hat{Q}_{\mathrm{G}, F_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, F_{o}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}\right)\right)
$$

In the case where the model, $F_{\mathrm{o}}$, is known, 'likelihood' is an abuse of terminology because there is no distribution histogram nor other unknown parameterisation of the probability function, $\hat{Q}_{\mathrm{G}, F_{0}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right) \in \mathcal{P}$.

In the case, however, where the model, $F_{\mathrm{o}}$, is unknown, the maximum likelihood estimate $\tilde{F}_{\mathrm{o}}$ can be defined as an optimisation of the specialising probability given the sample,

$$
\tilde{F}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(F, \hat{Q}_{\mathrm{G}, F, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): F \in \mathcal{F}_{U, V_{\mathrm{o}}}\right\}\right)
$$

That is, the probability function is now parameterised by the unknown model, $F_{\mathrm{o}}$, so a model is the argument to the corresponding likelihood function parameterised by the sample histogram, $A_{0}$.

In specialising fud induction, which is such that the history probability function is $P=P_{U, X, \mathrm{G}, F_{0}, \mathrm{H}}$, given some unknown substrate fud $F_{\mathrm{o}} \in \mathcal{F}_{U, V_{\mathrm{o}}}$, the maximum likelihood estimate of the model, $\tilde{F}_{\mathrm{o}}$, occurs at the minimisation of the specialising space of the sample history,

$$
\tilde{F}_{\mathrm{o}} \in \operatorname{mind}\left(\left\{\left(F, C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~F}, \mathrm{H}}\left(F^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right): F \in \mathcal{F}_{U, V_{\mathrm{o}}}\right\}\right)
$$

The maximum likelihood estimate for the model, $\tilde{F}_{\mathrm{o}}$, is non-trivial, $\tilde{F}_{\mathrm{o}} \notin$ $\left\{\left\{T_{\mathrm{s}}\right\},\left\{T_{\mathrm{u}}\right\}\right\}$, if there exists a model for which the specialising fud substrate history space is less than either the index space or the classification space, $C_{\mathrm{G}, \mathrm{V}_{\mathrm{o}}, \mathrm{F}, \mathrm{H}}\left(\tilde{F}_{\mathrm{o}}^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)<\operatorname{minimum}\left(C_{\mathrm{H}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right), C_{\mathrm{G}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right)$. This the case if the degree of structure is greater than zero,

$$
\operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, F_{o}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}\left(\tilde{F}_{\mathrm{o}}\right)\right)>0
$$

In the case where the histogram is sparse, $\operatorname{trim}\left(A_{\mathrm{o}}\right)=A_{\mathrm{o}}^{\mathrm{F}}$ or $A_{\mathrm{o}} * A_{\mathrm{o}}^{\mathrm{F}}=$ $A_{\mathrm{o}}^{\mathrm{F}}$, the maximum likelihood estimate for the model in specialising transform induction is the under-fitted effective binary transform,

$$
A_{\mathrm{o}} * A_{\mathrm{o}}^{\mathrm{F}}=A_{\mathrm{o}}^{\mathrm{F}} \Longrightarrow \tilde{T}_{\mathrm{o}}=\left\{A_{\mathrm{o}}^{\mathrm{FS}}, V_{\mathrm{o}}^{\mathrm{CS}} \backslash A_{\mathrm{o}}^{\mathrm{FS}}\right\}^{\mathrm{T}}
$$

In specialising fud induction, however, under-fitted or over-fitted models may sometimes be avoided if there exist reductions that are not sparse, $\exists K \subset$ $V_{\mathrm{o}}\left(\operatorname{trim}\left(A_{0} \% K\right) \neq\left(A_{0} \% K\right)^{\mathrm{F}}\right)$. In these cases the fud contains a transform $T \in \tilde{F}_{\mathrm{o}}$ on a subset of the substrate, $\operatorname{und}(T)=K$, such that $T \neq$ $\left\{\left(A_{0} \% K\right)^{\mathrm{FS}}, K^{\mathrm{CS}} \backslash\left(A_{0} \% K\right)^{\mathrm{FS}}\right\}^{\mathrm{T}}$ and $T \neq\left(\left(A_{0} \% K\right)^{\mathrm{FS}\{ \}} \cup\left\{K^{\mathrm{CS}} \backslash\left(A_{\mathrm{o}} \% K\right)^{\mathrm{FS}}\right\}\right)^{\mathrm{T}}$.

The sensitivity to model is defined as the negative logarithm of the cardinality of the maximum likelihood estimate models,

$$
-\ln \left|\max \left(\left\{\left(F, \hat{Q}_{\mathrm{G}, F, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): F \in \mathcal{F}_{U, V_{\mathrm{o}}}\right\}\right)\right|
$$

Conjecture that the cardinality of the modes varies against the negative gradient of the likelihood function of the singly parameterised exponential function fitted to the Boltzmann distribution, so the sensitivity to model varies with the negative gradient. Hence the sensitivity to model varies against the specialising structure,

$$
\begin{aligned}
-\ln \mid \max \left(\left\{\left(F, \hat{Q}_{\mathrm{G}, F, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right. & \left.\left.: F \in \mathcal{F}_{U, V_{\mathrm{o}}}\right\}\right) \mid \sim \\
& -\operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, F_{\mathrm{o}}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}\right)\right)
\end{aligned}
$$

As shown above, the the degree of structure varies with the log likelihood of the specialising fud probability distribution,

$$
\operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, F_{\mathrm{o}}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}\right)\right) \sim \ln \hat{Q}_{\mathrm{G}, F_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

so the sensitivity to model varies against the log likelihood,
$-\ln \left|\max \left(\left\{\left(F, \hat{Q}_{\mathrm{G}, F, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): F \in \mathcal{F}_{U, V_{\mathrm{o}}}\right\}\right)\right| \quad \sim-\ln \hat{Q}_{\mathrm{G}, F_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$
That is, maximisation of the log likelihood also tends to minimise the sensitivity to model.

It is shown above in classical uniform possible fud induction, where the history probability function is uniform possible iso-fud historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, F_{\mathrm{o}}}$, that, in the case where the size is less than the volume, $z_{\mathrm{o}}<v_{\mathrm{o}}$, but the sample approximates to the fud-independent, $A_{\mathrm{o}} \approx A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}\left(F_{\mathrm{o}}\right)}$, the log likelihood of the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate (a) varies against the sum of the possible derived volumes or size scaled log possible derived volumes,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \\
& \quad-\sum_{T \in F_{\mathrm{o}}}\left(\left(w_{T_{F_{\mathrm{o}}}^{\prime}}^{\prime}: w_{T_{F_{\mathrm{o}}}}^{\prime}<z_{\mathrm{o}}\right)+\left(z_{\mathrm{o}} \ln w_{T_{F_{\mathrm{o}}}}^{\prime}: w_{T_{F_{\mathrm{o}}}}^{\prime} \geq z_{\mathrm{o}}\right)\right)
\end{aligned}
$$

(b) varies with the size scaled component size cardinality relative entropies,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \sum_{T \in F_{\mathrm{o}}} \text { entropyRelative }\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{F_{\mathrm{o}}}\right)
$$

so (c) varies against the specialising fud substrate history coder space,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)
$$

and (d) varies against the specialising-canonical space difference,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) & \sim \\
& -\left(2 C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)-C_{\mathrm{H}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)-C_{\mathrm{G}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right)
\end{aligned}
$$

In classical specialising fud induction, where the history probability function is the specialising fud history probability function, $P=P_{U, X, \mathrm{G}, F_{0}, \mathrm{H}}$, the specialising fud history probability function is specifically defined such that the log likelihood of the specialising fud probability distribution is proportional to the classification space of the underlying histogram less the specialising space of the corresponding history,
$\ln \hat{Q}_{\mathrm{G}, F_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \propto \operatorname{spaceClassification}\left(A_{\mathrm{o}}\right)-\operatorname{space}\left(C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{F}, \mathrm{H}}\left(F_{\mathrm{o}}\right)\right)\left(H_{\mathrm{o}}\right)$
All iso-fud subsets of the distribution history for a given set of variables and size are defined as equally iso-fud conditional probable, and, because the specialising space is the same for all members of an iso-fud, all iso-fud subsets of the distribution history for a given set of variables and size are also equally specialising probable,

$$
\begin{aligned}
& \forall V \subseteq V_{\mathrm{h}} \forall H, G \subseteq H_{\mathrm{h}} \% V \\
& \quad\left(\forall T \in F_{\mathrm{o}}\left(A_{G} * T_{F_{\mathrm{o}}}=A_{H} * T_{F_{\mathrm{o}}}\right) \Longrightarrow P_{U, X, \mathrm{G}, F_{\mathrm{o}}, \mathrm{H}}(G)=P_{U, X, \mathrm{G}, F_{\mathrm{o}}, \mathrm{H}}(H)\right)
\end{aligned}
$$

Therefore, in the near-fud-independent case, insofar as the uniform possible iso-fud history probability function approximates to the specialising fud history probability function, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, F_{\mathrm{o}}} \approx P_{U, X, \mathrm{G}, F_{o}, \mathrm{H}}$, conjecture that (a) the log likelihood of the iso-fud conditional stuffed historical probability distribution varies with the log likelihood of the specialising fud probability distribution,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{o}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \ln \hat{Q}_{\mathrm{G}, F_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

and (b) the degree of structure of the uniform possible iso-fud history probability function with respect to the specialising coder varies with specialising degree of structure,

$$
\left.\left.\begin{array}{rl}
\operatorname{structure}(U, X)( & P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, F_{\mathrm{o}}}, \\
& C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}(
\end{array} F_{\mathrm{o}}\right)\right) \underset{\operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, F_{\mathrm{o}}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}\right)\right)}{\sim}
$$

So conjecture that, in the case where the sample history is modal, $H_{o} \in$ $\operatorname{maxd}\left(P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, F_{\mathrm{o}}}\right)$, the log-likelihood of the iso-fud conditional stuffed historical probability distribution also varies with its degree of structure,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{structure}(U, X)\left(P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, F_{\mathrm{o}}}, C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}\right)\right)
$$

In other words, when the iso-fud log-likelihood is high, the expected space of the specialising coder is low and so the compression of the coder with respect to the iso-fud historically distributed history probability function is high.

Further, conjecture that the sensitivity to model also varies against the log likelihood,

$$
\begin{aligned}
-\ln \mid \max \left(\left\{\left(F, \hat{Q}_{\mathrm{h}, \mathrm{~d}, F, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right. & \\
F \in \mathcal{F}_{U, V_{\mathrm{o}}}, \exists T \in F\left(W_{T}=W_{F}\right), & \left.\left.A_{\mathrm{o}} \approx A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}(F)}\right\}\right) \mid \sim \\
& -\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
\end{aligned}
$$

In the case where the relative entropies are high, $\forall T \in F_{\mathrm{o}}$ (entropyCross $\left(A_{\mathrm{o}} *\right.$ $\left.\left.T_{F_{\mathrm{o}}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{F_{\mathrm{o}}}\right)>\ln \left|T_{F_{\mathrm{o}}}^{-1}\right|\right)$, the sum sensitivity varies against the log likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

So in this case, in classical uniform possible modelled induction, both (a) the sensitivity to distribution histogram,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)
$$

and (b) the sensitivity to model,

$$
\begin{aligned}
& -\ln \mid \max \left(\left\{\left(F, \hat{Q}_{\mathrm{h}, \mathrm{~d}, F, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right. \\
& \left.\left.\quad F \in \mathcal{F}_{U, V_{\mathrm{o}}}, \exists T \in F\left(W_{T}=W_{F}\right), A_{\mathrm{o}} \approx A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}(F)}\right\}\right) \mid
\end{aligned}
$$

vary against the log-likelihood. That is, in classical modelled induction in some circumstances, the optimisation of the log-likelihood tends to minimise the sensitivity to parameter.

### 5.5.10 Specialising functional definition set decomposition induction

Again, consider extending the model for specialising induction from functional definition sets to functional definition set decompositions.

Consider the specialising functional definition set decomposition history probability function $P_{U, X, \mathrm{G}, D_{\circ}, \mathrm{H}} \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}$ which is defined such that the probability of a history is inversely proportional to the bounding integer, for which the space is the logarithm, of the integer encoding of the history in the specialising fud decomposition coder, given a non-empty known substrate fud decomposition in the sample variables $D_{\mathrm{o}} \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}$,

$$
\begin{aligned}
& P_{U, X, \mathrm{G}, D_{\mathrm{o}}, \mathrm{H}}:= \\
& \quad \begin{array}{l}
\left(\bigcup \left\{\left\{\left(H, \exp \left(-C_{\mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D_{\mathrm{o}}\right)^{\mathrm{s}}(H)\right)\right):\right.\right.\right. \\
\\
\left.\qquad H \in \mathcal{H}_{U, X}, \operatorname{vars}(H)=V_{H},|H|=z_{H}\right\}^{\wedge}: \\
\left.\left.\quad V_{H} \subseteq \operatorname{vars}(U), z_{H} \in\{1 \ldots|X|\}\right\}\right)^{\wedge} \cup
\end{array}
\end{aligned}
$$

where the specialising fud decomposition substrate history coder is

$$
\begin{aligned}
& C_{\mathrm{G}, V, \mathrm{D}, \mathrm{~F}, \mathrm{H}}(D)= \\
& \quad \text { coderHistorySubstrateFudDecompSpecialising }\left(U, X, F, D_{\mathrm{S}}, D_{\mathrm{X}}\right)
\end{aligned}
$$

and the expanded specialising fud decomposition history coder $C_{\mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}(D) \in$ $\operatorname{coders}\left(\mathcal{H}_{U, X}\right)$ is derived from the specialising fud decomposition substrate history coder, $C_{\mathrm{G}, V, \mathrm{D}, \mathrm{F}, \mathrm{H}}$,

$$
\begin{aligned}
C_{\mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}(D)^{\mathrm{s}}(H)= & \left(C_{\mathrm{G}, V_{H}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D^{V_{H}}\right)^{\mathrm{s}}(H)+s_{\left|V_{H}\right|}: V_{H} \supseteq V\right)+ \\
& \left(C_{\mathrm{H}}^{\mathrm{s}}(H): V_{H} \nsupseteq V\right)
\end{aligned}
$$

where $D^{V}$ is the expansion that adds a unary transform in the remaining underlying variables to the leaf fuds in the decomposition tree such that the fud of each path of the application tree has complete coverage of the substrate,

$$
\forall L \in \operatorname{paths}\left(D^{*}\right)\left(\bigcup_{(\cdot,(F, \cdot)) \in L} V_{F}=V\right)
$$

where $V_{F}=\operatorname{und}(D)$, and $s_{n}=\operatorname{spaceVariables}(U)(n)$.
All non-empty histories are possible in specialising fud decomposition induction, $\forall H \in \mathcal{H}_{U, X} \backslash\{\emptyset\}\left(P_{U, X, \mathrm{G}, D_{o}, \mathrm{H}}(H)>0\right)$.

All histories having the same specialising space for a given set of variables and size are defined as equally probable,

$$
\begin{aligned}
& \forall H, G \in \mathcal{H}_{U, V, z, X} \\
& \qquad\left(C_{\mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D_{\mathrm{o}}\right)^{\mathrm{s}}(G)=C_{\mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D_{\mathrm{o}}\right)^{\mathrm{s}}(H) \Longrightarrow P_{U, X, \mathrm{G}, D_{\mathrm{o}}, \mathrm{H}}(G)=P_{U, X, \mathrm{G}, D_{\mathrm{o}}, \mathrm{H}}(H)\right)
\end{aligned}
$$

Given a history $H \in \mathcal{H}_{U, X}$, such that $H \neq \emptyset$, the specialised historical probability of histogram $A_{H}=\operatorname{histogram}(H)+V_{H}^{\mathrm{CZ}} \in \mathcal{A}_{U, \mathrm{i}, V_{H}, z_{H}}$ is

$$
\hat{Q}_{\mathrm{G}, D_{\circ}, \mathrm{H}, U}\left(z_{H}\right)\left(A_{H}\right) \propto \sum\left(P_{U, X, \mathrm{G}, D_{\circ}, \mathrm{H}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}\right)
$$

where the specialising fud decomposition probability distribution is defined

$$
\begin{aligned}
& \hat{Q}_{\mathrm{G}, D, \mathrm{H}, U}(z):= \\
& \qquad\left\{\left(A, \frac{z!}{\prod_{S \in A^{\mathrm{FS}}} A_{S}!} \times \exp \left(-C_{\mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}(D)^{\mathrm{s}}\left(H_{A}\right)\right)\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}^{\wedge}
\end{aligned}
$$

where $V=\operatorname{und}(D)$ and $H_{A}=\operatorname{history}(A)$.
The log likelihood is proportional to the classification space of the underlying histogram less the specialising space of the corresponding history,
$\ln \hat{Q}_{\mathrm{G}, D, \mathrm{H}, U}(z)(A) \propto \operatorname{spaceClassification}(A)-\operatorname{space}\left(C_{\mathrm{G}, V, \mathrm{D}, \mathrm{F}, \mathrm{H}}(D)\right)\left(H_{A}\right)$
Let $H_{\mathrm{o}}$ be a sample history of known size $z_{\mathrm{o}}=\left|H_{\mathrm{o}}\right|>0$ in the known sample variables, $V_{\mathrm{o}}$, which has a known histogram $A_{\mathrm{o}}=\operatorname{histogram}\left(H_{\mathrm{o}}\right)+V_{\mathrm{o}}^{\mathrm{CZ}} \in$ $\mathcal{A}_{U, \mathrm{i}, V_{0}, z_{0}}$. In classical specialising fud decomposition induction, where the history probability function is the specialising fud decomposition history probability function, $P=P_{U, X, \mathrm{G}, D_{o}, \mathrm{H}}$, given some substrate fud decomposition in the sample variables $D_{\mathrm{o}} \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}}$, the log likelihood of the specialising fud decomposition probability distribution (a) varies with the size scaled underlying entropy,

$$
\ln \hat{Q}_{\mathrm{G}, D_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}}\right)
$$

(b) varies against the total possible derived volume or size scaled log possible derived volume

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{G}, D_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \\
& -\sum_{(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right)} \sum_{T \in F}\left(\left(\left|T_{F}^{-1}\right|:\left|T_{F}^{-1}\right|<z_{A_{\mathrm{o}} * C}\right)+\right. \\
& \left.\quad\left(z_{A_{\mathrm{o}} * C} \ln \left|T_{F}^{-1}\right|:\left|T_{F}^{-1}\right| \geq z_{A_{\mathrm{o}} * C}\right)\right)
\end{aligned}
$$

(c) varies against the total size scaled derived entropy
$\ln \hat{Q}_{\mathrm{G}, D_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\sum_{(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right)}\left(z_{A_{\mathrm{o}} * C} \times \sum_{T \in F} \operatorname{entropy}\left(A_{\mathrm{o}} * C * T_{F}\right)\right)$
(d) varies with the total size scaled component size cardinality cross entropy

$$
\ln \hat{Q}_{\mathrm{G}, D_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim
$$

and (e) varies with the total size scaled size expected component entropy,

$$
\ln \hat{Q}_{\mathrm{G}, D_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim
$$

where $\operatorname{cont}(D):=\operatorname{elements}(\operatorname{contingents}(D))$ and $T_{F}:=\operatorname{depends}(F, \operatorname{der}(T))^{\mathrm{T}}$.
So the specialising log likelihood is maximised when (a) the total possible derived volume is minimised, (b) the underlying entropy is maximised, (c) the total derived entropy is minimised, (d) high size components are low cardinality components and low size components are high cardinality components for each transform for all slices, and (e) the total expected component entropy is maximised. It is also conjectured that, for all fuds, (i) the derived entropy decreases up the layers, (ii) the possible derived volume decreases up the layers, (iii) the expected component entropy increases up the layers, and (iv) the component size cardinality cross entropy increases up the layers.

The specialising fud decomposition history probability function, $P_{U, X, G, D_{\circ}, H}$, is the history probability function $P$ that maximises the degree of structure with respect to the expanded specialising fud decomposition history coder, $C_{\mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}\left(D_{\mathrm{o}}\right)$, given arbitrary draw, $\left(V_{H}, z_{H}\right)$,

$$
\begin{aligned}
& P_{U, X, \mathrm{G}, D_{\mathrm{o}}, \mathrm{H}} \in \\
& \operatorname{maxd}\left(\left\{\left(P, \operatorname{structure}(U, X)\left(P, C_{\mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D_{\mathrm{o}}\right)\right)\right):\right.\right. \\
& \qquad P \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}, \\
& \quad \mid\left\{\left(\sum P_{H}: H \in \mathcal{H}_{U, X}, \operatorname{vars}(H)=V_{H},|H|=z_{H}\right):\right. \\
& \left.\quad V_{H} \subseteq \operatorname{vars}(U), z_{H} \in\{1 \ldots|X|\}\right\} \mid=1,
\end{aligned}
$$

In classical specialising fud decomposition induction, where (i) the history probability function is the specialising fud decomposition history probability function, $P=P_{U, X, \mathrm{G}, D_{0}, \mathrm{H}}$, given some substrate fud decomposition in the sample variables $D_{\mathrm{o}} \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}}$, and (ii) the sample history is modal, $H_{\mathrm{o}} \in$
$\operatorname{maxd}\left(P_{U, X, \mathrm{G}, D_{\mathrm{o}}, \mathrm{H}}\right)$, the log likelihood of the specialising fud decomposition probability distribution varies with the degree of structure,

$$
\ln \hat{Q}_{\mathrm{G}, D_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, D_{\mathrm{o}}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D_{\mathrm{o}}\right)\right)
$$

In the case where the model, $D_{\mathrm{o}}$, is unknown, the maximum likelihood estimate $\tilde{D}_{\mathrm{o}}$ can be defined as an optimisation of the specialising probability given the sample,

$$
\tilde{D}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(D, \hat{Q}_{\mathrm{G}, D, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}}\right\}\right)
$$

In specialising fud decomposition induction, which is such that the history probability function is $P=P_{U, X, \mathrm{G}, D_{0}, \mathrm{H}}$, given some unknown substrate fud decomposition $D_{\mathrm{o}} \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}}$, the maximum likelihood estimate of the model, $\tilde{D}_{\mathrm{o}}$, occurs at the minimisation of the specialising space of the sample history,

$$
\tilde{D}_{\mathrm{o}} \in \operatorname{mind}\left(\left\{\left(D, C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D^{V_{\mathrm{o}} \mathrm{~s}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right): D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}}\right\}\right)
$$

The maximum likelihood estimate for the model, $\tilde{D}_{\mathrm{o}}$, is non-trivial, $\tilde{D}_{\mathrm{o}} \notin$ $\left\{\left\{\left(\left(\emptyset,\left\{T_{\mathrm{s}}\right\}\right), \emptyset\right)\right\},\left\{\left(\left(\emptyset,\left\{T_{\mathrm{u}}\right\}\right), \emptyset\right)\right\}\right\}$, if there exists a model for which the specialising fud decomposition substrate history space is less than either the index space or the classification space,

$$
C_{\mathrm{G}, \mathrm{~V}_{\mathrm{o}}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(\tilde{D}_{\mathrm{o}}^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)<\operatorname{minimum}\left(C_{\mathrm{H}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right), C_{\mathrm{G}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right)
$$

Conjecture that the sensitivity to model varies against the specialising structure,

$$
\begin{aligned}
-\ln \mid \max \left(\left\{\left(D, \hat{Q}_{\mathrm{G}, D, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right. & \left.\left.: D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}}\right\}\right) \mid \sim \\
& \quad \operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, D_{\mathrm{o}}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D_{\mathrm{o}}\right)\right)
\end{aligned}
$$

so the sensitivity to model varies against the log likelihood,

$$
\begin{aligned}
-\ln \left|\max \left(\left\{\left(D, \hat{Q}_{\mathrm{G}, D, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}}\right\}\right)\right| & \sim \\
& -\ln \hat{Q}_{\mathrm{G}, D_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
\end{aligned}
$$

That is, maximisation of the log likelihood also tends to minimise the sensitivity to model.

It is shown above in classical uniform possible fud decomposition induction, where the history probability function is uniform possible iso-fud-decomposition historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, D_{\mathrm{o}}}$, that, in the case where the size is
less than the volume, $z_{0}<v_{\mathrm{o}}$, but the sample approximates to the fud-decomposition-independent, $A_{\mathrm{o}} \approx A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}\left(D_{\mathrm{o}}\right)}$, the log likelihood of the iso-fud-decomposition conditional stuffed historical probability distribution at the maximum likelihood estimate (a) varies against the sum of the possible derived volumes or size scaled log possible derived volumes of the slices,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \\
& -\sum_{(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right)} \sum_{T \in F}\left(\left(\left|T_{F}^{-1}\right|:\left|T_{F}^{-1}\right|<z_{A_{\mathrm{o}} * C}\right)+\right. \\
& \left.\quad\left(z_{A_{\mathrm{o}} * C} \ln \left|T_{F}^{-1}\right|:\left|T_{F}^{-1}\right| \geq z_{A_{\mathrm{o}} * C}\right)\right)
\end{aligned}
$$

(b) varies with the size scaled component size cardinality relative entropies of all transforms for all slices,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim
$$

so (c) varies against the specialising fud decomposition substrate history coder space,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D_{\mathrm{o}}^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)
$$

and (d) varies against the specialising-canonical space difference,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)( & \left.A_{\mathrm{o}}\right) \\
& \sim \\
& -\left(2 C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D_{\mathrm{o}}^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)-C_{\mathrm{H}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)-C_{\mathrm{G}, V_{\mathrm{o}}}^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right)
\end{aligned}
$$

In the near-fud-decomposition-independent case, insofar as the uniform possible iso-fud-decomposition history probability function approximates to the specialising fud decomposition history probability function, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, D_{\mathrm{o}}} \approx$ $P_{U, X, \mathrm{G}, D_{o}, \mathrm{H}}$, conjecture that (a) the log likelihood of the iso-fud-decomposition conditional stuffed historical probability distribution varies with the log likelihood of the specialising fud decomposition probability distribution,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \ln \hat{Q}_{\mathrm{G}, D_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

and (b) the degree of structure of the uniform possible iso-fud-decomposition history probability function with respect to the specialising coder varies with specialising degree of structure,

$$
\begin{aligned}
\operatorname{structure}(U, X)\left(P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, D_{\mathrm{o}}},\right. & \left.C_{\mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D_{\mathrm{o}}\right)\right)
\end{aligned} \quad \underset{ }{\quad \operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, D_{\mathrm{o}}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D_{\mathrm{o}}\right)\right)}
$$

So conjecture that, in the case where the sample history is modal, $H_{\mathrm{o}} \in$ $\operatorname{maxd}\left(P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, D_{\mathrm{o}}}\right)$, the log-likelihood of the iso-fud-decomposition conditional stuffed historical probability distribution also varies with its degree of structure,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{structure}(U, X)\left(P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, D_{\mathrm{o}}}, C_{\mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D_{\mathrm{o}}\right)\right)
$$

In other words, when the iso-fud-decomposition log-likelihood is high, the expected space of the specialising coder is low and so the compression of the coder with respect to the iso-fud-decomposition historically distributed history probability function is high.

Further, conjecture that the sensitivity to model also varies against the log likelihood,
$-\ln \mid \max \left(\left\{\left(D, \hat{Q}_{\mathrm{h}, \mathrm{d}, D, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right.$
$D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}, \forall F \in \operatorname{fuds}(D) \exists T \in F\left(W_{T}=W_{F}\right)$,

$$
\begin{aligned}
A_{\mathrm{o}} & \left.\left.\approx A_{\mathrm{o}}^{\mathrm{E}, \mathrm{~F}(D)}\right\}\right) \mid \sim \\
& -\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
\end{aligned}
$$

In the case where the relative entropies are high, $\forall(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right) \forall T \in$ $F$ (entropyCross $\left.\left(A_{\mathrm{o}} * C * T_{F}, C * T_{F}\right)>\ln \left|T_{F}^{-1}\right|\right)$, the sum sensitivity varies against the log likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

So in this case, in classical uniform possible modelled induction, both (a) the sensitivity to distribution histogram,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)
$$

and (b) the sensitivity to model,
$-\ln \mid \max \left(\left\{\left(D, \hat{Q}_{\mathrm{h}, \mathrm{d}, D, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right.$
$D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}, \forall F \in \operatorname{fuds}(D) \exists T \in F\left(W_{T}=W_{F}\right)$,

$$
\left.\left.A_{\mathrm{o}} \approx A_{\mathrm{o}}^{\mathrm{E}, \mathrm{~F}(D)}\right\}\right) \mid
$$

vary against the log-likelihood. That is, in classical modelled induction in some circumstances, the optimisation of the log-likelihood tends to minimise the sensitivity to parameter.

### 5.5.11 Tractable transform induction

It was noted at the beginning of section 'Specialising induction' that, although the maximum likelihood estimate for the model, $\tilde{T}_{\mathrm{o}}$, is computable for uniform possible derived induction,

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger}\right\}\right)
$$

the computation is not tractable. Insofar as the uniform possible iso-derived history probability function approximates to the specialising history probability function, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, T_{\mathrm{o}}} \approx P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}$, consider instead computing the maximum likelihood estimate for the model, $\tilde{T}_{\mathrm{o}}$, for specialising induction,

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{G}, T, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

or

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{mind}\left(\left\{\left(T, C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

This computation is more tractable, because there is no need to compute the derived function, $D_{U, \mathrm{i}, T, z_{0}} \in \mathcal{A}_{U, \mathrm{i}, V_{o}, z_{o}}: \rightarrow \mathcal{A}_{U, \mathrm{i}, W, z_{0}}$. However, it is still necessary to compute the set of substrate transforms, $\mathcal{T}_{U, V_{o}}$, and so the computation of the minimum coder space is still intractable.

It is conjectured in section 'Inducers and Compression', above, that, although the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, is defined completely separately of the notions of alignment and independence, the properties of the minimum coder space are similar in many ways to the properties of the maximum summed alignment valency-density of the tractable limited-models summed alignment valency-density substrate aligned non overlapping infinite-layer fud decomposition inducer,

$$
I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime} \in \operatorname{inducers}(z)
$$

Given non-independent substrate histogram $A \in \mathcal{A}_{z} \backslash\left\{A^{\mathrm{X}}\right\}$, the midising, idealising fud decomposition inducer is defined,

$$
\begin{aligned}
& I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)= \\
& \qquad\left\{\left(D, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algnValDensSum}\left(U_{A}\right)\left(A, D^{\mathrm{D}}\right)\right)\right):\right. \\
& \quad D \in \mathcal{D}_{\mathrm{F}, \infty, U_{A}, V_{A}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathbf{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right), \\
& \left.\quad \forall(C, F) \in \operatorname{cont}(D)\left(\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)>0\right)\right\}
\end{aligned}
$$

where (i) the limited-models fuds, $\mathcal{F}_{\mathrm{q}}$ is the intersection of limited-breadth, limited-layer, limited-underlying and limited-derived fuds, $\mathcal{F}_{\mathrm{q}}=\mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{d}} \cap$
$\mathcal{F}_{\mathrm{h}} \cap \mathcal{F}_{\mathrm{b}}$, (ii) cont $(D)=\operatorname{elements}(\operatorname{contingents}(D))$, (iii) ()$^{\mathrm{D}} \in \mathcal{D}_{\mathrm{F}} \rightarrow \mathcal{D}$, and (iv) the summed derived alignment valency density algnValDensSum $(U) \in$ $\mathcal{A} \times \mathcal{D} \rightarrow \mathbf{R}$ is defined as

$$
\begin{aligned}
& \operatorname{algnValDensSum}(U)(A, D):= \\
& \qquad \sum_{(C, T) \in \operatorname{cont}(D)} \operatorname{algn}(A * C * T) / \text { capacityValency }(U)\left((A * C * T)^{\mathrm{FS}}\right)
\end{aligned}
$$

The fud decomposition minimum space specialising derived search function for history $H \in \mathcal{H}_{U, X}$ is defined in terms of the expanded specialising derived history coder, $C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}(T) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$, as

$$
Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}(H)=\left\{\left(D,-C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(D^{\mathrm{T}}\right)^{\mathrm{s}}(H)\right): D \in \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}\right\}
$$

It is maximised by finding the fud decomposition $D \in \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}$ which minimises the specialising derived substrate history coder space, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\left(D^{\mathrm{PVT}}\right)^{\mathrm{s}}(H)$ where $V=\operatorname{vars}(H)$.

The summed alignment valency-density decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, application also defines a fud decomposition search function, but restricted to the limited-models non-overlapping fud decompositions, $\mathcal{D}_{\mathrm{F}, U, \mathrm{P}} \cap \operatorname{trees}(\mathcal{S} \times$ $\left.\left(\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right) \subseteq \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}$. Define the limited-models summed alignment valencydensity aligned non-overlapping fud decomposition search function

$$
\begin{aligned}
& Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)= \\
& \begin{aligned}
\left\{\left(D, I_{\approx \mathbf{R}}^{*}\left(\sum \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}}:(C, F) \in \operatorname{cont}(D)\right)\right):\right. \\
D \in \mathcal{D}_{\mathrm{F}, U, \mathrm{P}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right), \operatorname{und}(D) \subseteq V, \\
\left.\forall(C, F) \in \operatorname{cont}(D)\left(\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)>0\right)\right\} \cup
\end{aligned} \\
& \quad\left\{\left(D_{\mathrm{u}}, 0\right)\right\}
\end{aligned}
$$

where $W_{F}=\operatorname{der}(F), w_{F}=\left|W_{F}^{\mathrm{C}}\right|, m_{F}=\left|W_{F}\right|, V=\operatorname{vars}(H), A=\operatorname{histogram}(H)$, the unary fud decomposition $D_{\mathrm{u}}=\left\{\left(\left(\emptyset,\left\{T_{\mathrm{u}}\right\}\right), \emptyset\right)\right\}$, and the unary transform $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$.

The limited-models summed alignment valency-density aligned non-overlapping fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}(H)$, is maximised by searching for the fud decomposition $D \in \operatorname{maxd}\left(Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{S}}(H)\right) \subset \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}$, which maximises summed alignment valency-density,

$$
\operatorname{algnValDensSum}(U)\left(A, D^{\mathrm{D}}\right)=\sum_{(C, F) \in \operatorname{cont}(D)} \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}}
$$

In section 'Inducers and Compression', it is conjectured that for all finite systems and finite event identifier sets there exists a class of limited-models fuds such that the search functions are positively correlated for uniform history probability function,

$$
\begin{aligned}
& \forall U \in \mathcal{U} \forall X \subset \mathcal{X}\left(\left|\mathcal{H}_{U, X}\right|<\infty\right. \Longrightarrow \\
& \exists \mathcal{F}_{\mathrm{q}} \subset \mathcal{F}\left(\operatorname{covariance}\left(\mathcal{H}_{U, X} \times\left\{1 /\left|\mathcal{H}_{U, X}\right|\right\}\right)\right. \\
&\left.\left.\left(\operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}, \operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}\right) \geq 0\right)\right)
\end{aligned}
$$

The discussion considers the relations between the summed alignment valencydensity and the specialising space. In particular, it is shown that the summed alignment valency-density (a) varies against the derived entropy of the nullable transform,

$$
\operatorname{algnValDensSum}(U)\left(A, D^{\mathrm{D}}\right) \sim-\operatorname{entropy}\left(A * D^{\mathrm{T}}\right)
$$

(b) varies against the possible derived volume $w^{\prime}=\left|\left(D^{T}\right)^{-1}\right|$,

$$
\operatorname{algnValDensSum}(U)\left(A, D^{\mathrm{D}}\right) \sim 1 / w^{\prime}
$$

(c) varies with the expected component entropy,

$$
\operatorname{algnValDensSum}(U)\left(A, D^{\mathrm{D}}\right) \sim \text { entropyComponent }\left(A, D^{\mathrm{T}}\right)
$$

and (d) varies with the component size cardinality relative entropy,

$$
\operatorname{algnValDensSum}(U)\left(A, D^{\mathrm{D}}\right) \sim \text { entropyRelative }\left(A * D^{\mathrm{T}}, V^{\mathrm{C}} * D^{\mathrm{T}}\right)
$$

With regard to this last relation, note that although the maximisation of the midisation alignment tends to minimise the mid component size cardinality relative entropy, entropyRelative $\left(A * C * F^{\mathrm{T}}, C * F^{\mathrm{T}}\right) \approx 0$ where $(C, F) \in \operatorname{cont}(D)$, the subsequent maximisation of the idealisation alignment in the super-decomposition tends to increase the overall relative entropy.

Given this evidence for the correlation between the fud decomposition minimum space specialising derived search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$, and the tractable limited-models summed alignment valency-density aligned non-overlapping fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, conjecture that, in the case where the model, $T_{\mathrm{o}}$, is unknown, the maximum likelihood estimate for the model for specialising induction,

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{G}, T, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

or

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{mind}\left(\left\{\left(T, C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

can be tractably approximated by the maximisation of the tractable limitedmodels summed alignment valency-density substrate aligned non-overlapping infinite-layer fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$,

$$
\tilde{T}_{\mathrm{o}} \approx D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}
$$

where

$$
D_{\mathrm{o}, \mathrm{Sd}} \in \operatorname{maxd}\left(I_{z_{\mathrm{o}}, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}\left(A_{\mathrm{o}}\right)\right)
$$

and $A_{\mathrm{o}} \neq A_{\mathrm{o}}^{\mathrm{X}}$. The tractable model, $D_{\mathrm{o}, \mathrm{Sd}}$, is defined explicitly,

$$
\begin{aligned}
& D_{\mathrm{o}, \mathrm{Sd}} \in \operatorname{maxd}\left(\left\{\left(D, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algnValDensSum}(U)\left(A_{\mathrm{o}}, D^{\mathrm{D}}\right)\right)\right):\right.\right. \\
& \quad D \in \mathcal{D}_{\mathrm{F}, \infty, U, V_{\mathrm{o}}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right), \\
& \left.\left.\forall(C, F) \in \operatorname{cont}(D)\left(\operatorname{algn}\left(A_{\mathrm{o}} * C * F^{\mathrm{T}}\right)>0\right)\right\}\right)
\end{aligned}
$$

The approximation, $D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}$, can be compared to the maximum likelihood estimate, $\tilde{T}_{\mathrm{o}}$, by computing the relative entropy between derived,

$$
\text { entropyRelative }\left(A_{\mathrm{o}} * \tilde{T}_{\mathrm{o}}, A_{\mathrm{o}} * D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}\right)
$$

The approximation improves as the relative entropy decreases.

The accuracy of the approximation can be defined as the ratio of the tractable model specialising likelihood to the maximum model specialising likelihood,

$$
0<\frac{\hat{Q}_{\mathrm{G}, D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{T}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \leq 1
$$

The accuracy is computable, though not tractable and so not necessarily practicable. The definition of accuracy is consistent with the gradient of the likelihood function at the mode,

$$
\frac{\hat{Q}_{\mathrm{G}, D_{\mathrm{D}, \mathrm{Sd}_{d}}^{\mathrm{T}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{T}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \sim \partial\left(L_{n, U, X, T_{\mathrm{o}}}(0)\right)\left(\lambda_{\mathrm{o}}\right)
$$

So the accuracy varies against the sensitivity to model,

$$
\begin{aligned}
\frac{\hat{Q}_{\mathrm{G}, D_{\mathrm{o}, \mathrm{~S}}^{\mathrm{T}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{T}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} & \sim-\left(-\partial\left(L_{n, U, X, T_{\mathrm{o}}}(0)\right)\left(\lambda_{\mathrm{o}}\right)\right) \\
& \sim \operatorname{structure}(U, X)\left(P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right) \\
& \sim-\left(-\ln \left|\max \left(\left\{\left(T, \hat{Q}_{\mathrm{G}, T, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)\right|\right)
\end{aligned}
$$

It was noted above that, in specialising induction, where $P=P_{U, X, \mathrm{G}, T_{o}, \mathrm{H}}$, the maximisation of the log likelihood also tends to minimise the sensitivity to model,
$-\ln \left|\max \left(\left\{\left(T, \hat{Q}_{\mathrm{G}, T, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)\right| \sim-\ln \hat{Q}_{\mathrm{G}, T_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$
So, although the maximum model specialising likelihood, $\hat{Q}_{\mathrm{G}, \tilde{T}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$, appears in the denominator of the accuracy, the accuracy of the tractable model in fact varies with the log-likelihood,

$$
\frac{\hat{Q}_{\mathrm{G}, D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{T}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \sim \ln \hat{Q}_{\mathrm{G}, T_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

That is, although the model obtained from the tractable summed alignment valency-density inducer is merely an approximation, in the cases where the log-likelihood is high, and so the sensitivity to model is low, the approximation may be reasonably close nonetheless.

Consider the tractable model obtained by maximisation of the derived alignment valency-density of the tractable limited-models derived alignment valency-density substrate non-overlapping infinite-layer fud inducer,

$$
I_{z, \mathrm{ad}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime} \in \operatorname{inducers}(z)
$$

Given non-independent substrate histogram $A \in \mathcal{A}_{z} \backslash\left\{A^{\mathrm{X}}\right\}$, the midising fud inducer is defined,
$I_{z, \mathrm{ad}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)=\left\{\left(F, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}\left(A * F^{\mathrm{T}}\right) / w^{1 / m}\right)\right): F \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right\}$
Let the tractable derived alignment valency-density fud be

$$
F_{\mathrm{o}, \mathrm{ad}} \in \operatorname{maxd}\left(I_{z_{\mathrm{o}}, \mathrm{ad}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}\left(A_{\mathrm{o}}\right)\right)
$$

In order for the inducer to be alignment-bounded while tractably lifting to derived transform, it is necessary to maximise formal-abstract equality by the maximisation of midisation alignment, which is approximated by the maximisation of derived alignment valency-density. The maximisation of the midisation alignment, however, tends to minimise the mid component size cardinality relative entropy,

$$
\operatorname{entropyRelative}\left(A * F_{\mathrm{o}, \mathrm{ad}}^{\mathrm{T}}, V_{\mathrm{o}}^{\mathrm{C}} * F_{\mathrm{o}, \mathrm{ad}}^{\mathrm{T}}\right) \approx 0
$$

whereas the fud decomposition, $D_{\mathrm{o}, \mathrm{Sd}}$, which has the fud, $F_{\mathrm{o}, \mathrm{ad}}$, in its root, $\left\{\left(\left(\emptyset, F_{\mathrm{o}, \mathrm{ad}}\right), \cdot\right)\right\}=D_{\mathrm{o}, \mathrm{Sd}}$, restores the relative entropy by maximisation of the idealisation alignment during decomposition,

$$
\text { entropyRelative }\left(A * D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}, V_{\mathrm{o}}^{\mathrm{C}} * D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}\right)>0
$$

so the tractable derived alignment valency-density fud accuracy is less than tractable summed alignment valency-density fud decomposition accuracy,

$$
\frac{\hat{Q}_{\mathrm{G}, F_{\mathrm{o}, \mathrm{ad}}^{\mathrm{T}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{T}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}<\frac{\hat{Q}_{\mathrm{G}, D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{T}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}
$$

Consider the tractable model obtained by maximisation of the derived alignment of the tractable limited-models derived alignment substrate non-overlapping infinite-layer fud inducer,

$$
I_{z, \mathrm{a}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime} \in \operatorname{inducers}(z)
$$

Given non-independent substrate histogram $A \in \mathcal{A}_{z} \backslash\left\{A^{\mathrm{X}}\right\}$, the fud inducer is defined,

$$
I_{z, \mathrm{a}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)=\left\{\left(F, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algn}\left(A * F^{\mathrm{T}}\right)\right)\right): F \in \mathcal{F}_{\infty, U_{A}, V_{A}} \cap \mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right\}
$$

Let the tractable derived alignment fud be

$$
F_{\mathrm{o}, \mathrm{a}} \in \operatorname{maxd}\left(I_{z_{o}, \mathrm{a}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}\left(A_{\mathrm{o}}\right)\right)
$$

The component size cardinality relative entropy of the derived alignment fud is sometimes higher than that of the derived alignment valency-density fud, entropyRelative $\left(A * F_{\mathrm{o}, \mathrm{ad}}^{\mathrm{T}}, V_{\mathrm{o}}^{\mathrm{C}} * F_{\mathrm{o}, \mathrm{ad}}^{\mathrm{T}}\right)<\operatorname{entropyRelative}\left(A * F_{\mathrm{o}, \mathrm{a}}^{\mathrm{T}}, V_{\mathrm{o}}^{\mathrm{C}} * F_{\mathrm{o}, \mathrm{a}}^{\mathrm{T}}\right)$ although the derived entropy is sometimes higher,

$$
\operatorname{entropy}\left(A * F_{\mathrm{o}, \mathrm{ad}}^{\mathrm{T}}\right)<\operatorname{entropy}\left(A * F_{\mathrm{o}, \mathrm{a}}^{\mathrm{T}}\right)
$$

so conjecture that the accuracy is sometimes also greater,

$$
\frac{\hat{Q}_{\mathrm{G}, F_{\mathrm{o}, \mathrm{ad}}^{\mathrm{T}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{T}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}<\frac{\hat{Q}_{\mathrm{G}, F_{\mathrm{o}, \mathrm{a}}^{\mathrm{T}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{T}_{,}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}
$$

but the derived alignment fud inducer, $I_{z, \mathrm{a}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, has limited derived volume with respect to the summed alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, so conjecture that the accuracy is still less than that of the fud decomposition inducer,

$$
\frac{\hat{Q}_{\mathrm{G}, F_{\mathrm{o}, a}^{\mathrm{T}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{T}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}<\frac{\hat{Q}_{\mathrm{G}, D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{T}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}
$$

Consider the practicable model obtained by maximisation of the summed shuffle content alignment valency-density of the practicable highest-layer summed shuffle content alignment valency-density fud decomposition inducer,

$$
I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime} \in \operatorname{inducers}(z)
$$

Given substrate histogram $A \in \mathcal{A}_{z}$, the practicable fud decomposition inducer is defined in section 'Optimisation', above, as

$$
\begin{aligned}
& I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime *}(A)= \\
& \operatorname{if}\left(Q \neq \emptyset,\left\{\left(D, I_{\text {Scsd }}^{*}((A, D))\right)\right\},\left\{\left(D_{\emptyset}, 0\right)\right\}\right): \\
& \quad Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{~d}}\right)\right),\{D\}=Q
\end{aligned}
$$

Let the practicable fud decomposition be

$$
D_{\mathrm{o}, \mathrm{Scsd}, P} \in \operatorname{maxd}\left(I_{z_{\mathrm{o}}, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime *}\left(A_{\mathrm{o}}\right)\right)
$$

The practicable fud decomposition inducer imposes a sequence on the search and other constraints that do not apply to the tractable summed alignment valency-density decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, corresponding to the limited-models summed alignment valency-density aligned non-overlapping fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}$, so conjecture that the accuracy is less than that of the tractable fud decomposition inducer,

$$
\frac{\hat{Q}_{\mathrm{G}, D_{\mathrm{o}, \mathrm{Scsd}, P}^{\mathrm{T}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{T}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}<\frac{\hat{Q}_{\mathrm{G}, D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{T}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}
$$

It is shown above in classical uniform possible modelled induction, where the history probability function is uniform possible iso-derived historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, T_{o}}$, that, in the case where (i) the size is less than the volume, $z_{0}<v_{0}$, but the sample approximates to the naturalisation, $A_{\mathrm{o}} \approx A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, and (ii) the maximum likelihood estimate relative entropy is high, entropy $\operatorname{Cross}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)>\ln \left|T_{\mathrm{o}}^{-1}\right|$, (a) the log likelihood of the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate varies against the specialising derived substrate history coder space,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\operatorname{space}\left(C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)\left(H_{\mathrm{o}}\right)
$$

(b) the sensitivity to distribution varies against the log likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

and (c) the sensitivity to model varies against the log likelihood,

$$
\begin{aligned}
-\ln \mid \max \left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right.\right. & \left.\left., A_{\mathrm{o}} \approx A_{\mathrm{o}} * T * T^{\dagger}\right\}\right) \mid \sim \\
& -\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
\end{aligned}
$$

Insofar as the uniform possible iso-derived history probability function approximates to the specialising history probability function, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, T_{\mathrm{o}}} \approx$ $P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}$, conjecture that the model, $D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}$, obtained by the maximisation of the tractable summed alignment valency-density inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is also a tractable approximation to the maximum likelihood estimate for the model for uniform possible iso-derived induction,

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}} \approx A_{\mathrm{o}} * T * T^{\dagger}\right\}\right)
$$

That is, in the near-natural, high relative entropy case, a tractable maximum likelihood estimate for the model may be obtained for classical modelled induction by optimisation of the summed alignment valency-density inducer,

$$
\tilde{T}_{\mathrm{o}} \approx D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}
$$

The accuracy of the approximation can be defined as the ratio of the tractable model uniform possible iso-derived likelihood to the maximum model uniform possible iso-derived likelihood,

$$
0<\frac{\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{T}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \leq 1
$$

Just as the tractable model specialising accuracy varies with the log-likelihood, so too does the tractable model uniform possible iso-derived accuracy,

$$
\frac{\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}, \mathrm{~S} \mathrm{~d}} U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}} U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

Again, in the cases where the log-likelihood is high, and so the sensitivity to model is low, the tractable approximation in the near-natural, high relative entropy case may be reasonably close.

### 5.5.12 Tractable functional definition set induction

In section 'Uniform possible derived functional definition set induction' it is shown that the maximum likelihood estimate for the model, $\tilde{F}_{\mathrm{o}}$, is computable,
if an approximation is used for the fud-independent, $A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}(F)}$,

$$
\begin{array}{r}
\tilde{F}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(F, \frac{1}{\left|\operatorname{ran}\left(D_{U, \mathrm{i}, F, z_{\mathrm{o}}}\right)\right|} \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in D_{U, i, F, z_{\mathrm{o}}}^{-1}\left(D_{U, F, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)\right)} Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)(B)}\right):\right.\right. \\
\left.\left.F \in \mathcal{F}_{U, V_{\mathrm{o}}}, \exists T \in F\left(W_{T}=W_{F}\right), A_{\mathrm{o}}=Z_{1 /|F|} * \sum_{T \in F} A_{\mathrm{o}} * T_{F} * T_{F}^{\dagger}\right\}\right)
\end{array}
$$

However, the computation is not tractable. Insofar as the uniform possible iso-fud history probability function approximates to the specialising fud history probability function, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, F_{\mathrm{o}}} \approx P_{U, X, \mathrm{G}, F_{o}, \mathrm{H}}$, consider instead computing the maximum likelihood estimate for the model, $\tilde{F}_{\mathrm{o}}$, for specialising fud induction,

$$
\tilde{F}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(F, \hat{Q}_{\mathrm{G}, F, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): F \in \mathcal{F}_{U, V_{\mathrm{o}}}\right\}\right)
$$

or

$$
\tilde{F}_{\mathrm{o}} \in \operatorname{mind}\left(\left\{\left(F, C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~F}, \mathrm{H}}\left(F^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right): F \in \mathcal{F}_{U, V_{\mathrm{o}}}\right\}\right)
$$

This computation is more tractable, because there is no need to compute the derived set function, $D_{U, \mathbf{i}, F, z_{0}}$. However, it is still necessary to compute the set of substrate fuds, $\mathcal{F}_{U, V_{o}}$, and so the computation of the minimum coder space is still intractable.

It is conjectured in section 'Artificial neural networks and Compression', above, that the properties of the minimum coder space of the specialising fud substrate history coder, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}$, are similar, in some supervised cases of search parameters $P \in \mathcal{L}(\mathcal{X})$ and histogram $A \in \mathcal{A}_{U, \mathrm{i}, V, z}$, to the properties of the minimum least squares loss of the least squares gradient descent substrate net tree searcher, $Z_{P, A, \mathrm{gr}, \mathrm{lsq}}$.

Let the set of artificial neural networks be defined
nets $:=\{G: G \in \mathcal{L}(\mathrm{P}(\mathcal{V}) \times \mathcal{V} \times \mathcal{L}(\mathbf{R})), \forall(\cdot,(V, \cdot, Q)) \in G(|Q|=|V|+1)\}$
Define the graph, graph $\in$ nets $\rightarrow \mathcal{L}(\mathrm{P}(\mathcal{V}) \times \mathcal{V})$ as

$$
\operatorname{graph}(G):=\{(i,(V, w)):(i,(V, w, \cdot)) \in G\}
$$

Define the real weights, weights $\in$ nets $\rightarrow \mathcal{L}(\mathbf{R})$ as

$$
\text { weights }(G):=\operatorname{concat}(\{(i, Q):(i,(\cdot, \cdot, Q)) \in G\})
$$

Define the set of transforms, fud $(\sigma) \in$ nets $\rightarrow \mathrm{P}\left(\mathcal{T}_{\mathrm{f}}\right)$ as

$$
\begin{aligned}
& \operatorname{fud}(\sigma)(G):= \\
& \qquad \begin{array}{l}
\left\{\left(\left\{S^{V} \cup\left\{\left(w, \sigma\left(\sum_{i \in\{1 \ldots n\}} Q_{i} S_{i}+Q_{n+1}\right)\right)\right\}: S \in \mathbf{R}^{n}\right\} \times\{1\},\{w\}\right):\right. \\
\\
\quad(\cdot,(V, w, Q)) \in G, n=|V|\}
\end{array}
\end{aligned}
$$

where the activation function is $\sigma \in \mathbf{R}: \rightarrow \mathbf{R}$.
The least squares gradient descent substrate net tree searcher is defined

$$
Z_{P, A, \mathrm{gr}, \mathrm{lsq}}=\operatorname{searchTreer}\left(\operatorname{nets}(U, K, \sigma), P_{P, A, \mathrm{gr}, \mathrm{lsq}},\left\{G_{R}\right\}\right)
$$

where (i) the substrate net set is nets $(U, V, \sigma)=\{G: G \in \operatorname{nets}$, $\operatorname{fud}(\sigma)(G) \in$ $\left.\mathcal{F}_{\infty, U, V}\right\}$, (ii) the initial substrate net is $G_{R} \in \operatorname{nets}(U, K, \sigma)$, (iii) the neighbourhood function is

$$
\begin{aligned}
& P_{P, A, \mathrm{gr}, \mathrm{lsq}}(G)=\left\{G^{\prime}: \operatorname{lsq}(\sigma)(A, G, K)>t,\right. \\
& \quad G^{\prime} \in \operatorname{nets}(U, K, \sigma), \operatorname{graph}\left(G^{\prime}\right)=\operatorname{graph}(G), \\
& Q=\operatorname{weights}(G), Q^{\prime}=\operatorname{weights}\left(G^{\prime}\right), \\
& \left.Q^{\prime}=\left\{\left(i, Q_{i}-r \times \operatorname{dlsq}(\sigma)(i)(A, G, K)(Q)\right): i \in\{1 \ldots|Q|\}\right\}\right\}
\end{aligned}
$$

(iv) the loss threshold is $t \in \operatorname{set}(P)$, (v) the rate of descent is $r \in \operatorname{set}(P)$, (vi) the activation function is $\sigma \in \operatorname{set}(P)$, (vii) the query variables are $K \in$ $\operatorname{set}(P)$, (viii) the least squares loss function of the fud lsq $\in \mathcal{A} \times \mathcal{F} \times \mathrm{P}(\mathcal{V}) \rightarrow \mathbf{R}$ is

$$
\operatorname{lsq}(A, F, K):=\sum_{(S, c) \in A * X_{F}}\left(c \times \sum_{i \in\{1 \ldots m\}}\left(\left(S \% W_{F}\right)_{i}^{\square}-(S \%(V \backslash K))_{i}^{\square}\right)^{2}\right)
$$

(ix) the derived dimension is $m=\left|W_{F}\right|=|(V \backslash K)|$, (x) the least squares loss function of the net $\operatorname{lsq}(\sigma) \in \mathcal{A} \times$ nets $\times \mathrm{P}(\mathcal{V}) \rightarrow \mathbf{R}$ is

$$
\operatorname{lsq}(\sigma)(A, G, K):=\operatorname{lsq}(A, \operatorname{fud}(\sigma)(G), K)
$$

and (xi) the derivative with respect to the $i$-th weight is $\operatorname{dlsq}(\sigma)(i) \in \mathcal{A} \times$ nets $\times \mathrm{P}(\mathcal{V}) \rightarrow(\mathcal{L}(\mathbf{R}) \rightarrow \mathbf{R})$.

The fud minimum space specialising fud search function for history $H \in \mathcal{H}_{U, X}$ is defined in terms of the expanded specialising fud history coder, $C_{\mathrm{G}, \mathrm{F}, \mathrm{H}}(F) \in$ $\operatorname{coders}\left(\mathcal{H}_{U, X}\right)$, as

$$
Z_{\mathrm{F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{~F}, \mathrm{H}}(H)=\left\{\left(F,-C_{\mathrm{G}, \mathrm{~F}, \mathrm{H}}(F)^{\mathrm{s}}(H)\right): F \in \mathcal{F}_{U, \mathrm{P}}\right\}
$$

It is maximised by finding the fud $F \in \mathcal{F}_{U, \mathrm{P}}$ which minimises the specialising fud substrate history coder space, $C_{\mathrm{G}, V, \mathrm{~F}, \mathrm{H}}\left(F^{V}\right)^{\mathrm{s}}(H)$ where $V=\operatorname{vars}(H)$.

The least squares gradient descent substrate net tree searcher, $Z_{P, A, \mathrm{gr}, \mathrm{lsq}}$, also defines a fud search function, but restricted to the neural net substrate fud set, $\mathcal{F}_{\infty, U, V, \sigma}=\mathcal{F}_{\infty, U, V} \cap(\operatorname{fud}(\sigma) \circ$ nets $)$. Let history $H \in \mathcal{H}_{U, X}$ be such that its histogram $A=\operatorname{histogram}(H)$ satisfies the supervised constraints, of (i) real valued variables, (ii) causal histogram, and (iii) a literal frame, imposed by the search parameters $P$ of the least squares gradient descent substrate net tree searcher, $Z_{P, A, \mathrm{gr}, \mathrm{lsq}}$. Define the least squares gradient descent fud search function as

$$
\begin{aligned}
& Z_{\mathrm{F}, \mathrm{P}, P, \mathrm{gr}, \mathrm{lsq}}(H)= \\
& \quad\left\{(\operatorname{fud}(\sigma)(G),-\operatorname{lsq}(\sigma)(A, G, K)): Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, \mathrm{gr}, \mathrm{lsq}}\right)\right),\{G\}=Q\right\}
\end{aligned}
$$

In section 'Artificial neural networks and Compression' it is conjectured that, given search parameters $P$, there sometimes exists a subset of histories $\mathcal{H}_{U, X, P} \subset \mathcal{H}_{U, X}$ satisfying the constraints of (i) real valued variables, (ii) causal histogram, (iii) a literal frame, and (iv) clustered histogram such that there is a positive correlation between the least squares gradient descent fud search function, $Z_{\mathrm{F}, \mathrm{P}, P, \mathrm{gr}, \mathrm{ls}}$, and the fud minimum space specialising fud search function, $Z_{\mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{F}, \mathrm{H}}$,

$$
\operatorname{covariance}\left(P_{U, X, P}\right)\left(\operatorname{maxr} \circ Z_{\mathrm{F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{~F}, \mathrm{H}}, \operatorname{maxr} \circ Z_{\mathrm{F}, \mathrm{P}, P, \mathrm{gr}, \mathrm{lsq}}\right) \geq 0
$$

where $P_{U, X, P}=\mathcal{H}_{U, X, P} \times\left\{1 /\left|\mathcal{H}_{U, X, P}\right|\right\}$. The generalisation of a correlation to all cases of finite systems and finite event identifier sets cannot be made because the history, $H$, is not independent of the search parameters, $P$. Least squares gradient descent supervised neural net optimisation requires specific configuration for each history.

The discussion considers the relations between the negative least squares loss and the specialising space. In the computations of alignment and entropy that follow, the derived variables are discretised to the values of the label variables, $D=\cup\left\{U_{v}: v \in(V \backslash K)\right\}$. It is shown that the negative least squares loss (a) varies against the derived entropy of the fud transform,

$$
-\operatorname{lsq}\left(A, F_{D}, K\right) \sim-\operatorname{entropy}\left(A * F_{D}^{\mathrm{T}}\right)
$$

(b) varies against the effective derived volume

$$
-\operatorname{lsq}\left(A, F_{D}, K\right) \sim-\left|\left(A * F_{D}^{\mathrm{T}}\right)^{\mathrm{F}}\right|
$$

(c) varies with the expected component entropy,

$$
-\operatorname{lsq}\left(A, F_{D}, K\right) \sim \text { entropyComponent }\left(A, F_{D}^{\mathrm{T}}\right)
$$

and (d) varies with the component size cardinality relative entropy,

$$
-\operatorname{lsq}\left(A, F_{D}, K\right) \sim \text { entropyRelative }\left(A * F_{D}^{\mathrm{T}}, V^{\mathrm{C}} * F_{D}^{\mathrm{T}}\right)
$$

This last property only holds where the histogram is clustered by the label variables, which requires alignment within the query variables, algn $(A \% K)>$ 0.

The discussion goes on to consider the relations between the negative least squares loss and the specialising fud space with regard to the entropy properties by layer. That is, the least squares gradient descent fud search function is also such that (a) the derived entropy decreases up the layers,

$$
\forall i \in\{2 \ldots l\}\left(\operatorname{entropy}\left(A * F_{\{1 \ldots i\}, D}^{\mathrm{T}}\right)<\operatorname{entropy}\left(A * F_{\{1 \ldots i-1\}, D}^{\mathrm{T}}\right)\right)
$$

(b) the effective derived volume decreases up the layers,

$$
\forall i \in\{2 \ldots l\}\left(\left|\left(A * F_{\{1 . . . i\}, D}^{\mathrm{T}}\right)^{\mathrm{F}}\right|<\left|\left(A * F_{\{1 \ldots i-1\}, D}^{\mathrm{T}}\right)^{\mathrm{F}}\right|\right)
$$

(c) the expected component entropy increases up the layers,

```
\(\forall i \in\{2 \ldots l\}\)
    (entropyComponent \(\left.\left(A, F_{\{1 \ldots i\}, D}^{\mathrm{T}}\right)>\operatorname{entropyComponent}\left(A, F_{\{1 \ldots i-1\}, D}^{\mathrm{T}}\right)\right)\)
```

and (d) the component size cardinality relative entropy increases up the layers,

```
\(\forall i \in\{2 \ldots l\}\)
    (entropyRelative \(\left(A * F_{\{1 . . . i\}, D}^{\mathrm{T}}, V_{D}^{\mathrm{C}} * F_{\{1 . . . i\}, D}^{\mathrm{T}}\right)>\)
        entropyRelative \(\left.\left(A * F_{\{1 . . i-1\}, D}^{\mathrm{T}}, V_{D}^{\mathrm{C}} * F_{\{1 \ldots i-1\}, D}^{\mathrm{T}}\right)\right)\)
```

Given this evidence for the correlation in some cases between the fud minimum space specialising fud search function, $Z_{\mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{F}, \mathrm{H}}$, and the least squares gradient descent fud search function, $Z_{\mathrm{F}, \mathrm{P}, P, \mathrm{gr}, \mathrm{lsq}}$, conjecture that, in the case where the model, $F_{\mathrm{o}}$, is unknown, the maximum likelihood estimate for the model for specialising induction,

$$
\tilde{F}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(F, \hat{Q}_{\mathrm{G}, F, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): F \in \mathcal{F}_{U, V_{\mathrm{o}}}\right\}\right)
$$

or

$$
\tilde{F}_{\mathrm{o}} \in \operatorname{mind}\left(\left\{\left(F, C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~F}, \mathrm{H}}\left(F^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right): F \in \mathcal{F}_{U, V_{\mathrm{o}}}\right\}\right)
$$

can be tractably approximated by the maximisation of the least squares gradient descent fud search function,

$$
\tilde{F}_{\mathrm{o}} \approx F_{\mathrm{o}, \mathrm{gr}, \mathrm{lsq}}
$$

where

$$
F_{\mathrm{o}, \mathrm{gr}, \mathrm{lsq}} \in \operatorname{maxd}\left(Z_{\mathrm{F}, \mathrm{P}, P_{\mathrm{o}}, \mathrm{gr}, \mathrm{lsq}}\left(H_{\mathrm{o}}\right)\right)
$$

and the search parameters, $P_{\mathrm{o}}$, are configured for the given sample history, $H_{0}$.

The tractable model is defined explicitly, $F_{\mathrm{o}, \mathrm{gr}, \mathrm{lsq}}=\operatorname{fud}(\sigma)(G)$ where $\{G\}=$ leaves $\left(\operatorname{tree}\left(Z_{P_{\mathrm{o}}, A_{\mathrm{o}}, \mathrm{gr}, \mathrm{lsq}}\right)\right)$.

The accuracy of the approximation can be defined as the ratio of the tractable model specialising likelihood to the maximum model specialising likelihood,

$$
0<\frac{\hat{Q}_{\mathrm{G}, F_{\mathrm{o}}, \mathrm{gr}, \mathrm{ls}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{F}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \leq 1
$$

The accuracy varies against the sensitivity to model,
$\frac{\hat{Q}_{\mathrm{G}, F_{\mathrm{F}, \mathrm{g}, \mathrm{l}, \mathrm{s} q} \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{F}_{\mathrm{F}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \sim-\left(-\ln \left|\max \left(\left\{\left(F, \hat{Q}_{\mathrm{G}, F, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): F \in \mathcal{F}_{U, V_{o}}\right\}\right)\right|\right)$
and varies with the log-likelihood,

$$
\frac{\hat{Q}_{\mathrm{G}, F_{\mathrm{o}, \mathrm{gr}, \mathrm{ls}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}}{\hat{Q}_{\mathrm{G}, \tilde{F}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \sim \ln \hat{Q}_{\mathrm{G}, F_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

That is, although the model obtained from the least squares gradient descent fud search function is merely an approximation, in the cases where the loglikelihood is high, and so the sensitivity to model is low, the approximation may be reasonably close nonetheless.

It is shown above in classical uniform possible fud induction, where the history probability function is uniform possible iso-fud historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, F_{\mathrm{o}}}$, that, in the case where (i) the size is less than the volume, $z_{\mathrm{o}}<v_{\mathrm{o}}$, but the sample approximates to the fud-independent, $A_{\mathrm{o}} \approx A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}\left(F_{\mathrm{o}}\right)}$, and (ii) the maximum likelihood estimate relative entropies are high, $\forall T \in$ $F_{\mathrm{o}}\left(\right.$ entropy $\left.\operatorname{Cross}\left(A_{\mathrm{o}} * T_{F_{\mathrm{o}}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{F_{\mathrm{o}}}\right)>\ln \left|T_{F_{\mathrm{o}}}^{-1}\right|\right)$, (a) the log likelihood of the iso-fud conditional stuffed historical probability distribution at the maximum likelihood estimate varies against the specialising fud substrate history coder space,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~F}, \mathrm{H}}\left(F_{\mathrm{o}}^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)
$$

(b) the sensitivity to distribution varies against the log likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{o}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

and (c) the sensitivity to model varies against the log likelihood,
$-\ln \mid \max \left(\left\{\left(F, \hat{Q}_{\mathrm{h}, \mathrm{d}, F, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right.$

$$
\begin{aligned}
& F \in \mathcal{F}_{U, V_{\mathrm{o}}}, \exists T \in F\left(W_{T}=W_{F}\right), A_{\mathrm{o}} \\
&\left.\left.\approx A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}(F)}\right\}\right) \mid \sim \\
&-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
\end{aligned}
$$

Insofar as the uniform possible iso-fud history probability function approximates to the specialising history probability function, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, F_{\mathrm{o}}} \approx P_{U, X, \mathrm{G}, F_{\mathrm{o}}, \mathrm{H}}$, conjecture that the model, $F_{\mathrm{o}, \mathrm{gr}, \mathrm{lsq}}$, obtained by the maximisation of the least squares gradient descent fud search function, $Z_{\mathrm{F}, \mathrm{P}, P, \mathrm{gr}, \mathrm{lsq}}$, is also a tractable approximation to the maximum likelihood estimate for the model for uniform possible iso-fud induction,

$$
\begin{aligned}
& \tilde{F}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(F, \hat{Q}_{\mathrm{h}, \mathrm{~d}, F, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right. \\
& \left.\left.\quad F \in \mathcal{F}_{U, V_{\mathrm{o}}}, \exists T \in F\left(W_{T}=W_{F}\right), A_{\mathrm{o}} \approx A_{\mathrm{o}}^{\mathrm{E} F}(F)\right\}\right)
\end{aligned}
$$

That is, in the near-natural, high relative entropy case, a tractable maximum likelihood estimate for the model may be obtained for classical modelled induction by optimisation of the least squares gradient descent fud search,

$$
\tilde{F}_{\mathrm{o}} \approx F_{\mathrm{o}, \mathrm{gr}, \mathrm{lsq}}
$$

The accuracy of the approximation can be defined as the ratio of the tractable model uniform possible iso-fud likelihood to the maximum model uniform possible iso-fud likelihood,

$$
\left.0<\frac{\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, \mathrm{gr}, \mathrm{lsq}}, U}{}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \right\rvert\, \hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{F}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \quad \leq 1
$$

Just as the tractable model specialising accuracy varies with the log-likelihood, so too does the tractable model uniform possible iso-fud accuracy,

$$
\frac{\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}, \mathrm{gr}, \mathrm{ls}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{F}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, \tilde{z}_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

Again, in the cases where the log-likelihood is high, and so the sensitivity to model is low, the tractable approximation in the near-natural, high relative entropy case may be reasonably close.

### 5.5.13 Tractable functional definition set decomposition induction

In section 'Uniform possible derived functional definition set decomposition induction' it is shown that the maximum likelihood estimate for the model, $\tilde{D}_{\mathrm{o}}$, is computable, if an approximation is used for the fud-decompositionindependent, $A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}(D)}$,
$\tilde{D}_{\mathrm{o}} \in$

$$
\begin{array}{r}
\operatorname{maxd}\left(\left\{\left(D, \frac{1}{\left|\operatorname{ran}\left(D_{\left.U, i, D, F, z_{\mathrm{o}}\right)}\right)\right|} \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in D_{U, i, D, \mathrm{~F}, z_{\mathrm{o}}}^{-1}\left(D_{U, D, \mathrm{~F}, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)\right)} Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)(B)}\right):\right.\right. \\
D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}, \forall F \in \operatorname{fuds}(D) \exists T \in F\left(W_{T}=W_{F}\right), \\
\left.\left.A_{\mathrm{o}}=Z_{z_{\mathrm{o}}} *\left(\sum_{(C, F) \in \operatorname{cont}(D)}\left(Z_{1 /|F|} * \sum_{T \in F} A_{\mathrm{o}} * C * T_{F} * T_{F}^{\dagger}\right)\right)^{\wedge}\right\}\right)
\end{array}
$$

However, the computation is not tractable. Insofar as the uniform possible iso-fud-decomposition history probability function approximates to the specialising fud decomposition history probability function, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, D_{\mathrm{o}}} \approx$ $P_{U, X, \mathrm{G}, D_{\mathrm{o}}, \mathrm{H}}$, consider instead computing the maximum likelihood estimate for the model, $\tilde{D}_{\mathrm{o}}$, for specialising fud decomposition induction,

$$
\tilde{D}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(D, \hat{Q}_{\mathrm{G}, D, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}}\right\}\right)
$$

or

$$
\tilde{D}_{\mathrm{o}} \in \operatorname{mind}\left(\left\{\left(D, C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right): D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}}\right\}\right)
$$

This computation is more tractable, because there is no need to compute the component derived set function, $D_{U, i, D, F, z_{o}}$. However, it is still necessary to compute the set of substrate fud decompositions, $\mathcal{D}_{\mathrm{F}, U, V_{o}}$, and so the computation of the minimum coder space is still intractable.

Section 'Tractable transform induction', above, also considers tractable approximations to the model for uniform possible derived induction, where the model is a transform instead of a fud decomposition. There it is shown that there are tractable and practicable inducers that have entropy properties similar to the entropy properties of the specialising coder. The tractable models then approximate to the maximum likelihood estimate model in specialising induction and thence uniform possible derived induction.

Section 'Tractable functional definition set induction', above, extended the model from transforms to fuds. Rather than approximating to tractable models derived from inducers, it is shown that, in some cases, artificial neural networks can provide approximations to the model in specialising fud induction and thence uniform possible derived fud induction.

Now the model is extended to fud decompositions. Tractable functional definition set decomposition induction is more closely related to tractable transform induction than tractable fud induction because again tractable and practicable inducers are shown to provide approximations to the model in specialising fud decomposition induction and thence uniform possible derived fud decomposition induction.

It is conjectured in section 'Inducers and Compression', above, that the properties of the minimum coder space of the specialising fud decomposition substrate history coder, $C_{\mathrm{G}, V, \mathrm{D}, \mathrm{F}, \mathrm{H}}$, are similar in many ways to the properties of the maximum summed shuffle content alignment valency-density of the practicable highest-layer summed shuffle content alignment valency-density fud decomposition inducer,

$$
I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime} \in \operatorname{inducers}(z)
$$

Given parameter tuple $P \in \mathcal{L}(\mathcal{X})$ and substrate histogram $A \in \mathcal{A}_{z}$, the practicable fud decomposition inducer is defined in section 'Optimisation', above, as

$$
\begin{aligned}
& I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}(A)= \\
& \operatorname{if}\left(Q \neq \emptyset,\left\{\left(D, I_{\text {Scsd }}^{*}((A, D))\right)\right\},\left\{\left(D_{\emptyset}, 0\right)\right\}\right): \\
& \quad Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{~d}}\right)\right),\{D\}=Q
\end{aligned}
$$

where the summed shuffle content alignment valency-density computer $I_{\text {Scsd }} \in$ computers is defined as

$$
\begin{aligned}
& I_{\mathrm{Scsd}}^{*}((A, D))= \\
& \quad \sum\left(I_{\mathrm{a}}^{*}\left(A * C * F^{\mathrm{T}}\right)-I_{\mathrm{a}}^{*}\left((A * C)_{R(A * C)} * F^{\mathrm{T}}\right)\right) / I_{\mathrm{cv1}}^{*}(F):(C, F) \in \operatorname{cont}(D)
\end{aligned}
$$

The fud decomposition minimum space specialising fud decomposition search function is defined in terms of the expanded specialising fud decomposition history coder $C_{\mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}(D) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$,

$$
Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}(H)=\left\{\left(D,-C_{\mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}(D)^{\mathrm{s}}(H)\right): D \in \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}\right\}
$$

The search function is maximised by finding the fud decomposition $D \in$ $\mathcal{D}_{\mathrm{F}, U, \mathrm{P}}$ which minimises the specialising fud decomposition substrate history coder space, $C_{\mathrm{G}, V, \mathrm{D}, \mathrm{F}, \mathrm{H}}\left(D^{V}\right)^{\mathrm{s}}(H)$ where $V=\operatorname{vars}(H)$.

The highest-layer summed shuffle content alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Scs}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}$, also defines a fud decomposition search function. Define the practicable highest-layer summed shuffle content alignment valency-density fud decomposition search function

$$
\begin{aligned}
& Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{q}, \mathrm{~d}, P, \mathrm{Scsd}}(H)= \\
& \quad\left\{\left(D, I_{\mathrm{Scsd}}^{*}\left(\left(A_{H}, D\right)\right)\right): Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A_{H}, \mathrm{D}, \mathrm{~F}, \mathrm{~d}}\right)\right), Q \neq \emptyset,\{D\}=Q\right\} \cup \\
& \quad\left\{\left(D_{\mathrm{u}}, 0\right)\right\}
\end{aligned}
$$

where unary fud decomposition $D_{\mathrm{u}}=\left\{\left(\left(\emptyset,\left\{T_{\mathrm{u}}\right\}\right), \emptyset\right)\right\}$.
In section 'Inducers and Compression', it is conjectured that for all finite systems and finite event identifier sets there exists a tuple of parameters such that the search functions are positively correlated for uniform history probability function,

$$
\begin{aligned}
& \forall U \in \mathcal{U} \forall X \subset \mathcal{X}\left(\left|\mathcal{H}_{U, X}\right|<\infty \Longrightarrow\right. \\
& \exists P \in \mathcal{L}(\mathcal{X})\left(\operatorname{covariance}\left(P_{U, X}\right)\right. \\
&\left.\left.\quad\left(\operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}, \operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{q}, \mathrm{~d}, P, \mathrm{Scsd}}\right) \geq 0\right)\right)
\end{aligned}
$$

The discussion considers the relations between the summed shuffle content alignment valency-density and the specialising space.

Depending on the parameters, $P$, which imply a set of limited-models, $\mathcal{F}_{\mathrm{q}} \subset$ $\mathcal{F}$, there is a high correlation between the practicable highest-layer summed shuffle content alignment valency-density fud decomposition inducer and the tractable summed alignment valency-density decomposition inducer,

$$
\operatorname{covariance}\left(P_{U, X}\right)\left(\operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{q}, \mathrm{~d}, P, \mathrm{Scsd}}, \operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}\right)
$$

so, given the relations between the summed alignment valency-density and the specialising space, it is conjectured that the summed shuffle content alignment valency-density (a) varies against the derived entropy of the nullable
transform,

$$
I_{\text {Scsd }}^{*}((A, D)) \sim-\operatorname{entropy}\left(A * D^{\mathrm{T}}\right)
$$

(b) varies against the possible derived volume $w^{\prime}=\left|\left(D^{\mathrm{T}}\right)^{-1}\right|$,

$$
I_{\mathrm{Scsd}}^{*}((A, D)) \sim 1 / w^{\prime}
$$

(c) varies with the expected component entropy,

$$
I_{\text {Scsd }}^{*}((A, D)) \sim \text { entropyComponent }\left(A, D^{\mathrm{T}}\right)
$$

and (d) varies with the component size cardinality relative entropy,

$$
I_{\mathrm{Scsd}}^{*}((A, D)) \sim \text { entropyRelative }\left(A * D^{\mathrm{T}}, V^{\mathrm{C}} * D^{\mathrm{T}}\right)
$$

The discussion goes on to consider the relations between the summed shuffle content alignment valency-density and the specialising fud decomposition space with regard to the entropy properties by layer and slice. That is, the summed shuffle content alignment valency-density is such that within each slice, $(C, F) \in \operatorname{cont}(D)$, (a) the derived entropy decreases up the layers,

$$
\forall i \in\{2 \ldots l\}\left(\operatorname{entropy}\left(A * C * F_{\{1 \ldots i\}}^{\mathrm{T}}\right)<\operatorname{entropy}\left(A * C * F_{\{1 \ldots i-1\}}^{\mathrm{T}}\right)\right)
$$

(b) the derived volume decreases up the layers,

$$
\forall i \in\{2 \ldots l\}\left(\left|W_{F, i}^{\mathrm{C}}\right|<\left|W_{F, i-1}^{\mathrm{C}}\right|\right)
$$

(c) the expected component entropy increases up the layers,

$$
\begin{aligned}
& \forall i \in\{2 \ldots l\} \\
& \quad\left(\operatorname{entropyComponent}\left(A * C, F_{\{1 \ldots i\}}^{\mathrm{T}}\right)>\operatorname{entropyComponent}\left(A * C, F_{\{1 . . i-1\}}^{\mathrm{T}}\right)\right)
\end{aligned}
$$

and (d) the component size cardinality relative entropy increases up the layers,
$\forall i \in\{2 \ldots l\}$
(entropyRelative $\left(A * C * F_{\{1 \ldots i\}}^{\mathrm{T}}, C * F_{\{1 \ldots i\}}^{\mathrm{T}}\right)>$

$$
\left.\operatorname{entropyRelative}\left(A * C * F_{\{1 \ldots i-1\}}^{\mathrm{T}}, C * F_{\{1 \ldots i-1\}}^{\mathrm{T}}\right)\right)
$$

Given this evidence for the correlation between the fud decomposition minimum space specialising fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}$, and the practicable highest-layer summed shuffle content alignment valencydensity fud decomposition search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{q}, \mathrm{d}, P, \mathrm{Scsd}}$, conjecture that, in
the case where the model, $D_{\mathrm{o}}$, is unknown, the maximum likelihood estimate for the model for specialising fud decomposition induction,

$$
\tilde{D}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(D, \hat{Q}_{\mathrm{G}, D, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}}\right\}\right)
$$

or

$$
\tilde{D}_{\mathrm{o}} \in \operatorname{mind}\left(\left\{\left(D, C_{\mathrm{G}, V_{o}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right): D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}}\right\}\right)
$$

can be tractably approximated by the maximisation of the practicable highestlayer summed shuffle content alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}$,

$$
\tilde{D}_{\mathrm{o}} \approx D_{\mathrm{o}, \mathrm{Scs}, P}
$$

where

$$
D_{\mathrm{o}, \mathrm{Scsd}, P} \in \operatorname{maxd}\left(I_{z_{\mathrm{o}}, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime *}\left(A_{\mathrm{o}}\right)\right)
$$

The tractable model is defined explicitly, $\left\{D_{\mathrm{o}, \mathrm{Scsd}, P}\right\}=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A_{0}, \mathrm{D}, \mathrm{F}, \mathrm{d}}\right)\right)$.
The accuracy of the approximation can be defined as the ratio of the tractable model specialising likelihood to the maximum model specialising likelihood,

$$
0<\frac{\hat{Q}_{\mathrm{G}, D_{\mathrm{o}}, \mathrm{Scsd}, P, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{D}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \leq 1
$$

The accuracy varies against the sensitivity to model,
$\frac{\hat{Q}_{\mathrm{G}, D_{\mathrm{o}, \mathrm{Scs}, P}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{D}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \sim-\left(-\ln \left|\max \left(\left\{\left(D, \hat{Q}_{\mathrm{G}, D, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}}\right\}\right)\right|\right)$
and varies with the log-likelihood,

$$
\frac{\hat{Q}_{\mathrm{G}, D_{\mathrm{o}}, \mathrm{Scs}, P, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{D}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \sim \ln \hat{Q}_{\mathrm{G}, D_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

That is, although the model obtained from the practicable highest-layer summed shuffle content alignment valency-density fud decomposition inducer is merely an approximation, in the cases where the log-likelihood is high, and so the sensitivity to model is low, the approximation may be reasonably close nonetheless.

Given that, depending on the parameters, $P$, there is a high correlation between the practicable highest-layer summed shuffle content alignment valency-density fud decomposition inducer and the tractable summed alignment valency-density decomposition inducer,

$$
\operatorname{covariance}\left(P_{U, X}\right)\left(\operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{q}, \mathrm{~d}, P, \mathrm{Scsd}}, \operatorname{maxr} \circ Z_{\mathrm{D}, \mathrm{~F}, \mathrm{P}, \mathrm{n}, \mathrm{q}, \mathrm{Sd}}\right)
$$

consider the tractable model obtained by maximisation of the summed alignment valency-density of the tractable summed alignment valency-density decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$,

$$
D_{\mathrm{o}, \mathrm{Sd}} \in \operatorname{maxd}\left(I_{z_{\mathrm{o}}, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}\left(A_{\mathrm{o}}\right)\right)
$$

The tractable model, $D_{\mathrm{o}, \mathrm{Sd}}$, is defined explicitly,

$$
\begin{aligned}
& D_{\mathrm{o}, \mathrm{Sd}} \in \operatorname{maxd}\left(\left\{\left(D, I_{\approx \mathrm{R}}^{*}\left(\operatorname{algnValDensSum}(U)\left(A_{\mathrm{o}}, D^{\mathrm{D}}\right)\right)\right):\right.\right. \\
& \quad D \in \mathcal{D}_{\mathrm{F}, \infty, U, V_{\mathrm{o}}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right) \\
& \left.\left.\forall(C, F) \in \operatorname{cont}(D)\left(\operatorname{algn}\left(A_{\mathrm{o}} * C * F^{\mathrm{T}}\right)>0\right)\right\}\right)
\end{aligned}
$$

The entropy properties of the tractable fud decomposition inducer do not depend directly on the transforms of the fuds of the decomposition, only on the transform of the decomposition, $D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}$. There is no constraint that the derived entropy and the possible derived volume decreases up the layers, nor any constraint that the expected component entropy increases up the layers. There is no sense that the fuds are built layer by layer in sequence. Hence conjecture that the accuracy is less than that of the practable fud decomposition inducer,

$$
\frac{\hat{Q}_{\mathrm{G}, D_{\mathrm{o}, \mathrm{Sd}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{D}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}<\frac{\hat{Q}_{\mathrm{G}, D_{\mathrm{o}}, \mathrm{Scs}, P, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{D}_{\mathrm{o}}, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}
$$

It is shown above in classical uniform possible fud decomposition induction, where the history probability function is uniform possible iso-fud-decomposition historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, D_{o}}$, that, in the case where (i) the size is less than the volume, $z_{0}<v_{0}$, but the sample approximates to the fud-decomposition-independent, $A_{\mathrm{o}} \approx A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{F}}\left(D_{\mathrm{o}}\right)}$, and (ii) the maximum likelihood estimate relative entropies are high, $\forall(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right) \forall T \in$ $F$ (entropyCross $\left.\left(A_{\mathrm{o}} * C * T_{F}, C * T_{F}\right)>\ln \left|T_{F}^{-1}\right|\right)$, (a) the log likelihood of the iso-fud-decomposition conditional stuffed historical probability distribution at the maximum likelihood estimate varies against the specialising fud substrate history coder space,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D_{\mathrm{o}}^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)
$$

(b) the sensitivity to distribution varies against the log likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

and (c) the sensitivity to model varies against the log likelihood,
$-\ln \mid \max \left(\left\{\left(D, \hat{Q}_{\mathrm{h}, \mathrm{d}, D, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right.$

$$
\begin{aligned}
D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}, \forall F \in \operatorname{fuds}(D) \exists T \in F & \left(W_{T}=W_{F}\right), \\
A_{\mathrm{o}} & \left.\left.\approx A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{~F}}(D)}\right\}\right) \mid \sim \\
& -\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
\end{aligned}
$$

Insofar as the uniform possible iso-fud-decomposition history probability function approximates to the specialising history probability function, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, D_{\mathrm{o}}} \approx$ $P_{U, X, \mathrm{G}, D_{\mathrm{o}}, \mathrm{H}}$, conjecture that the model, $D_{\mathrm{o}, \mathrm{Scs}, P}$, obtained by the maximisation of the practicable highest-layer summed shuffle content alignment valencydensity fud decomposition inducer, $I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}$, is also a tractable approximation to the maximum likelihood estimate for the model for uniform possible iso-fud-decomposition induction,

$$
\begin{aligned}
& \tilde{D}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(D, \hat{Q}_{\mathrm{h}, \mathrm{~d}, D, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right. \\
& D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}, \forall F \in \operatorname{fuds}(D) \exists T \in F\left(W_{T}=W_{F}\right), \\
& A_{\mathrm{o}}\left.\left.\approx A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{o}, \mathrm{~F}}(D)}\right\}\right)
\end{aligned}
$$

That is, in the near-natural, high relative entropy case, a tractable maximum likelihood estimate for the model may be obtained for classical modelled induction by optimisation of the practicable highest-layer summed shuffle content alignment valency-density fud decomposition inducer,

$$
\tilde{D}_{\mathrm{o}} \approx D_{\mathrm{o}, \mathrm{Scs}, P}
$$

The accuracy of the approximation can be defined as the ratio of the tractable model uniform possible iso-fud-decomposition likelihood to the maximum model uniform possible iso-fud-decomposition likelihood,

$$
0<\frac{\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}, \mathrm{Scss}, P}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{D}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \leq 1
$$

Just as the tractable model specialising accuracy varies with the log-likelihood, so too does the tractable model uniform possible iso-fud-decomposition accuracy,

$$
\frac{\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}, \mathrm{Scs}, P}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{D}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

Again, in the cases where the log-likelihood is high, and so the sensitivity to model is low, the tractable approximation in the near-natural, high relative entropy case may be reasonably close.

### 5.6 Aligned induction

Having considered the case of classical non-modelled induction, where the history probability function is historically distributed, $P=P_{U, X, H_{\mathrm{h}}}$, now consider the special case of aligned non-modelled induction.

In aligned induction, while the distribution probability histogram, $\hat{E}_{\mathrm{h}}$, remains unknown, the independent distribution probability histogram, $\hat{E}_{\mathrm{h}}^{\mathrm{X}}$, is necessary. Now the history probability function, $P$, is historically distributed but constrained such that all drawn histories have an independent probability histogram equal to the reduced independent distribution probability histogram, $\hat{A}_{H}^{\mathrm{X}}=\hat{E}_{\mathrm{h}}^{\mathrm{X}} \% V_{H}$. Define the iso-independent historically distributed history probability function $P_{U, X, H_{\mathrm{h}}, \mathrm{Y}} \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}$,

$$
\begin{aligned}
& P_{U, X, H_{\mathrm{h}}, \mathrm{y}}:= \\
& \qquad \begin{array}{l}
\quad \bigcup\left\{\left\{(H, 1): H \subseteq H_{\mathrm{h}} \% V_{H},|H|=z_{H}, \hat{A}_{H}^{\mathrm{x}}=\hat{E}_{\mathrm{h}}^{\mathrm{x}} \% V_{H}\right\}^{\wedge}:\right. \\
\left.\left.\quad V_{H} \subseteq V_{\mathrm{h}}, z_{H} \in\left\{1 \ldots z_{\mathrm{h}}\right\}\right\}\right)^{\wedge} \cup \\
\left\{(H, 0): H \in \mathcal{H}_{U, X}, \hat{A}_{H}^{\mathrm{X}} \neq \hat{E}_{\mathrm{h}}^{\mathrm{x}} \% V_{H}\right\} \cup \\
\left\{(H, 0): H \in \mathcal{H}_{U, X}, H \nsubseteq H_{\mathrm{h}} \% V_{H}\right\} \cup\{(\emptyset, 0)\}
\end{array}
\end{aligned}
$$

That is, drawn histories necessarily have normalised independent histogram equal to that of the distribution histogram, $\forall H \in \mathcal{H}_{U, X}\left(P_{U, X, H_{\mathrm{h}}, y}(H)>\right.$ $\left.0 \Longrightarrow \hat{A}_{H}^{\mathrm{X}}=\hat{E}_{\mathrm{h}}^{\mathrm{X}} \% V_{H}\right)$.

In aligned induction the history probability function is iso-independent historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{y}}$.

The independent distribution probability histogram reduced to observation variables, $\hat{E}_{\mathrm{o}}^{\mathrm{X}}=\hat{E}_{\mathrm{h}}^{\mathrm{X}} \% V_{\mathrm{o}}$, is known, $\hat{E}_{\mathrm{o}}^{\mathrm{X}}=\hat{A}_{\mathrm{o}}^{\mathrm{X}}$.

Given a drawn history $H \in \mathcal{H}_{U, X}$, where $P_{U, X, H_{\mathrm{h}}, \mathrm{y}}(H)>0$, the iso-independent historical probability of histogram $A_{H}=\operatorname{histogram}(H)+V_{H}^{\mathrm{CZ}} \in \mathcal{A}_{U, \mathrm{i}, V_{H}, z_{H}}$ is now conditional,

$$
\begin{aligned}
& \frac{Q_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right)}{\sum_{B \in Y_{U, i, V_{0}, z_{H}}^{-1}\left(A_{H}^{\mathrm{X}}\right)} Q_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)(B)}= \\
& \frac{\sum P_{U, X, H_{\mathrm{h}, \mathrm{y}}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}}{\sum P_{U, X, H_{\mathrm{h}}, \mathrm{y}}(G): G \in \mathcal{H}_{U, X}, V_{G}=V_{H},|G|=z_{H}}
\end{aligned}
$$

The iso-derived historical probability may be expressed in terms of a histogram distribution which is not explicitly conditional on the necessary independent,
$\hat{E}_{\mathrm{o}}^{\mathrm{X}}$,

$$
\hat{Q}_{\mathrm{h}, \mathrm{y}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right) \propto \sum\left(P_{U, X, H_{\mathrm{h}, \mathrm{y}}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}\right)
$$

where the iso-independent conditional stuffed historical probability distribution is defined

$$
\begin{aligned}
\hat{Q}_{\mathrm{h}, \mathrm{y}, U} & (E, z) \\
:= & \left\{\left(A, \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum_{B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)} Q_{\mathrm{h}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \leq E\right\}^{\wedge} \cup \\
& \left\{(A, 0): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \not \leq E\right\}
\end{aligned}
$$

which is defined if $z \leq \operatorname{size}(E)$. The independent histogram valued integral histogram function $Y_{U, \mathrm{i}, V, z}$ is defined

$$
Y_{U, \mathrm{i}, V, z}=\left\{\left(A, A^{\mathrm{X}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\} \subset \text { independent }
$$

The finite set of iso-independents of independent histogram $A^{\mathrm{X}}$ is

$$
Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{X}}=A^{\mathrm{X}}\right\}
$$

In the case where all the independent are possible,

$$
\forall A^{\prime} \in \operatorname{ran}\left(Y_{U, \mathbf{i}, V, z}\right) \exists A \in \mathcal{A}_{U, \mathbf{i}, V, z}\left(\left(A^{\mathrm{X}}=A^{\prime}\right) \wedge(A \leq E)\right)
$$

the normalisation of the iso-derived conditional stuffed historical probability distribution is a fraction $1 /\left|\operatorname{ran}\left(Y_{U, i, V, z}\right)\right|$,

$$
\begin{aligned}
& \hat{Q}_{\mathrm{h}, \mathrm{y}, U}(E, z) \\
& \quad=\left\{\left(A, \frac{1}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)\right|} \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} Q_{\mathrm{h}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
\end{aligned}
$$

The corresponding iso-independent conditional generalised multinomial probability distribution is defined

$$
\begin{aligned}
\hat{Q}_{\mathrm{m}, \mathrm{y}, U} & (E, z) \\
:= & \left\{\left(A, \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} Q_{\mathrm{m}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A^{\mathrm{F}} \leq E^{\mathrm{F}}\right\}^{\wedge} \cup \\
& \left\{(A, 0): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A^{\mathrm{F}} \not \leq E^{\mathrm{F}}\right\}
\end{aligned}
$$

which is defined if $\operatorname{size}(E)>0$.

The case where all the independent are possible is weaker than for historical,

$$
\forall A^{\prime} \in \operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right) \exists A \in \mathcal{A}_{U, \mathrm{i}, V, z}\left(\left(A^{\mathrm{X}}=A^{\prime}\right) \wedge\left(A^{\mathrm{F}} \leq E^{\mathrm{F}}\right)\right)
$$

In this case the iso-independent conditional generalised multinomial probability distribution is

$$
\begin{aligned}
& \hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z) \\
& \quad=\left\{\left(A, \frac{1}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)\right|} \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} Q_{\mathrm{m}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
\end{aligned}
$$

Assume that the distribution history size, $z_{\mathrm{h}}$, is large with respect to the sample size $z_{\mathrm{o}}=\operatorname{size}\left(A_{\mathrm{o}}\right)$, so that, in the limit, the iso-independent conditional stuffed historical probability, $\hat{Q}_{\mathrm{h}, \mathrm{y}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$, approximates to the isoindependent conditional multinomial probability, $\hat{Q}_{\mathrm{m}, \mathrm{y}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$. That is, if $z_{\mathrm{o}} \ll z_{\mathrm{h}}$ then

$$
\hat{Q}_{\mathrm{h}, \mathrm{y}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \approx \hat{Q}_{\mathrm{m}, \mathrm{y}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

The iso-independent multinomial parameterised probability density function, $\operatorname{myppdf}(z) \in \operatorname{ppdfs}(v, v)$, and iso-independent multinomial likelihood function, $\operatorname{mylf}(z) \in \operatorname{lfs}(v, v)$, corresponding to the iso-independent multinomial probability distribution, $\hat{Q}_{\mathrm{m}, \mathrm{y}, U}$, are not given explicitly here, but are such that

$$
\operatorname{myppdf}(z)\left(\hat{E}^{\rrbracket}\right)\left(A^{\square}\right)=\operatorname{mylf}(z)\left(A^{\square}\right)\left(\hat{E}^{\square}\right)=\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(E, z)(A)
$$

Now in the case of aligned induction the real maximum likelihood estimate $\tilde{E}_{\mathrm{o}}^{\prime} \in \mathbf{R}_{(0,1)}^{v_{\mathrm{o}}}$ for the parameter of the iso-independent multinomial parameterised probability density function is

$$
\left\{\tilde{E}_{\mathrm{o}}^{\prime}\right\}=\operatorname{maxd}\left(\operatorname{mylf}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}^{\square}\right)\right)
$$

which is such that $\forall i \in\left\{1 \ldots v_{\mathrm{o}}\right\}\left(\partial_{i}\left(\operatorname{mylf}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}^{\square}\right)\right)\left(\tilde{E}_{\mathrm{o}}^{\prime}\right)=0\right)$. The maximum likelihood estimate $\tilde{E}_{\mathrm{o}}^{\prime}$ is only defined in the case where the sample histogram is completely effective, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}} \Longrightarrow \hat{A}_{\mathrm{o}}^{\|} \in \mathbf{R}_{(0,1)}^{v_{\mathrm{o}}}$, because the binomial likelihood function is only defined for the open set. That is, $\mathrm{d}\left(\mathrm{blf}\left(z_{0}\right)(0)\right)$ is undefined and so the derivative of the iso-independent multinomial parameterised probability density function is undefined where there are ineffective states.

In the case of completely effective sample histogram, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$, the maximisation of the iso-independent conditional generalised multinomial probability parameterised by the complete congruent histograms of unit size is a singleton of the rational maximum likelihood estimate

$$
\left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \mathrm{y}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{o}, 1}\right\}\right)
$$

The real maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}^{\prime}$, is not necessarily a rational coordinate, $\mathbf{R}_{(0,1)}^{v_{0}} \supset \mathbf{Q}_{(0,1)}^{v_{0}}$, and so the rational maximum likelihood estimate is not necessarily equal to the real maximum likelihood estimate. However, it is conjectured that the maximisation of the distribution approximates to the maximisation of the likelihood function,

$$
\tilde{E}_{\mathrm{o}}^{\square} \approx \tilde{E}_{\mathrm{o}}^{\prime}
$$

In the case where the sample histogram is not completely effective, $A_{\mathrm{o}}^{\mathrm{F}}<V_{\mathrm{o}}^{\mathrm{C}}$, the maximisation of the iso-independent conditional generalised multinomial probability distribution is well defined, unlike the parameterised probability density function, but is not necessarily a singleton

$$
\left|\max \left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \mathrm{y}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}\right\}\right)\right| \geq 1
$$

In the case where the maximisation of the iso-independent conditional generalised multinomial probability distribution is a singleton, it is equal to the normalised dependent, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{Y}}$, where the dependent $A^{\mathrm{Y}} \in \mathcal{A}_{U, V, z}$ is defined in 'Likely histograms', above, as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, A, conditional that it is an iso-independent,

$$
\left\{A^{\mathrm{Y}}\right\}=\operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

The dependent, $A^{\mathrm{Y}}$, is sometimes not computable. The finite approximation to the dependent is

$$
\begin{aligned}
& \left\{A_{k}^{\mathrm{Y}}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D / Z_{k}, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)}\right): D \in \mathcal{A}_{U, \mathrm{i}, V, k z}\right\}\right)
\end{aligned}
$$

The approximation, $A_{k}^{\mathrm{Y}} \approx A^{\mathrm{Y}}$, improves as the scaling factor, $k$, increases.
Unlike in classical non-modelled induction where the maximum likelihood
estimate, $\tilde{E}_{\mathrm{o}}$, is equal to the sample probability histogram, $\hat{A}_{\mathrm{o}}$, in aligned nonmodelled induction the maximum likelihood estimate is not necessarily equal to the sample probability histogram. In the case where the sample histogram is independent the maximum likelihood estimate is necessarily equal to the sample probability histogram,

$$
A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{X}} \Longrightarrow A_{\mathrm{o}}^{\mathrm{Y}}=A_{\mathrm{o}} \Longrightarrow \tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

In general, the overall maximum likelihood estimate, which is the dependent, is near the histogram, $\tilde{E}_{\mathrm{o}} \sim \hat{A}_{\mathrm{o}}$, only in as much as it is far from the independent, $\tilde{E}_{\mathrm{o}} \nsim \hat{A}_{\mathrm{o}}^{\mathrm{X}}$.

In section 'Iso-sets', above, the degree to which an integral iso-set $I \subseteq \mathcal{A}_{U, \mathrm{i}, V, z}$, where $A \in I$, is said to be aligned-like, or the iso-independence, is defined as

$$
\frac{\left|I \cap Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|I \cup Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}
$$

In the case of aligned non-modelled induction the integral iso-set is the integral iso-independents, $I=Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, and so aligned non-modelled induction is maximally aligned-like.

The requirement that the distribution history itself be drawable, $P_{U, X, H_{\mathrm{h}}, \mathrm{Y}}\left(H_{\mathrm{h}}\right)>$ 0 , has been ignored so far. This requirement modifies the maximisation to add the constraint that the maximum likelihood estimate be iso-independent, $\tilde{E}_{\mathrm{o}}^{\mathrm{X}}=\hat{A}_{\mathrm{o}}^{\mathrm{X}}$,

$$
\left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \mathrm{y}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{o}, 1}, E^{\mathrm{x}}=\hat{A}_{\mathrm{o}}^{\mathrm{x}}\right\}\right)
$$

So, strictly speaking, the maximum likelihood estimate is only approximately equal to the normalised dependent, $\tilde{E}_{\mathrm{o}} \approx \hat{A}_{\mathrm{o}}^{\mathrm{Y}}$, if the dependent is not isoindependent, $A_{\mathrm{o}}^{\mathrm{YX}} \neq A_{\mathrm{o}}^{\mathrm{X}}$.

Consider the maximum likelihood estimate of the iso-independent conditional generalised multinomial probability distribution, $\hat{Q}_{\mathrm{m}, \mathrm{y}, U}$. In section 'Likely histograms', above, the logarithm of the maximum conditional probability with respect to the dependent-analogue is conjectured to vary with the relative space with respect to the independent-analogue, which, in the case of iso-independent conditional, is the alignment,

$$
\begin{aligned}
\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}}, z\right)(B): B \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)} & \sim \operatorname{spaceRelative}\left(A^{\mathrm{X}}\right)(A) \\
& =\operatorname{algn}(A)
\end{aligned}
$$

In aligned induction, where (i) the history probability function is iso-independent historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{y}}$, (ii) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{0}$, and such that (iii) the scaled estimate distribution histogram is integral, $\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, the log likelihood of the iso-independent conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the alignment

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{algn}\left(A_{\mathrm{o}}\right)
$$

It is conjectured that if the independent is integral, the relative space of the histogram is positive and less than or equal to the relative space of the dependent,

$$
A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}} \Longrightarrow 0 \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}}\right)(A) \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}}\right)\left(A^{\mathrm{Y}}\right)
$$

In 'Dependent alignment', above, it is conjectured that in the case where the independent of the dependent equals the independent, $A^{\mathrm{YX}}=A^{\mathrm{X}}$, then the inequality is

$$
A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}} \Longrightarrow 0 \leq \operatorname{algn}(A) \leq \operatorname{algn}\left(A^{\mathrm{Y}}\right)
$$

and that if the histogram is at maximum alignment the dependent equals the histogram,

$$
\operatorname{algn}(A)=\operatorname{algnMax}(U)(V, z) \Longrightarrow A^{\mathrm{Y}}=A
$$

where algnMax $=$ alignmentMaximum .
So conjecture that the scaled maximum likelihood estimate, $Z_{\mathrm{o}} * \tilde{E}_{\mathrm{o}}$, is at least as aligned as the sample histogram, $A_{\mathrm{o}}$,

$$
\operatorname{algn}\left(Z_{\mathrm{o}} * \tilde{E}_{\mathrm{o}}\right) \geq \operatorname{algn}\left(A_{\mathrm{o}}\right)
$$

where $Z_{\mathrm{o}}=\operatorname{scalar}\left(z_{\mathrm{o}}\right)$.
This may be compared to classical induction in which the alignments are equal,

$$
\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}} \Longrightarrow \operatorname{algn}\left(Z_{\mathrm{o}} * \tilde{E}_{\mathrm{o}}\right)=\operatorname{algn}\left(A_{\mathrm{o}}\right)
$$

It is conjectured that it is also in the case where the sample alignment is maximised that the maximum likelihood estimate equals the sample probability histogram,

$$
\operatorname{algn}\left(A_{\mathrm{o}}\right)=\operatorname{algnMax}(U)\left(V_{\mathrm{o}}, z_{\mathrm{o}}\right) \Longrightarrow A_{\mathrm{o}}^{\mathrm{Y}}=A_{\mathrm{o}} \Longrightarrow \tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

That is, in aligned non-modelled induction there are two cases where the maximum likelihood estimate equals the sample probability histogram, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, which are (i) minimum alignment, algn $\left(A_{\mathrm{o}}\right)=0$, and (ii) maximum alignment, $\operatorname{algn}\left(A_{\mathrm{o}}\right)=\operatorname{algnMax}(U)\left(V_{\mathrm{o}}, z_{\mathrm{o}}\right)$.

In aligned induction, where (i) the history probability function is iso-independent historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{y}}$, (ii) the volume is non-singleton, $v_{\mathrm{o}}>$ 1, (iii) the sample histogram is completely effective, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$, if (iv) the sample alignment is minimised, $\operatorname{algn}\left(A_{\mathrm{o}}\right)=0$, or maximised, $\operatorname{algn}\left(A_{\mathrm{o}}\right)=$ $\operatorname{algnMax}(U)\left(V_{\mathrm{o}}, z_{\mathrm{o}}\right)$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{O}}$, in the iso-independent conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{y}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is

$$
\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

Now consider the iso-independent conditional generalised multinomial distribution sum sensitivity at the maximum likelihood estimate,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{y}, U}\left(\tilde{E}_{\mathrm{o}}, z_{\mathrm{o}}\right)\right)\right)
$$

In section 'Iso-sets', above, it is conjectured that the cardinality of the isoindependents corresponding to $A^{\mathrm{X}}$ varies with the entropy of the independent, $A^{\mathrm{X}}$

$$
\ln \left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right| \sim z \times \operatorname{entropy}\left(A^{\mathrm{X}}\right)
$$

so, as the independent entropy, entropy $\left(A^{\mathrm{X}}\right)$, increases, the set of iso independents, $Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, tends to the set of substrate histograms, $\mathcal{A}_{U, \mathrm{i}, V, z}$, and the sum sensitivity of the denominator decreases, increasing the overall sum sensitivity. Also, as shown above for classical induction, the sum sensitivity of the numerator varies against the scaled entropy,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(E, z)\right)\right) \sim-z \times \operatorname{entropy}(E)
$$

The alignment approximates to the difference in entropies,

$$
\operatorname{algn}(A) \approx z \times \operatorname{entropy}\left(A^{\mathrm{X}}\right)-z \times \operatorname{entropy}(A)
$$

So at low alignments where the maximum likelihood estimate approximates to the histogram, $\operatorname{algn}(A) \approx 0 \Longrightarrow \tilde{E} \approx \hat{A}$, the sum sensitivity varies with the sample alignment,

$$
\begin{aligned}
& \operatorname{algn}(A) \approx 0 \Longrightarrow \\
& \quad \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(\tilde{E}, z)\right)\right) \sim \operatorname{algn}(A)
\end{aligned}
$$

However, as the alignment of the scaled maximum likelihood estimate, algn $(Z *$ $\tilde{E})$, increases, the probability of the independent term, $Q_{\mathrm{m}, U}(\tilde{E}, z)\left(A^{\mathrm{X}}\right)$, decreases and the sensitivity of the denominator tends to be correlated with the numerator, lowering the overall sensitivity. Therefore conjecture that at high alignments where the maximum likelihood estimate approximates to the histogram, $\operatorname{algn}(A) \approx \operatorname{algnMax}(U)(V, z) \Longrightarrow \tilde{E} \approx \hat{A}$, the sum sensitivity varies against the sample alignment,

$$
\begin{aligned}
& \operatorname{algn}(A) \approx \operatorname{algnMax}(U)(V, z) \Longrightarrow \\
& \quad \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(\tilde{E}, z)\right)\right) \sim-\operatorname{algn}(A)
\end{aligned}
$$

This implies that there is some intermediate alignment where the sum sensitivity is constant,

$$
\begin{aligned}
& 0 \ll \operatorname{algn}(A) \ll \operatorname{algnMax}(U)(V, z) \Longrightarrow \\
& \quad \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(\tilde{E}, z)\right)\right)=c
\end{aligned}
$$

where $c$ is a constant.

In aligned induction, where (i) the history probability function is iso-independent historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{y}}$, (ii) the volume is non-singleton, $v_{\mathrm{o}}>$ 1 , (iii) the sample histogram is completely effective, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$, if (iv) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{0}$, and such that (v) the scaled probability sample histogram is integral, $A_{0, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$ where $A_{\mathrm{o}, z_{\mathrm{h}}}=\operatorname{scalar}\left(z_{\mathrm{h}}\right) * \hat{A}_{\mathrm{o}}$, then (a) the iso-independent conditional stuffed historical distribution sum sensitivity at the maximum likelihood estimate varies with the sample alignment in the case where the sample alignment is small,

$$
\begin{aligned}
& \operatorname{algn}\left(A_{\mathrm{o}}\right) \approx 0 \Longrightarrow \\
& \quad \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{y}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim \operatorname{algn}\left(A_{\mathrm{o}}\right)
\end{aligned}
$$

and (b) the iso-independent conditional stuffed historical distribution sum sensitivity at the maximum likelihood estimate varies against the sample alignment in the case where the sample alignment is large,

$$
\begin{aligned}
& \operatorname{algn}\left(A_{\mathrm{o}}\right) \approx \operatorname{algnMax}(U)\left(V_{\mathrm{o}}, z_{\mathrm{o}}\right) \Longrightarrow \\
& \quad \quad \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{y}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\operatorname{algn}\left(A_{\mathrm{o}}\right)
\end{aligned}
$$

### 5.7 Idealisation induction

Having considered (i) classical modelled induction, which requires necessary derived, and (ii) aligned non-modelled induction, which requires necessary independent, now consider (iii) idealisation induction, which is a stricter
intersection between the two, requiring necessary idealisation.
Given some known substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{0}}$, the idealisation histogram of the distribution probability histogram is $\hat{E}_{\mathrm{h}} *$ $T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger E_{\mathrm{h}}}$. In idealisation induction, while the distribution probability histogram, $\hat{E}_{\mathrm{h}}$, remains unknown, the idealisation distribution probability histogram, $\hat{E}_{\mathrm{h}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger E_{\mathrm{h}}}$, is known and necessary. That is, the history probability function, $P$, is historically distributed but constrained such that all drawn histories have a idealisation probability histogram equal to the known idealisation distribution probability histogram, $\hat{A}_{H} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{H}}=\hat{E}_{\mathrm{h}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger} E_{\mathrm{h}} \% V_{H}$. Define the iso-idealisation historically distributed history probability function $P_{U, X, H_{\mathrm{h}}, \dagger, T_{o}} \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}$,

$$
\begin{aligned}
& P_{U, X, H_{\mathrm{h}}, \uparrow, T_{\mathrm{o}}}:= \\
& \qquad \begin{array}{l}
\left(\bigcup \left\{\left\{(H, 1): H \subseteq H_{\mathrm{h}} \% V_{H},|H|=z_{H},\right.\right.\right. \\
\\
\left.\hat{A}_{H} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{H}}=\hat{E}_{\mathrm{h}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger E_{\mathrm{h}}} \% V_{H}\right\}^{\wedge} \\
\left.\left.V_{H} \subseteq V_{\mathrm{h}}, z_{H} \in\left\{1 \ldots z_{\mathrm{h}}\right\}\right\}\right)^{\wedge} \cup \\
\left\{(H, 0): H \in \mathcal{H}_{U, X}, \hat{A}_{H} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{H}} \neq \hat{E}_{\mathrm{h}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger E_{\mathrm{h}}} \% V_{H}\right\} \cup \\
\left\{(H, 0): H \in \mathcal{H}_{U, X}, H \nsubseteq H_{\mathrm{h}} \% V_{H}\right\} \cup\{(\emptyset, 0)\}
\end{array}
\end{aligned}
$$

For drawn histories the idealisation probability histogram is necessary, $\forall H \in$ $\mathcal{H}_{U, X}\left(P_{U, X, H_{\mathrm{h}}, \dagger, T_{\mathrm{o}}}(H)>0 \Longrightarrow \hat{A}_{H} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{H}}=\hat{E}_{\mathrm{h}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger E_{\mathrm{h}}} \% V_{H}\right)$. Not all sizes and sets of variables are necessarily drawable. That is, in some cases, $\exists z \in\left\{1 \ldots z_{\mathrm{h}}\right\} \exists V \subseteq V_{\mathrm{h}} \forall H \in \mathcal{H}_{U, X}\left(\left(z_{H}=z\right) \wedge\left(V_{H}=V\right) \Longrightarrow\right.$ $\left.P_{U, X, H_{\mathrm{h}}, \dagger, T_{\mathrm{o}}}(H)=0\right)$. The distribution history can always be drawn, so the probability function is not a weak probability function, $\sum_{H \in \mathcal{H}_{U, X}} P_{U, X, H_{\mathrm{h}}, \dagger, T_{\mathrm{o}}}(H)=$ 1.

All iso-idealisation subsets of the distribution history for a given set of variables and size are defined as equally probable,
$\forall V \subseteq V_{\mathrm{h}} \forall H, G \subseteq H_{\mathrm{h}} \% V$

$$
\left(A_{G} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{G}}=A_{H} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{H}} \Longrightarrow P_{U, X, H_{\mathrm{h}}, \dagger, T_{\mathrm{o}}}(G)=P_{U, X, H_{\mathrm{h}}, \uparrow, T_{\mathrm{o}}}(H)\right)
$$

In idealisation induction the history probability function is iso-idealisation historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \uparrow, T_{\mathrm{o}}}$.

Given a drawn history $H \in \mathcal{H}_{U, X}$, where $P_{U, X, H_{h}, \dagger, T_{o}}(H)>0$, the isoidealisation historical probability of histogram $A_{H}=\operatorname{histogram}(H)+V_{H}^{\mathrm{CZ}} \in$
$\mathcal{A}_{U, \mathrm{i}, V_{H}, z_{H}}$ is now conditional,

$$
\begin{aligned}
& \frac{Q_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right)}{\sum_{B \in \operatorname{isoi}(U)\left(T_{o}, A_{o}\right)} Q_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)(B)}= \\
& \frac{\sum P_{U, X, H_{\mathrm{h}}, \uparrow, T_{\circ}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}}{\sum P_{U, X, H_{\mathrm{h}}, \uparrow, T_{\circ}}(G): G \in \mathcal{H}_{U, X}, V_{G}=V_{H},|G|=z_{H}}
\end{aligned}
$$

where isoi $(U)(T, A):=Y_{U, i, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)$ and the independent components valued histogram function $Y_{U, \mathrm{i}, T, \mathrm{t}, z}$ is defined

$$
Y_{U, \mathbf{i}, T, \uparrow, z}=\left\{\left(A, A * T * T^{\dagger A}\right): A \in \mathcal{A}_{U, \mathbf{i}, V, z}\right\}
$$

The finite set of iso-idealisations of independent components $\left\{\left(A * C^{\mathrm{U}}\right)^{\mathrm{X}}\right.$ : $\left.C \in T^{\mathrm{P}}\right\}$ is

$$
Y_{U,, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)=\left\{B: B \in \mathcal{A}_{U, \mathbf{i}, V, z}, B * T * T^{\dagger B}=A * T * T^{\dagger A}\right\}
$$

The iso-idealisation historical probability may be expressed in terms of a histogram distribution which is not explicitly conditional on the necessary idealisation, $\hat{E}_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}{ }^{\dagger}$,

$$
\hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right) \propto \sum\left(P_{U, X, H_{\mathrm{h}}, \uparrow, T_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}\right)
$$

where the iso-idealisation conditional stuffed historical probability distribution is defined

$$
\begin{aligned}
& \hat{Q}_{\mathrm{h}, \uparrow, T, U}(E, z) \\
&:=\left\{\left(A, \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum_{B \in \operatorname{isoi}(U)(T, A)} Q_{\mathrm{h}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \leq E\right\}^{\wedge} \cup \\
&\left\{(A, 0): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \not \leq E\right\}
\end{aligned}
$$

which is defined if $z \leq \operatorname{size}(E)$.
In the case where all the idealisations are possible,

$$
\forall A^{\prime} \in \operatorname{ran}\left(Y_{U, \mathbf{i}, T, \dagger, z}\right) \exists A \in \mathcal{A}_{U, \mathbf{i}, V, z}\left(\left(A * T * T^{\dagger A}=A^{\prime}\right) \wedge(A \leq E)\right)
$$

the normalisation of the iso-idealisation conditional stuffed historical probability distribution is a fraction $1 /\left|\operatorname{ran}\left(Y_{U, i, T, \uparrow, z}\right)\right|$,

$$
\begin{aligned}
& \hat{Q}_{\mathrm{h}, \uparrow, T, U}(E, z) \\
& \quad=\left\{\left(A, \frac{1}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, T, \uparrow, z}\right)\right|} \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum_{B \in \mathrm{isoi}(U)(T, A)} Q_{\mathrm{h}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
\end{aligned}
$$

In the case of a full functional transform, $T_{\mathrm{s}}=\left\{\{w\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: w \in V\right\}^{\mathrm{T}}$, the iso-idealisation is a singleton of the sample histogram, $Y_{U, i, T, \uparrow, \eta}^{-1}\left(A * T_{\mathrm{s}} *\right.$ $\left.T_{\mathrm{s}}^{\dagger A}\right)=\left\{A * T_{\mathrm{s}} * T_{\mathrm{s}}^{\dagger A}\right\}=\{A\}$, and so the denominator equals the numerator, $\sum^{\mathrm{s}}\left(Q_{\mathrm{h}, U}(E, z)(B): B \in\{A\}\right)=Q_{\mathrm{h}, U}(E, z)(A)$. Thus the iso-idealisation historically distributed history probability is a constant, $\hat{Q}_{\mathrm{h}, \dagger, T_{s}, U}(E, z)(Z * \hat{E})=$ $1 /\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right|$, where $Z=\operatorname{scalar}(z)$. In this case, the distribution probability histogram, $\hat{E}$, is known, because $\hat{E} * T_{\mathrm{s}} * T_{\mathrm{s}}^{\dagger E}$ is known, and so everything is known.

At the other extreme of a unary transform, $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$, the set of isoidealisations equals the iso-independents, $Y_{U, \mathrm{i}, T_{\mathrm{u}}, \uparrow, z}^{-1}\left(A * T_{\mathrm{u}} * T_{\mathrm{u}}^{\dagger A}\right)=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$. Thus the iso-idealisation conditional stuffed historical probability distribution equals the iso-independent conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{u}}, U}(E, z)=\hat{Q}_{\mathrm{h}, \mathrm{y}, U}(E, z)$. In this case idealisation induction reduces to aligned non-modelled induction.

The iso-idealisation conditional generalised multinomial probability distribution is defined

$$
\begin{aligned}
& \hat{Q}_{\mathrm{m}, \uparrow, T, U}(E, z) \\
&:=\left\{\left(A, \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \operatorname{isoi}(U)(T, A)} Q_{\mathrm{m}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A^{\mathrm{F}} \leq E^{\mathrm{F}}\right\}^{\wedge} \cup \\
&\left\{(A, 0): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A^{\mathrm{F}} \not \leq E^{\mathrm{F}}\right\}
\end{aligned}
$$

which is defined if $\operatorname{size}(E)>0$.
The case where all the idealisations are possible is weaker than for historical,

$$
\forall A^{\prime} \in \operatorname{ran}\left(Y_{U, \mathbf{i}, T, \dagger, z}\right) \exists A \in \mathcal{A}_{U, \mathbf{i}, V, z}\left(\left(A * T * T^{\dagger A}=A^{\prime}\right) \wedge\left(A^{\mathrm{F}} \leq E^{\mathrm{F}}\right)\right)
$$

In this case the iso-idealisation conditional generalised multinomial probability distribution is

$$
\begin{aligned}
& \hat{Q}_{\mathrm{m}, \uparrow, T, U}(E, z) \\
& \quad=\left\{\left(A, \frac{1}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, T, \uparrow, t, z}\right)\right|} \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \mathrm{isoi}(U)(T, A)} Q_{\mathrm{m}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
\end{aligned}
$$

It is assumed that the distribution history size, $z_{\mathrm{h}}$, is large with respect to the sample size $z_{0}=\operatorname{size}\left(A_{0}\right)$, so that, in the limit, the iso-idealisation historical probability, $\hat{Q}_{\mathrm{h}, \dagger, T_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$, approximates to the iso-idealisation multinomial probability, $\hat{Q}_{\mathrm{m}, \dagger, T_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$. That is, if $z_{\mathrm{o}} \ll z_{\mathrm{h}}$ then

$$
\hat{Q}_{\mathrm{h}, \dagger, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \approx \hat{Q}_{\mathrm{m}, \dagger, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

In the case of completely effective sample histogram, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$, the maximisation for known transform, $T_{\mathrm{o}}$, of the iso-idealisation conditional generalised multinomial probability parameterised by the complete congruent histograms of unit size is a singleton of the rational maximum likelihood estimate

$$
\left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \uparrow, T_{\mathrm{o}}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{o}, 1}\right\}\right)
$$

In the case where the sample histogram is not completely effective, $A_{\mathrm{o}}^{\mathrm{F}}<V_{\mathrm{o}}^{\mathrm{C}}$, the maximisation of the iso-idealisation conditional generalised multinomial probability distribution for known transform is not necessarily a singleton

$$
\left|\max \left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \uparrow, T_{\mathrm{o}}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{o}, 1}\right\}\right)\right| \geq 1
$$

In the case where the maximisation of the iso-idealisation conditional generalised multinomial probability distribution is a singleton, it is equal to the normalised idealisation-dependent, $\tilde{E}_{\mathrm{o}}=\hat{A}_{o}^{\dagger\left(T_{o}\right)}$, where the idealisation-dependent $A^{\dagger(T)} \in \mathcal{A}_{U, V, z}$ is defined in 'Likely histograms', above, as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, $A$, conditional that it is an iso-idealisation,

$$
\begin{aligned}
& \left\{A^{\dagger(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isoi}(U)(T, A)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The idealisation-dependent, $A^{\dagger(T)}$, is sometimes not computable. The finite approximation to the idealisation-dependent is

$$
\begin{aligned}
& \left\{A_{k}^{\dagger(T)}\right\}= \\
& \quad \quad \operatorname{maxd}\left(\left\{\left(D / Z_{k}, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isoi}(U)(T, A)}\right): D \in \mathcal{A}_{U, \mathrm{i}, V, k z}\right\}\right)
\end{aligned}
$$

The approximation, $A_{k}^{\dagger(T)} \approx A^{\dagger(T)}$, improves as the scaling factor, $k$, increases.

Unlike in classical non-modelled induction where the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, is equal to the sample probability histogram, $\hat{A}_{\mathrm{o}}$, in idealisation induction the maximum likelihood estimate is not necessarily equal to the sample probability histogram. It is only in the case where the sample histogram is ideal that the maximum likelihood estimate is necessarily equal to the sample probability histogram,

$$
A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}} \Longrightarrow A_{\mathrm{o}}^{\dagger\left(T_{\mathrm{o}}\right)}=A_{\mathrm{o}} \Longrightarrow \tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

Otherwise, the overall maximum likelihood estimate, which is the idealisationdependent, is near the histogram, $\tilde{E}_{\mathrm{o}} \sim \hat{A}_{\mathrm{o}}$, only in as much as it is far from the idealisation, $\tilde{E}_{\mathrm{o}} \nsim \hat{A}_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$.

The requirement that the distribution history itself be drawable, $P_{U, X, H_{\mathrm{h}}, \uparrow, T_{\mathrm{o}}}\left(H_{\mathrm{h}}\right)>$ 0 , has been ignored so far. This requirement modifies the maximisation to add the constraint that the maximum likelihood estimate be an iso-idealisation, $\tilde{E}_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger \tilde{E}_{\mathrm{o}}}=\hat{A}_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger \hat{A}_{\mathrm{o}}}$,

$$
\begin{aligned}
\left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \uparrow, T_{\mathrm{o}}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E\right.\right. & \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}, \\
& \left.\left.E * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger E}=\hat{A}_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger \hat{A}_{\mathrm{o}}}\right\}\right)
\end{aligned}
$$

So, strictly speaking, the maximum likelihood estimate is only approximately equal to the normalised idealisation-dependent, $\tilde{E}_{\mathrm{o}} \approx \hat{A}_{\mathrm{o}}^{\dagger\left(T_{\mathrm{o}}\right)}$, if the idealisationdependent is not an iso-idealisation, $A_{\mathrm{o}}^{\dagger\left(T_{\mathrm{o}}\right)} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}^{\dagger\left(T_{\mathrm{o}}\right)}} \neq \hat{A}_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger \hat{A}_{\mathrm{o}}}$. In the special case, however, where the sample histogram is ideal, the maximum likelihood estimate is exactly equal to the normalised idealisation-dependent, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}} \Longrightarrow \tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\dagger\left(T_{\mathrm{o}}\right)}=\hat{A}_{\mathrm{o}}$.

In idealisation induction, where (i) the history probability function is isoidealisation historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \dagger, T_{\mathrm{o}}}$, given some substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{0}}$, if it is the case that (ii) the sample histogram is ideal, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the iso-idealisation conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is

$$
\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

The set of iso-idealisations is a subset of the iso-deriveds, so it is a law-like iso-set of the histogram, A,

$$
Y_{U, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right) \subseteq D_{U, T, z}^{-1}(A * T)
$$

The iso-derivedence or degree of law-likeness is

$$
\frac{\left|Y_{U, i, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)\right|}{\left|D_{U, i, T, z}^{-1}(A * T)\right|} \leq 1
$$

So idealisation induction is not maximally law-like if the iso-deriveds is a proper superset of the iso-idealisations, $D_{U, T, z}^{-1}(A * T) \supset Y_{U, T, \dagger, z}^{-1}\left(A * T * T^{\dagger A}\right)$.

The set of iso-idealisations is a subset of the iso-abstracts, so it is an entitylike iso-set of the histogram, $A$,

$$
Y_{U, T, \mathrm{t}, z}^{-1}\left(A * T * T^{\dagger A}\right) \subseteq Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)
$$

The iso-abstractence or degree of entity-likeness is less than or equal to the iso-derivedence

$$
\frac{\left|Y_{U, i, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|} \leq \frac{\left|Y_{U, \mathrm{i}, T, \mathrm{t}, z}^{-1}\left(A * T * T^{\dagger A}\right)\right|}{\left|D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right|}
$$

so idealisation induction is less entity-like and more law-like.
The set of iso-idealisations is a subset of the iso-independents, $Y_{U, T, \uparrow, z}^{-1}(A *$ $\left.T * T^{\dagger A}\right) \subseteq Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, so the degree to which the iso-idealisations is alignedlike, or the iso-independence, is $\left|Y_{U, i, T, \dagger, z}^{-1}\left(A * T * T^{\dagger A}\right)\right| /\left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|$.

In some cases the iso-independence of the iso-idealisations is greater than or equal to the iso-independence of the iso-derived,

$$
\frac{\left|Y_{U, \mathrm{i}, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)\right|}{\left|Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|} \geq \frac{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|}
$$

and so idealisation induction may be said to be more aligned-like than classical modelled induction.

As the iso-independence increases, the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, which equals the idealisation-dependent, $\hat{A}_{0}^{\dagger\left(T_{0}\right)}$, tends to the dependent, $\hat{A}_{\mathrm{o}}^{\mathrm{Y}}$, which is independent of the model, $T_{\mathrm{o}}$, because the independent analogue, $A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, tends to the independent, $A_{\mathrm{o}}^{\mathrm{X}}$, which is also independent of the model, as the transform becomes more unary.

Given the known substrate transform, $T_{\mathrm{o}}$, consider the maximum likelihood estimate of the iso-idealisation conditional generalised multinomial probability distribution, $\hat{Q}_{\mathrm{m}, \uparrow, T_{o}, U}$. In section 'Likely histograms', above, the logarithm of the maximum conditional probability with respect to the dependentanalogue is conjectured to vary with the relative space with respect to the independent-analogue. In the case of iso-idealisation conditional,
$\ln \frac{Q_{\mathrm{m}, U}\left(A^{\dagger(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\dagger(T)}, z\right)(B): B \in \operatorname{isoi}(U)(T, A)} \sim \operatorname{spaceRelative}\left(A * T * T^{\dagger A}\right)(A)$
where the distribution-relative multinomial space is defined, in section 'Likely histograms', above, as

$$
\text { spaceRelative }(E)(A):=-\ln \frac{\operatorname{mpdf}(U)(E, z)(A)}{\operatorname{mpdf}(U)(E, z)(E)}
$$

In section 'Transform alignment', above, because the set of iso-idealisations is law-like, it is shown that, in the case where the dependent analogue is in the iso-set, the difference in relative space between the histogram and the dependent must be in the relative spaces of the components,

$$
\begin{aligned}
A^{\dagger(T)} & \in D_{U, T, z}^{-1}(A * T) \Longrightarrow \\
& \sum_{(\cdot, C) \in T^{-1}} \operatorname{spaceRelative}\left(A * T * T^{\dagger A} * C\right)(A * C) \\
& \leq \sum_{(\cdot, C) \in T^{-1}} \text { spaceRelative }\left(A * T * T^{\dagger A} * C\right)\left(A^{\dagger(T)} * C\right)
\end{aligned}
$$

So, in the case of the idealisation-dependent, the component alignments must be greater than or equal to the component alignments of the histogram,

$$
\begin{aligned}
& A^{\dagger(T)} \in D_{U, T, z}^{-1}(A * T) \Longrightarrow \\
& \quad \sum_{(\cdot, C) \in T^{-1}} \operatorname{algn}(A * C) \leq \sum_{(\cdot, C) \in T^{-1}} \operatorname{algn}\left(A^{\dagger(T)} * C\right)
\end{aligned}
$$

The idealisation-dependent varies with the histogram, $\tilde{E}_{\mathrm{o}} \sim \hat{A}_{\mathrm{o}}$, so conjecture that in the case where the sample is not ideal, $A \neq A * T * T^{\dagger A} \Longrightarrow$ spaceRelative $\left(A * T * T^{\dagger A}\right)(A)>0$, the log-likelihood varies with the sum of the component alignments,

$$
\ln \frac{Q_{\mathrm{m}, U}\left(A^{\dagger(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\dagger(T)}, z\right)(B): B \in \operatorname{isoi}(U)(T, A)} \sim \sum_{(\cdot, C) \in T^{-1}} \operatorname{algn}(A * C)
$$

In idealisation induction, where (i) the history probability function is isoidealisation historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \dagger, T_{\mathrm{o}}}$, given some substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{o}}$, if it is the case that (ii) the sample histogram is not ideal, $A_{\mathrm{o}} \neq A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, (iii) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}}>\tilde{z}_{0}$, and such that (iv) the scaled estimate distribution histogram is integral, $\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the log likelihood of the iso-idealisation conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the relative space of the sample with respect to the idealisation,

$$
\ln \hat{Q}_{\mathrm{h}, \dagger, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \text { spaceRelative }\left(A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}\right)\left(A_{\mathrm{o}}\right)
$$

and varies with the sum of the component alignments of the sample components,

$$
\ln \hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \sum_{(,, C) \in T_{\mathrm{o}}^{-1}} \operatorname{algn}\left(A_{\mathrm{o}} * C\right)
$$

The set of iso-idealisations is a subset of the intersection of the iso-independents and iso-deriveds which is a subset of the iso-liftisations which is a subset of the iso-transform-independents,

$$
\begin{aligned}
Y_{U, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right) & \\
& \subseteq Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right) \cap D_{U, T, z}^{-1}(A * T) \\
& \subseteq Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap D_{U, T, z}^{-1}(A * T) \\
& \subseteq Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)
\end{aligned}
$$

Since the idealisation entropy is conjectured (i) to be less than or equal to the independent entropy, entropy $\left(A * T * T^{\dagger A}\right) \leq \operatorname{entropy}\left(A^{\mathrm{X}}\right)$, and (ii) to be less than or equal to the naturalisation entropy, entropy $\left(A * T * T^{\dagger A}\right) \leq$ entropy $\left(A * T * T^{\dagger}\right)$, the idealisation relative space is conjectured (a) to be less than or equal to the independent relative space, which is the alignment,

$$
\text { spaceRelative }\left(A * T * T^{\dagger A}\right)(A) \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}}\right)(A)=\operatorname{algn}(A)
$$

and (b) to be less than or equal to the naturalisation relative space,

$$
\text { spaceRelative }\left(A * T * T^{\dagger A}\right)(A) \leq \operatorname{spaceRelative}\left(A * T * T^{\dagger}\right)(A)
$$

Given the known substrate transform, $T_{\mathrm{o}}$, consider the log likelihood of the iso-idealisation conditional generalised multinomial probability distribution, $\hat{Q}_{\mathrm{m}, \dagger, T_{o}, U}$, at the maximum likelihood estimate, in the special case where the histogram is ideal, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}} \Longrightarrow \tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\dagger\left(T_{\mathrm{o}}\right)}=\hat{A}_{\mathrm{o}}$.

The set of iso-idealisations is a subset of the intersection of the iso-independents and iso-deriveds,

$$
Y_{U, T,, t, z}^{-1}\left(A * T * T^{\dagger A}\right) \subseteq Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right) \cap D_{U, T, z}^{-1}(A * T)
$$

In section 'Iso-sets', above, it is conjectured that the cardinality of the integral iso-independents varies with the scaled entropy of the independent, $A^{\mathrm{X}}$,

$$
\ln \left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right| \sim z \times \operatorname{entropy}\left(A^{\mathrm{X}}\right)
$$

Alignment is approximately the difference in the scaled entropies of the independent and the histogram,

$$
\operatorname{algn}(A) \approx z \times \operatorname{entropy}\left(A^{\mathrm{X}}\right)-z \times \operatorname{entropy}(A)
$$

so the cardinality of the iso-independents varies with the alignment,

$$
\ln \left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right| \sim \operatorname{algn}(A)
$$

At high alignments, the integral iso-independents, $Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, tends to the integral substrate histograms, $\mathcal{A}_{U, \mathrm{i}, V, z}$, so the iso-independence of the set of iso-idealisations, $\left|Y_{U, i, T, t, z}^{-1}\left(A * T * T^{\dagger A}\right)\right| /\left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|$, decreases, and the isoderivedence, $\left|Y_{U, i, T, \dagger, z}^{-1}\left(A * T * T^{\dagger A}\right)\right| /\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|$, increases. The sample is the independent-analogue, so it equals the dependent-analogue and the maximum likelihood estimate is just the sample probability histogram, $\tilde{E}=\hat{A}$. So the numerator of the iso-idealisation probability for ideal sample equals the numerator of the iso-derived probability for natural sample, $Q_{\mathrm{m}, U}(A, z)(A)$. At high alignments, the set of iso-idealisations of the denominator approximates to the iso-deriveds, $Y_{U, T, \dagger, z}^{-1}\left(A * T * T^{\dagger A}\right) \approx D_{U, T, z}^{-1}(A * T)$, so conjecture that the iso-idealisation conditional generalised multinomial probability varies with the iso-derived conditional generalised multinomial probability,

$$
\begin{aligned}
& \ln \frac{Q_{\mathrm{m}, U}(A, z)(A)}{\sum Q_{\mathrm{m}, U}(A, z)(B): B \in \operatorname{isoi}(U)(T, A)} \sim \\
& \ln \frac{Q_{\mathrm{m}, U}(A, z)(A)}{\sum Q_{\mathrm{m}, U}(A, z)(B): B \in D_{U, \mathbf{i}, T, z}^{-1}(A * T)}
\end{aligned}
$$

and that the iso-idealisation log likelihood varies with the iso-derived log likelihood,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{\downarrow}, T, U}(A, z)(A) \sim \ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A)
$$

So the log likelihood varies with the size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
& \ln \hat{Q}_{\mathrm{m}, \uparrow, T, U}(A, z)(A) \sim \\
& \begin{aligned}
(z+v) \times \operatorname{entropy}(A * T & \left.+V^{\mathrm{C}} * T\right) \\
& \quad-z \times \operatorname{entropy}(A * T)-v \times \operatorname{entropy}\left(V^{\mathrm{C}} * T\right)
\end{aligned}
\end{aligned}
$$

The set of iso-idealisations is a subset of the intersection of the iso-independents and iso-deriveds, $Y_{U, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right) \subseteq Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right) \cap D_{U, T, z}^{-1}(A * T)$, so conjecture
that the iso-idealisation conditional multinomial distribution sum sensitivity varies with the iso-independent sum sensitivity,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \uparrow, T, U}(A, z)\right)\right) \sim \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(A, z)\right)\right)
$$

and the iso-derived sum sensitivity,
$\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \dagger, T, U}(A, z)\right)\right) \sim \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{d}, T, U}(A, z)\right)\right)$
In section 'Aligned induction', above, it is conjectured that at low alignments, $\operatorname{algn}(A) \approx 0$, the sum sensitivity varies with the sample alignment,

$$
\begin{aligned}
\operatorname{algn}(A) & \approx 0 \Longrightarrow \\
& \quad \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(A, z)\right)\right) \sim \operatorname{algn}(A)
\end{aligned}
$$

but at high alignments, $\operatorname{algn}(A) \approx \operatorname{algnMax}(U)(V, z)$, the sum sensitivity varies against the sample alignment,

$$
\begin{aligned}
\operatorname{algn}(A) & \approx \operatorname{algnMax}(U)(V, z) \Longrightarrow \\
& \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(A, z)\right)\right) \sim-\operatorname{algn}(A)
\end{aligned}
$$

and so there is some intermediate alignment where the sum sensitivity is independent of the alignment,

$$
\begin{aligned}
0 \ll \operatorname{algn}(A) \ll & \operatorname{algnMax}(U)(V, z) \Longrightarrow \\
& \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(A, z)\right)\right)=c
\end{aligned}
$$

where $c$ is a constant. So in the case of intermediate alignment the isoindependent sum sensitivity is constant and the iso-idealisation sum sensitivity varies only with the iso-derived sum sensitivity,
$\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \dagger, T, U}(A, z)\right)\right) \sim \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{d}, T, U}(A, z)\right)\right)$
In section 'Classical modelled induction', above, it is shown that, given necessary derived, in the special case where the histogram is natural, $A=$ $A * T * T^{\dagger} \Longrightarrow \tilde{E}=\hat{A}^{\mathrm{D}(T)}=\hat{A}$, and the component size cardinality cross entropy is greater than the logarithm of the possible derived volume, entropyCross $\left(A * T, V^{\mathrm{C}} * T\right)>\ln w^{\prime}$, so the relative entropy is high, the iso-derived conditional multinomial probability at the maximum likelihood estimate varies with the underlying-derived relative multinomial probability,
$\frac{\hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right)}{\sum_{B \in D_{U, i, T, z}^{-1}(A * T)} \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)(B)} \sim \frac{\hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)\left(A * T * T^{\dagger}\right)}{\hat{Q}_{\mathrm{m}, U}(A * T, z)(A * T)}$

Similarly, given necessary idealisation, if (i) the sample is ideal, $A=A * T *$ $T^{\dagger A} \Longrightarrow E=A^{\dagger(T)}=A$, (ii) the relative entropy is high, entropy $\operatorname{Cross}(A *$ $\left.T, V^{\mathrm{C}} * T\right)>\ln w^{\prime}$, and (iii) the alignment is intermediate, $\operatorname{algn}(A) \approx$ $\operatorname{algnMax}(U)(V, z) / 2$, then the iso-idealisation conditional multinomial probability at the maximum likelihood estimate varies with the underlying-derived relative multinomial probability,
$\frac{\hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger A}, z\right)\left(A * T * T^{\dagger A}\right)}{\sum_{B \in \operatorname{isoi}(U)(T, A)} \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger A}, z\right)(B)} \sim \frac{\hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger A}, z\right)\left(A * T * T^{\dagger A}\right)}{\hat{Q}_{\mathrm{m}, U}(A * T, z)(A * T)}$
Thus, at intermediate alignments where the sample is ideal, the sum sensitivity of the iso-idealisation conditional multinomial probability distribution, $\hat{Q}_{\mathrm{m}, \downarrow, T, U}$, is conjectured to vary with the unknown-known multinomial probability distribution sum sensitivity difference,

$$
\begin{aligned}
& \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \uparrow, T, U}(A, z)\right)\right) \sim \\
& \quad \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(A, z)\right)\right)-\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(A * T, z)\right)\right)
\end{aligned}
$$

and so the sum sensitivity of the iso-idealisation conditional multinomial probability distribution is sometimes less than or equal to the sum sensitivity of the multinomial probability distribution,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \uparrow, T, U}(A, z)\right)\right) \leq \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}(A, z)\right)\right)
$$

Note that in classical modelled induction the denominator,

$$
\sum_{B \in D_{U, i, T, z}^{-1}(A * T)} \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)(B)
$$

is lifted to the derived, $\hat{Q}_{\mathrm{m}, U}(A * T, z)(A * T)$, while in idealisation induction a rather different denominator,

$$
\sum_{B \in \mathrm{isoi}(U)(T, A)} \hat{Q}_{\mathrm{m}, U}\left(A * T * T^{\dagger A}, z\right)(B)
$$

is lifted to the same derived. It is assumed that, although the set of isoidealisations is only a subset of the iso-deriveds because of the intersections of the iso-independents, these intersections are arbitrary with respect to the iso-derived at intermediate alignments. That is, the set of iso-idealisations, $\operatorname{isoi}(U)(T, A)$, is assumed to be a representative subset of the set of isoderived, $D_{U, \mathbf{i}, T, z}^{-1}(A * T)$, and so can be lifted.

The iso-idealisation sum sensitivity varies with the unknown-known sum sensitivity difference similarly to the iso-derived sum sensitivity, and so has similar characteristics. However, note that the expected component entropy of the idealisation components is less than or equal to that of the naturalisation,

$$
\begin{aligned}
& \text { entropyComponent }\left(A * T * T^{\dagger A}, T\right) \\
= & \operatorname{expected}(\hat{A} * T)\left(\left\{\left(R, \operatorname{entropy}\left((A * C)^{\mathrm{x}}\right)\right):(R, C) \in T^{-1}\right\}\right) \\
\leq & \operatorname{expected}(\hat{A} * T)\left(\left\{(R, \text { entropy }(C)):(R, C) \in T^{-1}\right\}\right) \\
= & \operatorname{entropyComponent}\left(A * T * T^{\dagger}, T\right)
\end{aligned}
$$

though, because the components are independent, the expected component entropy of the idealisation is greater than or equal to the expected component entropy where the sample is not ideal,

$$
\begin{aligned}
& \text { entropyComponent }(A, T) \\
= & \operatorname{expected}(\hat{A} * T)\left(\left\{(R, \text { entropy }(A * C)):(R, C) \in T^{-1}\right\}\right) \\
\leq & \operatorname{expected}(\hat{A} * T)\left(\left\{\left(R, \text { entropy }\left((A * C)^{\mathrm{x}}\right)\right):(R, C) \in T^{-1}\right\}\right) \\
= & \operatorname{entropyComponent}\left(A * T * T^{\dagger A}, T\right)
\end{aligned}
$$

Overall, in the case where the histogram is ideal and the alignment is intermediate or higher, the properties of necessary idealisation induction are expected to be similar to those of necessary derived induction.

In idealisation induction, where (i) the history probability function is isoidealisation historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \dagger, T_{\mathrm{o}}}$, given some substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, if it is the case that (ii) the sample histogram is ideal, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the iso-idealisation conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, so, if it is also the case that (iii) the alignment is intermediate or $\operatorname{high}, \operatorname{algn}\left(A_{\mathrm{o}}\right) \geq \operatorname{algnMax}(U)\left(V_{\mathrm{o}}, z_{\mathrm{o}}\right) / 2$, (iv) the relative entropy is high, entropy $\operatorname{Cross}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)>\ln \left|T_{\mathrm{o}}^{-1}\right|$, (v) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{\mathrm{o}}$, and such that (vi) the scaled probability sample histogram is integral, $A_{0, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the iso-idealisation conditional stuffed historical probability distribution at the maximum likelihood estimate is such that (a) the log likelihood varies with the iso-derived log likelihood,

$$
\ln \hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

(b) the log likelihood varies with the size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) & \sim \\
\left(z_{\mathrm{o}}+v_{\mathrm{o}}\right) \times \operatorname{entropy}\left(A_{\mathrm{o}}\right. & \left.* T_{\mathrm{o}}+V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right) \\
& -z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)-v_{\mathrm{o}} \times \operatorname{entropy}\left(V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)
\end{aligned}
$$

and (c) the sum sensitivity is less than or equal to the sum sensitivity of the stuffed historical probability distribution at the maximum likelihood estimate,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\right.\right. & \left.\left.\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \\
& \leq \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)
\end{aligned}
$$

If, in addition, (vii) the size is less than the volume, $z_{0}<v_{\mathrm{o}}$, but the sample approximates to the idealisation, $A_{\mathrm{o}} \approx A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, then (d) the log likelihood varies with the scaled component size cardinality relative entropy,

$$
\ln \hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \text { entropyRelative }\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)
$$

and (e) the log likelihood varies against the specialising derived substrate history coder space,

$$
\ln \hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\operatorname{space}\left(C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)\left(H_{\mathrm{o}}\right)
$$

where
$C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)=\operatorname{coderHistorySubstrateDerivedSpecialising}\left(U, X, T, D_{\mathrm{S}}, D_{\mathrm{X}}\right)$
So (f) the sum sensitivity varies against the log-likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

and (g) the sensitivity to model also varies against the log likelihood,
$-\ln \left|\max \left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \dagger, T, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}} \approx A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}}\right\}\right)\right| \sim$

$$
-\ln \hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

Note that the anti-correlation between the log-likelihood and specialising space,

$$
\ln \hat{Q}_{\mathrm{h}, \dagger, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\operatorname{space}\left(C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)\left(H_{\mathrm{o}}\right)
$$

is conjectured to be weaker than that of classical modelled induction,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\operatorname{space}\left(C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)\left(H_{\mathrm{o}}\right)
$$

because the expected component entropy of the idealisation is less than or equal to that of the naturalisation.

In section 'Classical modelled induction', above, it is shown that the isoderived conditional stuffed historical probability distribution at the maximum likelihood estimate, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{o}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)$, can be related to queries on the maximum likelihood estimate of the distribution histogram, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, in the special case where the sample histogram is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$. The given substrate transform must be such that its contraction has underlying variables that are a subset of the query variables, und $\left(T_{\mathrm{o}}^{\%}\right) \subseteq K$. In the case where the query histogram consists of one effective state, $Q=\left\{\left(S_{Q}, 1\right)\right\}$, the application of the query in terms of a modified sample histogram is

$$
\begin{aligned}
& \left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)= \\
& \quad\left\{\left(N,\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{Q, N}\right)\right)^{1 / z_{\mathrm{o}}}\right): N \in\left(V_{\mathrm{o}} \backslash K\right)^{\mathrm{CS}}\right. \\
& \left.\quad A_{Q, N}=A_{\mathrm{o}}-\left(A_{\mathrm{o}} * C_{Q}\right)+\left(\left(A_{\mathrm{o}} * C_{Q}\right) \% K *\{N\}^{\mathrm{U}}\right)\right\}^{\wedge}
\end{aligned}
$$

where $\left\{R_{Q}\right\}=\left(Q * T_{\mathrm{o}}^{\%}\right)^{\mathrm{FS}}, C_{Q}=T_{\mathrm{o}}^{-1}\left(R_{Q}\right)$ and his $=$ histogram $\in \mathcal{T} \rightarrow \mathcal{A}$. If the sample histogram is completely effective, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$, the modified sample histogram, $A_{Q, N}$, can be drawn from the distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{o}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{Q, N}\right)>$ 0 , because its derived is equal to the known derived, $A_{Q, N} * T_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}}$. That is, the modified sample histogram is in the iso-deriveds, $A_{Q, N} \in D_{U, i, T_{0}, z_{0}}^{-1}\left(A_{\mathrm{o}} *\right.$ $T_{\mathrm{o}}$ ).

However, in the case of idealisation induction, where the idealisation is necessary, the modified sample histogram is not in the iso-idealisations, $A_{Q, N} \notin$ isoi $(U)\left(T_{\mathrm{o}}, A_{\mathrm{o}}\right)$, if the volume of the label variables is non-singular, $\mid\left(V_{\mathrm{o}} \backslash\right.$ $K)^{\mathrm{C}} \mid>1$. That is, strictly speaking, even if the transform is ideal, $A_{\mathrm{o}}=A_{\mathrm{o}} *$ $T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, the application of the query via the model, $Q * T_{\mathrm{o}}^{\%} *$ his $\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}$, cannot be expressed in terms of the iso-idealisation conditional stuffed historical probability distribution at the maximum likelihood estimate, $\hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)$.

However, it is conjectured that, especially in the case of small label volume, $\left|\left(V_{\mathrm{o}} \backslash K\right)^{\mathrm{C}}\right| \approx 2$, the query sensitivity to the distribution histogram varies as the iso-idealisation sum sensitivity divided by the size

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}}
$$

Although the query application via the model is sometimes not equal to the estimated transformed conditional product, the query sensitivity to the distribution histogram is sometimes lower,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\right.\right. & \left.\left.\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}} \\
\leq & \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{o}\right)\right)\right) / z_{\mathrm{o}}
\end{aligned}
$$

Similarly, the model likelihood of the distribution histogram is sometimes higher,

$$
\hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z\right)\left(A_{Q, N}\right) \geq \hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z\right)\left(A_{Q, N}\right)
$$

In other words, querying via the known derived of the model sometimes reduces the sensitivity to the unknown and increases the likelihood at the cost of modifying the query. Note that the degree to which this is case is lower in idealisation induction than it is in classical modelled induction.

In the discussion above, the model, $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, is known and the idealisation, $\hat{E}_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger} \hat{E}_{\mathrm{o}}$, is both necessary and known. Optimisation can be done to find the maximum likelihood estimate of the distribution histogram for known model,

$$
\left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \uparrow, T_{\mathrm{o}}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}\right\}\right)
$$

Just as in the discussion above of classical modelled induction, consider the case where the idealisation, $\hat{E}_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger \hat{E}_{\mathrm{o}}}$, is still necessary but the model, $T_{\mathrm{o}}$, is unknown and so the idealisation is unknown. Again, the maximum likelihood estimate for the pair $\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right)$ can be defined as an optimisation of the multinomial probability conditional on the iso-idealisations where both the distribution histogram and transform are treated as arguments to a likelihood function,

$$
\begin{aligned}
& \left\{\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right)\right\} \\
& \qquad=\operatorname{maxd}\left(\left\{\left((E, T), \frac{Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in \operatorname{isoi}(U)\left(T, A_{\mathrm{o}}\right)} Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)(B)}\right):\right.\right. \\
& \left.\left.\quad E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}, T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
\end{aligned}
$$

There is, however, no singular solution to this optimisation,

$$
\begin{aligned}
& \operatorname{maxd}\left(\left\{\left((E, T), \frac{Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in \operatorname{isoi}(U)\left(T, A_{\mathrm{o}}\right)} Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)(B)}\right):\right.\right. \\
& \left.\left.E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}, T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right) \supseteq \mathcal{A}_{U, V_{\mathrm{o}}, 1} \times\left\{T_{\mathrm{s}}\right\}
\end{aligned}
$$

where $T_{\mathrm{s}}$ is a self transform. That is, the maximisation does not yield a single solution for the pair $\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right)$. Similarly to classical modelled induction in the case where the derived is necessary but unknown, in the case where the idealisation is necessary but unknown, the maximum likelihood estimate for the model, $\tilde{T}_{\mathrm{o}}$, is just the self transform, $\tilde{T}_{\mathrm{o}}=T_{\mathrm{s}}$, which is the trivial case where everything is known.

Again, this singular solution for unknown transform can be addressed by relaxing the constraint that the sample be necessarily drawn from the isoidealisations of the distribution to the constraint that the sample be possibly drawn from the iso-idealisations of the distribution. This is equivalent to assuming that the sample is drawn from the uniform possible iso-idealisation historically distributed history probability function, $P_{U, X, H_{\mathrm{h}}, \dagger, \mathrm{p}, T_{\mathrm{o}}}$, which is defined as the solution to

## $P_{U, X, H_{\mathrm{h}}, \dagger_{, \mathrm{p}, T_{\mathrm{o}}}}:=$

$$
\begin{aligned}
& \left(\bigcup \left\{\left\{\left(H, 1 / \sum\left(P_{U, X, H_{\mathrm{h}}, \dagger, \mathrm{p}, T_{\mathrm{o}}}(G):\right.\right.\right.\right.\right. \\
& \left.\left.G \subseteq H_{\mathrm{h}} \% V_{H},|G|=z_{H}, A_{G} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{G}}=A_{H} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{H}}\right)\right): \\
& \\
& \left.H \subseteq H_{\mathrm{h}} \% V_{H},|H|=z_{H}\right\}^{\wedge}: \\
& \left.\left.\quad V_{H} \subseteq V_{\mathrm{h}}, z_{H} \in\left\{1 \ldots z_{\mathrm{h}}\right\}\right\}\right)^{\wedge} \cup \\
& \left\{(H, 0): H \in \mathcal{H}_{U, X}, H \nsubseteq H_{\mathrm{h}} \% V_{H}\right\} \cup\{(\emptyset, 0)\}
\end{aligned}
$$

The uniform possible iso-idealisation historically distributed history probability function is such that given a drawn history $H \in \mathcal{H}_{U, X}$

$$
\begin{aligned}
\hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right)= & \frac{\sum P_{U, X, H_{\mathrm{h}}, \uparrow, \mathrm{p}, T_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}}{\sum P_{U, X, H_{\mathrm{h}}, \uparrow, \mathrm{p}, T_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, V_{G}=V_{H},|G|=z_{H}}
\end{aligned}
$$

The possible history probability function, $P_{U, X, H_{\mathrm{h}}, \dagger, \mathrm{p}, T_{\mathrm{o}}}$, is related to the isoidealisation conditional historical probability distribution, $\hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)$, in the same way as for the necessary case, $P_{U, X, H_{\mathrm{h}}, \uparrow, T_{o}}$, except that the normalising fraction is restored. In the case where all idealisations are possible the normalising fraction is $1 /\left|\operatorname{ran}\left(Y_{U, \mathbf{i}, T_{o}, \dagger, z_{H}}\right)\right|$. Any historically drawn history is possible,

$$
\forall H \subseteq H_{\mathrm{h}} \% V_{H}\left(P_{U, X, H_{\mathrm{h}}, \uparrow, \mathrm{p}, T_{\mathrm{o}}}(H)>0\right)
$$

but sometimes the probability is lower than in the necessary case,
$\forall H \subseteq H_{\mathrm{h}} \% V_{H}\left(P_{U, X, H_{\mathrm{h}}, \dagger, T_{\mathrm{o}}}(H)>0 \Longleftrightarrow P_{U, X, H_{\mathrm{h}}, \dagger, \mathrm{p}, T_{\mathrm{o}}}(H) \leq P_{U, X, H_{\mathrm{h}}, \dagger, T_{\mathrm{o}}}(H)\right)$
The uniform possible log likelihood has similar properties to the necessary log likelihood but restores the normalising fraction,
$\ln \hat{Q}_{\mathrm{m}, \uparrow, T, U}(E, z)(A)=\ln \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \mathrm{isoi}(U)(T, A)} Q_{\mathrm{m}, U}(E, z)(B)}-\ln \left|\operatorname{ran}\left(Y_{U, \mathrm{i}, T, \uparrow, z}\right)\right|$
The cardinality of the idealisations, $\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, T, \uparrow, z}\right)\right|$, varies with the cardinality of the derived, $\left|\operatorname{ran}\left(D_{U, i, T, z}\right)\right|$, which is equal to the cardinality of the possible
derived substrate histograms,

$$
\begin{aligned}
\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, T, \uparrow, z}\right)\right| & \sim\left|\operatorname{ran}\left(D_{U, \mathbf{i}, T, z}\right)\right| \\
& =\frac{\left(z+w^{\prime}-1\right)!}{z!\left(w^{\prime}-1\right)!}
\end{aligned}
$$

where $w^{\prime}=\left|T^{-1}\right|$. So the additional term in the uniform possible log likelihood, $-\ln \left|\operatorname{ran}\left(Y_{U, i, T, \dagger, z}\right)\right|$, varies against the possible derived volume, $w^{\prime}$, where the possible derived volume is less than the size, $w^{\prime}<z$, otherwise against the size scaled log possible derived volume, $z \ln w^{\prime}$,

$$
\begin{aligned}
-\ln \left|\operatorname{ran}\left(Y_{U, \mathbf{i}, T, \uparrow, z}\right)\right| & \sim-\operatorname{spaceCountsDerived}(U)(A, T) \\
& \sim-\left(\left(w^{\prime}: w^{\prime}<z\right)+\left(z \ln w^{\prime}: w^{\prime} \geq z\right)\right)
\end{aligned}
$$

In uniform possible idealisation induction, where (i) the history probability function is uniform possible iso-idealisation historically distributed, $P=$ $P_{U, X, H_{\mathrm{h}}, \dagger, \mathrm{p}, T_{\mathrm{o}}}$, given some substrate transform in the sample variables $T_{\mathrm{o}} \in$ $\mathcal{T}_{U, V_{\mathrm{o}}}$, if it is the case that (ii) the sample histogram is ideal, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger} A_{\mathrm{o}}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the iso-idealisation conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \dagger, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, so, if it is also the case that (iii) the alignment is intermediate or $\operatorname{high}, \operatorname{algn}\left(A_{\mathrm{o}}\right) \geq \operatorname{algnMax}(U)\left(V_{\mathrm{o}}, z_{\mathrm{o}}\right) / 2$, (iv) the relative entropy is high, entropyCross $\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)>\ln \left|T_{\mathrm{o}}^{-1}\right|$, (v) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{\mathrm{o}}$, and such that (vi) the scaled probability sample histogram is integral, $A_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the iso-idealisation conditional stuffed historical probability distribution at the maximum likelihood estimate is such that in addition to the properties for necessary idealisation induction, formally stated above, the log likelihood varies against the possible derived volume, $w_{\mathrm{o}}^{\prime}$, where the possible derived volume is less than the size, $w_{\mathrm{o}}^{\prime}<z_{\mathrm{o}}$, otherwise against the size scaled $\log$ possible derived volume, $z_{\mathrm{o}} \ln w_{\mathrm{o}}^{\prime}$,

$$
\ln \hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\left(\left(w_{\mathrm{o}}^{\prime}: w_{\mathrm{o}}^{\prime}<z_{\mathrm{o}}\right)+\left(z_{\mathrm{o}} \ln w_{\mathrm{o}}^{\prime}: w_{\mathrm{o}}^{\prime} \geq z_{\mathrm{o}}\right)\right)
$$

If, in addition, (vii) the size is less than the volume, $z_{\mathrm{o}}<v_{\mathrm{o}}$, but the sample approximates to the idealisation, $A_{\mathrm{o}} \approx A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger} A_{\mathrm{o}}$, then conjecture that, in the case where the sample history is modal, $H_{\mathrm{o}} \in \operatorname{maxd}\left(P_{U, X, H_{\mathrm{h}}, \dagger, \mathrm{p}, T_{\mathrm{o}}}\right)$, the log-likelihood of the iso-idealisation conditional stuffed historical probability distribution varies with its degree of structure with respect to the expanded specialising derived history coder, $C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}$,

$$
\ln \hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{structure}(U, X)\left(P_{U, X, H_{\mathrm{h}}, \uparrow, \mathrm{p}, T_{\mathrm{o}}}, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)
$$

Note that this correlation is conjectured to be weaker than that of classical modelled induction,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{structure}(U, X)\left(P_{U, X, H_{\mathrm{h}}, \mathrm{~d}, \mathrm{p}, T_{\mathrm{o}}}, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)
$$

because the correlation between the log-likelihood and the specialising coder space is weaker.

The maximum likelihood estimate for the pair $\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right)$ in the possible case is
$\left\{\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right)\right\}=\operatorname{maxd}\left(\left\{\left((E, T), \hat{Q}_{\mathrm{m}, \uparrow, T, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}, T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)$
if there is a unique maximum. This can be rewritten in terms of the idealisationdependent,

$$
\left\{\tilde{T}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{m}, \dagger, T, U}\left(A_{\mathrm{o}}^{\dagger(T)}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

Strictly speaking, this is only the case for the subset of substrate transforms, $\mathcal{T}_{U, V_{0}}$, for which the idealisation-dependent histogram, $A_{0}^{\dagger(T)}$, is defined.

If the optimisation is restricted to ideal transforms, $A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}} \Longrightarrow$ $A_{\mathrm{o}}^{\dagger(T)}=A_{\mathrm{o}}$, then the optimisation is
$\left\{\tilde{T}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{m}, \dagger, T, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}}\right\}\right)$
In this case, all the idealisations are possible because the distribution equals the sample, so the optimisation is

$$
\begin{aligned}
& \left\{\tilde{T}_{\mathrm{o}}\right\} \\
& =\operatorname{maxd}\left(\left\{\left(T, \frac{1}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, T, \dagger, z_{\mathrm{o}}}\right)\right|} \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in \operatorname{isoi}(U)\left(T, A_{\mathrm{o}}\right)} Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)(B)}\right):\right.\right. \\
& \\
& \left.\left.\quad T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}}\right\}\right)
\end{aligned}
$$

Now, if the maximum likelihood estimate for the model, $\tilde{T}_{\mathrm{o}}$, is unique, it is computable.

In this case, the numerator, $Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$, is constant.
The maximum likelihood estimate for the model is not self, $\tilde{T}_{\mathrm{o}} \neq T_{\mathrm{s}}$, if

$$
\frac{1}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, \tilde{T}_{\mathrm{o}}, \uparrow, z_{\mathrm{o}}}\right)\right|} \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in \operatorname{isoi}(U)\left(\tilde{T}_{\mathrm{o}}, A_{\mathrm{o}}\right)} Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)(B)}>\frac{1}{\left|\operatorname{ran}\left(\mathcal{A}_{U, \mathrm{i}, V_{o}, z_{\mathrm{o}}}\right)\right|}
$$

which is the case if the iso-idealisation conditional multinomial probability is greater than the inverted average cardinality of the iso-idealisations,

$$
\frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in \operatorname{iso}(U)\left(\tilde{T}_{\mathrm{o}}, A_{\mathrm{o}}\right)} Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)(B)}>\frac{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, \tilde{T}_{\mathrm{o}}, t, z_{\mathrm{o}}}\right)\right|}{\left|\operatorname{dom}\left(Y_{U, \mathrm{i}, \tilde{T}_{\mathrm{o}}, \uparrow, z_{\mathrm{o}}}\right)\right|}
$$

The sample is ideal, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, so the maximum likelihood estimate for the model is not unary, $\tilde{T}_{\mathrm{o}} \neq T_{\mathrm{u}}$, if the sample is not cartesian, $\hat{A}_{\mathrm{o}} \neq \hat{V}_{\mathrm{o}}^{\mathrm{C}}$.

In some cases the maximum likelihood estimate for the model is neither self nor unary, $\tilde{T}_{\mathrm{o}} \notin\left\{T_{\mathrm{s}}, T_{\mathrm{u}}\right\}$.

In idealisation induction, where (i) the history probability function is uniform possible iso-idealisation historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \dagger, \mathrm{p}, T_{\mathrm{o}}}$, given some unknown substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, if it is the case that (ii) the sample histogram is ideal, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, then the maximum likelihood estimate of the distribution histogram, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the iso-idealisation conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, and, if it is also the case that (iii) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{\mathrm{o}}$, and such that (iv) the scaled probability sample histogram is integral, $A_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the maximum likelihood estimate of the model, $\tilde{T}_{\mathrm{o}}$, in the iso-idealisation conditional stuffed historical probability distribution at the maximum likelihood estimate of the distribution, $\tilde{E}_{\mathrm{o}}$, is

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \uparrow, T, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}}\right\}\right)
$$

and in some cases the maximum likelihood estimate for the model, $\tilde{T}_{\mathrm{o}}$, is non-trivial,

$$
\tilde{T}_{\mathrm{o}} \notin\left\{T_{\mathrm{s}}, T_{\mathrm{u}}\right\}
$$

### 5.8 Abstract induction

In classical modelled induction, above, it was shown that if the model, $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, were unknown then for necessary derived there would be no unique solution for the maximum likelihood estimate for the pair ( $\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}$ ),

$$
\begin{aligned}
& \operatorname{maxd}\left(\left\{\left((E, T), \frac{Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in D_{U, i, T, z_{\mathrm{o}}}^{-1}\left(A_{\mathrm{o}} * T\right)} Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)(B)}\right):\right.\right. \\
& \left.\left.E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}, T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right) \neq\left\{\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right)\right\}
\end{aligned}
$$

If the iso-derived condition is weakened from necessary to possible,

$$
\operatorname{maxd}\left(\left\{\left((E, T), \hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{o}, 1}, T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

then in some cases the maximum likelihood estimate for the model, $\tilde{T}_{\mathrm{T}}$, is nontrivial, $\tilde{T}_{\mathrm{o}} \notin\left\{T_{\mathrm{s}}, T_{\mathrm{u}}\right\}$, but at the cost of lower likelihood, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{\mathrm{o}}}(H)>$ $0 \Longrightarrow P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, T_{\mathrm{o}}}(H) \leq P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{o}}(H)$. Similarly in idealisation induction, above, where instead of necessary derived the stricter necessary idealisation is required, the iso-idealisation condition must also be weakened from necessary to possible at the cost of lower likelihood, $P_{U, X, H_{\mathrm{h}}, \dagger, T_{\mathrm{o}}}(H)>0 \Longrightarrow$ $P_{U, X, H_{\mathrm{h}}, \uparrow, \mathrm{p}, T_{\mathrm{o}}}(H) \leq P_{U, X, H_{\mathrm{h}}, \uparrow, T_{\mathrm{o}}}(H)$. Now, instead of weakening the condition from necessary derived to possible derived, consider weakening the condition to necessary abstract. Now there is a unique solution for the maximum likelihood estimate for the pair $\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right)$.

First, however, consider the case where the given substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, is known.

Given some known substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, the abstract histogram of the distribution probability histogram is $\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$. In abstract induction, while the distribution probability histogram, $\hat{E}_{\mathrm{h}}$, remains unknown, the abstract distribution probability histogram, $\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, is known and necessary. That is, the history probability function, $P$, is historically distributed but constrained such that all drawn histories have a abstract probability histogram equal to the known abstract distribution probability histogram, $\left(\hat{A}_{H} * T_{\mathrm{o}}\right)^{\mathrm{X}}=\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$. Define the iso-abstract historically distributed history probability function $P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{\mathrm{o}}} \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}$,

$$
\begin{aligned}
& P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{\mathrm{o}}}:= \\
& \left.\qquad \begin{array}{l}
\left(\bigcup \left\{\left\{(H, 1): H \subseteq H_{\mathrm{h}} \% V_{H},|H|=z_{H}\right.\right.\right. \\
\qquad\left(\hat{A}_{H} * T_{\mathrm{o}}\right)^{\mathrm{X}}
\end{array}=\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{x}}\right\} \wedge \\
& \left.\left.V_{H} \subseteq V_{\mathrm{h}}, z_{H} \in\left\{1 \ldots z_{\mathrm{h}}\right\}\right\}\right)^{\wedge} \cup \\
& \left\{(H, 0): H \in \mathcal{H}_{U, X},\left(\hat{A}_{H} * T_{\mathrm{o}}\right)^{\mathrm{x}} \neq\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}\right\} \cup \\
& \left\{(H, 0): H \in \mathcal{H}_{U, X}, H \nsubseteq H_{\mathrm{h}} \% V_{H}\right\} \cup\{(\emptyset, 0)\}
\end{aligned}
$$

For drawn histories the abstract probability histogram is necessary, $\forall H \in$ $\mathcal{H}_{U, X}\left(P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{\mathrm{o}}}(H)>0 \Longrightarrow\left(\hat{A}_{H} * T_{\mathrm{o}}\right)^{\mathrm{X}}=\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}\right)$. Not all sizes and sets of variables are necessarily drawable. That is, in some cases, $\exists z \in$ $\left\{1 \ldots z_{\mathrm{h}}\right\} \exists V \subseteq V_{\mathrm{h}} \forall H \in \mathcal{H}_{U, X}\left(\left(z_{H}=z\right) \wedge\left(V_{H}=V\right) \Longrightarrow P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{\mathrm{o}}}(H)=\right.$ $0)$. The distribution history can always be drawn, so the probability function
is not a weak probability function, $\sum_{H \in \mathcal{H}_{U, X}} P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{o}}(H)=1$.
All iso-abstract subsets of the distribution history for a given set of variables and size are defined as equally probable,
$\forall V \subseteq V_{\mathrm{h}} \forall H, G \subseteq H_{\mathrm{h}} \% V$

$$
\left(\left(A_{G} * T_{\mathrm{o}}\right)^{\mathrm{X}}=\left(A_{H} * T_{\mathrm{o}}\right)^{\mathrm{X}} \Longrightarrow P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{\mathrm{o}}}(G)=P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{\mathrm{o}}}(H)\right)
$$

In abstract induction the history probability function is iso-abstract historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{\mathrm{o}}}$.

Given a drawn history $H \in \mathcal{H}_{U, X}$, where $P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{\mathrm{o}}}(H)>0$, the iso-abstract historical probability of histogram $A_{H}=\operatorname{histogram}(H)+V_{H}^{\mathrm{CZ}} \in \mathcal{A}_{U, \mathrm{i}, V_{H}, z_{H}}$ is now conditional,

$$
\begin{aligned}
& \frac{Q_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right)}{\sum_{B \in Y_{U, \mathrm{i}, T_{o}, \mathrm{~W}, z_{H}}\left(\left(A_{o} * T_{\mathrm{o}}\right)^{\mathrm{x}}\right)} Q_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)(B)}= \\
& \frac{\sum P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}}{\sum P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{o}}(G): G \in \mathcal{H}_{U, X}, V_{G}=V_{H},|G|=z_{H}}
\end{aligned}
$$

where the abstract valued histogram function $Y_{U, \mathrm{i}, T, \mathrm{~W}, z}$ is defined

$$
Y_{U, \mathrm{i}, T, \mathrm{~W}, z}=\left\{\left(A,(A * T)^{\mathrm{X}}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
$$

The finite set of integral iso-abstracts of abstract $(A * T)^{\mathrm{X}}$ is

$$
Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z},(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}\right\}
$$

The iso-abstract historical probability may be expressed in terms of a histogram distribution which is not explicitly conditional on the necessary abstract, $\left(\hat{E}_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$,
$\hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right) \propto \sum\left(P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}\right)$
where the iso-abstract conditional stuffed historical probability distribution is defined

$$
\begin{aligned}
& \hat{Q}_{\mathrm{h}, \mathrm{w}, T, U}(E, z) \\
&:=\left\{\left(A, \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum_{B \in Y_{U, \mathrm{i}, T, \mathrm{w}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)} Q_{\mathrm{h}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \leq E\right\}^{\wedge} \cup \\
&\left\{(A, 0): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \not \leq E\right\}
\end{aligned}
$$

which is defined if $z \leq \operatorname{size}(E)$.
In the case where all the abstracts are possible,

$$
\forall A^{\prime} \in \operatorname{ran}\left(Y_{U, \mathrm{i}, T, \mathrm{~W}, z}\right) \exists A \in \mathcal{A}_{U, \mathrm{i}, V, z}\left(\left((A * T)^{\mathrm{X}}=A^{\prime}\right) \wedge(A \leq E)\right)
$$

the normalisation of the iso-abstract conditional stuffed historical probability distribution is a fraction $1 /\left|\operatorname{ran}\left(Y_{U, i, T, \mathrm{~W}, z}\right)\right|$,

$$
\begin{aligned}
& \hat{Q}_{\mathrm{h}, \mathrm{w}, T, U}(E, z) \\
& \quad=\left\{\left(A, \frac{1}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, T, \mathrm{~W}, z}\right)\right|} \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum_{B \in Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)} Q_{\mathrm{h}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
\end{aligned}
$$

In the case of a full functional transform, $T_{\mathrm{f}}=\left\{\{w\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: w \in V\right\}^{\mathrm{T}}$, the iso-abstracts equals the iso-independents, $Y_{U, i, T, T, W, z}^{-1}\left(\left(A * T_{\mathrm{f}}\right)^{\mathrm{X}}\right)=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$. Thus the iso-abstract conditional stuffed historical probability distribution equals the iso-independent conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{f}}, U}(E, z)=\hat{Q}_{\mathrm{h}, \mathrm{y}, U}(E, z)$. In this case abstract induction reduces to aligned non-modelled induction.

At the other extreme of a unary transform, $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$, the set of isoabstracts equals the substrate histograms, $Y_{U, \mathrm{i}, T_{\mathrm{u}}, \mathrm{W}, z}^{-1}\left(\left(A * T_{\mathrm{u}}\right)^{\mathrm{X}}\right)=A_{U, \mathrm{i}, V, z}$. Thus the iso-abstract conditional stuffed historical probability distribution equals the stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{f}}, U}(E, z)=\hat{Q}_{\mathrm{h}, U}(E, z)$. In this case abstract induction reduces to classical non-modelled induction.

The iso-abstract conditional generalised multinomial probability distribution is defined

$$
\begin{aligned}
& \hat{Q}_{\mathrm{m}, \mathrm{w}, T, U}(E, z) \\
&:=\left\{\left(A, \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in Y_{U U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)} Q_{\mathrm{m}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A^{\mathrm{F}} \leq E^{\mathrm{F}}\right\}^{\wedge} \cup \\
&\left\{(A, 0): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A^{\mathrm{F}} \not \leq E^{\mathrm{F}}\right\}
\end{aligned}
$$

which is defined if $\operatorname{size}(E)>0$.
The case where all the abstracts are possible is weaker than for historical,

$$
\forall A^{\prime} \in \operatorname{ran}\left(Y_{U, \mathbf{i}, T, \mathrm{~W}, z}\right) \exists A \in \mathcal{A}_{U, \mathrm{i}, V, z}\left(\left((A * T)^{\mathrm{X}}=A^{\prime}\right) \wedge\left(A^{\mathrm{F}} \leq E^{\mathrm{F}}\right)\right)
$$

In this case the iso-abstract conditional generalised multinomial probability distribution is

$$
\begin{aligned}
& \hat{Q}_{\mathrm{m}, \mathrm{w}, T, U}(E, z) \\
& \quad=\left\{\left(A, \frac{1}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, T, \mathrm{~W}, z}\right)\right|} \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in Y_{U, i, T, \mathrm{w}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)} Q_{\mathrm{m}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
\end{aligned}
$$

It is assumed that the distribution history size, $z_{\mathrm{h}}$, is large with respect to the sample size $z_{0}=\operatorname{size}\left(A_{0}\right)$, so that, in the limit, the iso-abstract historical probability, $\hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$, approximates to the iso-abstract multinomial probability, $\hat{Q}_{\mathrm{m}, \mathrm{w}, T_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$. That is, if $z_{\mathrm{o}} \ll z_{\mathrm{h}}$ then

$$
\hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \approx \hat{Q}_{\mathrm{m}, \mathrm{w}, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

In the case of completely effective sample histogram, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$, the maximisation for known transform, $T_{\mathrm{o}}$, of the iso-abstract conditional generalised multinomial probability parameterised by the complete congruent histograms of unit size is a singleton of the rational maximum likelihood estimate

$$
\left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \mathrm{w}, T_{o}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}\right\}\right)
$$

In the case where the sample histogram is not completely effective, $A_{\mathrm{o}}^{\mathrm{F}}<$ $V_{\mathrm{o}}^{\mathrm{C}}$, the maximisation of the iso-abstract conditional generalised multinomial probability distribution for known transform is not necessarily a singleton

$$
\left|\max \left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \mathrm{w}, T_{\mathrm{o}}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{o}, 1}\right\}\right)\right| \geq 1
$$

In the case where the maximisation of the iso-abstract conditional generalised multinomial probability distribution is a singleton, it is equal to the normalised abstract-dependent, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{W}\left(T_{\mathrm{o}}\right)}$, where the abstract-dependent $A^{\mathrm{W}(T)} \in \mathcal{A}_{U, V, z}$ is defined in 'Likely histograms', above, as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, A, conditional that it is an iso-abstract,

$$
\begin{aligned}
& \left\{A^{\mathrm{W}(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The abstract-dependent, $A^{\mathrm{W}(T)}$, is sometimes not computable. The finite approximation to the abstract-dependent is

$$
\begin{aligned}
& \left\{A_{k}^{\mathrm{W}(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D / Z_{k}, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)}\right): D \in \mathcal{A}_{U, \mathrm{i}, V, k z}\right\}\right)
\end{aligned}
$$

The approximation, $A_{k}^{\mathrm{W}(T)} \approx A^{\mathrm{W}(T)}$, improves as the scaling factor, $k$, increases.

Unlike in classical non-modelled induction where the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, is equal to the sample probability histogram, $\hat{A}_{\mathrm{o}}$, in abstract induction the maximum likelihood estimate is not necessarily equal to the sample probability histogram. It is only in the case where the sample histogram is naturalised abstract that the maximum likelihood estimate is necessarily equal to the sample probability histogram,

$$
A_{\mathrm{o}}=\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}} * T_{\mathrm{o}}^{\dagger} \Longrightarrow A_{\mathrm{o}}^{\mathrm{W}\left(T_{\mathrm{o}}\right)}=A_{\mathrm{o}} \Longrightarrow \tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

Otherwise, the overall maximum likelihood estimate, which is the abstractdependent, is near the histogram, $\tilde{E}_{\mathrm{o}} \sim \hat{A}_{\mathrm{o}}$, only in as much as it is far from the naturalised abstract, $\tilde{E}_{\mathrm{o}} \nsim\left(\hat{A}_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}} * T_{\mathrm{o}}^{\dagger}$.

The requirement that the distribution history itself be drawable, $P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{\mathrm{o}}}\left(H_{\mathrm{h}}\right)>$ 0 , has been ignored so far. This requirement modifies the maximisation to add the constraint that the maximum likelihood estimate be an iso-abstract, $\left(\tilde{E}_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}=\left(\hat{A}_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$,

$$
\begin{aligned}
\left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \mathrm{w}, T_{\mathrm{o}}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E\right.\right. & \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}, \\
& \left.\left.\left(E * T_{\mathrm{o}}\right)^{\mathrm{X}}=\left(\hat{A}_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}\right\}\right)
\end{aligned}
$$

So, strictly speaking, the maximum likelihood estimate is only approximately equal to the normalised abstract-dependent, $\tilde{E}_{\mathrm{o}} \approx \hat{A}_{\mathrm{o}}^{\mathrm{W}\left(T_{0}\right)}$, if the abstractdependent is not an iso-abstract, $\left(A_{\mathrm{o}}^{\mathrm{W}\left(T_{\mathrm{o}}\right)} * T_{\mathrm{o}}\right)^{\mathrm{X}} \neq\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$. In the special case, however, where the sample histogram is naturalised abstract, the maximum likelihood estimate is exactly equal to the normalised abstractdependent, $A_{\mathrm{o}}=\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}} * T_{\mathrm{o}}^{\dagger} \Longrightarrow \tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{W}\left(T_{\mathrm{o}}\right)}=\hat{A}_{\mathrm{o}}$.

In abstract induction, where (i) the history probability function is iso-abstract historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{\mathrm{o}}}$, given some substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, if it is the case that (ii) the sample histogram is naturalised abstract, $A_{\mathrm{o}}=\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}} * T_{\mathrm{o}}^{\dagger}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the iso-abstract conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is

$$
\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

Classical modelled induction is termed law-like because the set of isoderiveds, $D_{U, T, z}^{-1}(A * T)$, where the derived, $A * T$, is necessary, is defined
as law-like. All iso-sets that are subsets of the iso-deriveds are also lawlike because the derived is still necessary. So idealisation induction is also termed law-like, because the set of iso-idealisations is a subset of the set of iso-deriveds, $Y_{U, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right) \subseteq D_{U, T, z}^{-1}(A * T)$.

The iso-derivedence, or degree of law-likeness, of the iso-abstracts equals the iso-abstractence of the iso-deriveds,

$$
\frac{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|} \leq 1
$$

So abstract induction is not maximally law-like if the iso-deriveds is a proper subset of the iso-abstracts, $D_{U, T, z}^{-1}(A * T) \subset Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$.

Abstract induction is termed entity-like because the set of iso-abstracts, $Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$, where the abstract, $(A * T)^{\mathrm{X}}$, is necessary, is defined as entity-like. That is, the iso-abstractence or degree of entity-likeness of the iso-abstracts is one, and so abstract induction is maximally entity-like. Law-like iso-sets are subsets of the set of iso-abstracts, $D_{U, T, z}^{-1}(A * T) \subseteq$ $Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$, and so are also entity-like. So abstract induction may be said to be more entity-like and less law-like than either classical modelled induction or idealisation induction.

As conditions are added to abstract induction that increase the law-likeness, or the degree to which the derived is necessary, the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, tends from the abstract-dependent, $\hat{A}_{\mathrm{o}}^{\mathrm{W}\left(T_{\mathrm{o}}\right)}$, to the deriveddependent, $\hat{A}_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)}$. That is, given iso-set $I \subset \mathcal{A}_{U, \mathrm{i}, V, z}$, which is such that $D_{U, \mathrm{i}, T, z}^{-1}(A * T) \subseteq I \subseteq Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$, as the iso-derivedence increases and the iso-abstractence decreases, the type of induction moves from entity-like to law-like, implying a more classical dependent analogue, $\hat{A}_{o}^{\left(T_{\mathrm{o}}\right)} \approx \hat{A}_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)}$, and so a more classical maximum likelihood estimate, $\tilde{E}_{\mathrm{o}} \approx \hat{A}_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)}$.

Also, even if there are no additional conditions and the iso-set remains equal to the iso-abstracts, $I=Y_{U, \mathbf{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$, constraints on the sample can make the denominator, $\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{W}(T)}, z\right)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$, more approximate to the iso-derived denominator, $\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{D}(T)}, z\right)(B)$ : $B \in D_{U, \mathbf{i}, T, z}^{-1}(A * T)$. In this way also abstract induction can sometimes be more like classical modelled induction even if the iso-derivedence remains unchanged.

The iso-independence of the iso-abstracts is

$$
\frac{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}
$$

In some cases the iso-independence of the iso-idealisations is greater than or equal to the iso-independence of the iso-abstracts,

$$
\frac{\left|Y_{U, i, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)\right|}{\left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|} \geq \frac{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}
$$

and so abstract induction may be said to be less aligned-like than idealisation induction. However, the derived iso-independence of the integral lifted isoabstracts is necessarily greater than or equal to the derived iso-independence of any law-like iso-set,

$$
\frac{\left|\left\{B * T: B \in Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right\}\right|}{\left|Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right|} \geq \frac{1}{\left|Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right|}
$$

and so abstract induction may be said to be more derived aligned-like than either classical modelled induction or idealisation induction.

As the iso-independence increases, the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, which equals the abstract-dependent, $\hat{A}_{\mathrm{o}}^{\mathrm{W}\left(T_{\mathrm{o}}\right)}$, tends to the dependent, $\hat{A}_{\mathrm{o}}^{\mathrm{Y}}$, which is independent of the model, $T_{\mathrm{o}}$, because the independent analogue, $\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}} * T_{\mathrm{o}}^{\dagger}$, tends to the independent, $A_{\mathrm{o}}^{\mathrm{X}}$, which is also independent of the model, as the transform tends to full functional. As the derived isoindependence increases, however, the lifted independent analogue, $A_{\mathrm{o}}^{\mathrm{U}\left(T_{\mathrm{o}}\right)^{\prime}}$, tends to the abstract, $\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, which is not independent of the model, $T_{\mathrm{o}}$.

Given the known substrate transform, $T_{\mathrm{o}}$, consider the maximum likelihood estimate of the iso-abstract conditional generalised multinomial probability distribution, $\hat{Q}_{\mathrm{m}, \mathrm{w}, T_{o}, U}$.

The independent-analogue or naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$, is the maximum likelihood estimate of the distribution histogram of the multinomial probability of membership of the iso-abstracts,

$$
\begin{aligned}
& \left\{(A * T)^{\mathrm{X}} * T^{\dagger}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The corresponding dependent-analogue or abstract-dependent, $A^{\mathrm{W}(T)}$, is the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, A, conditional that it is an iso-abstract,

$$
\begin{aligned}
& \left\{\left(A^{\mathrm{W}(T)}, \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{W}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{W}(T)}, z\right)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)}\right)\right\}= \\
& \quad \max \left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

In section 'Likely histograms', above, the logarithm of the maximum conditional probability with respect to the dependent-analogue is conjectured to vary with the relative space with respect to the independent-analogue. In the case of iso-abstract conditional,

$$
\begin{aligned}
& \ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{W}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{W}(T)}, z\right)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)} \sim \\
& \quad \text { spaceRelative }\left((A * T)^{\mathrm{x}} * T^{\dagger}\right)(A)
\end{aligned}
$$

where the distribution-relative multinomial space is defined, in section 'Likely histograms', above, as

$$
\text { spaceRelative }(E)(A):=-\ln \frac{\operatorname{mpdf}(U)(E, z)(A)}{\operatorname{mpdf}(U)(E, z)(E)}
$$

The set of iso-abstracts is entity-like so the derived, $A * T$, and the dependent derived, $A^{\mathrm{W}(T)} * T$, are not necessarily equal to each other and nor are they necessarily equal to the abstract, $(A * T)^{\mathrm{X}}$. In section 'Transform alignment', above, it is conjectured that the relation between the relative spaces,

$$
\begin{aligned}
0 & =\operatorname{spaceRelative}\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)\left((A * T)^{\mathrm{X}} * T^{\dagger}\right) \\
& \leq \operatorname{spaceRelative}\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)(A) \\
& \leq \operatorname{spaceRelative}\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)\left(A^{\mathrm{W}(T)}\right)
\end{aligned}
$$

can be lifted and so the dependent analogue derived alignment is conjectured to be greater than or equal to the derived alignment which in turn is greater than or equal to the independent analogue derived alignment,

$$
0=\operatorname{algn}\left((A * T)^{\mathrm{x}}\right) \leq \operatorname{algn}(A * T) \leq \operatorname{algn}\left(A^{\mathrm{W}(T)} * T\right)
$$

The abstract-dependent varies with the histogram, $A^{\mathrm{W}(T)} \sim A$, so conjecture that the log-likelihood varies with the derived alignment,

$$
\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{W}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{W}(T)}, z\right)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)} \sim \operatorname{algn}(A * T)
$$

The derivation of this correlation can be seen more clearly in terms of a decomposition into three separate correlations. First, conjecture that the logarithm of the iso-abstract conditional multinomial probability of the histogram, $A$, with respect to the dependent analogue or abstract-dependent, $A^{\mathrm{W}(T)}$, varies against the logarithm of the iso-abstract conditional multinomial probability with respect to the independent analogue or naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$,

$$
\begin{aligned}
& \ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{W}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{W}(T)}, z\right)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)} \sim \\
& \quad-\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}} * T^{\dagger}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}} * T^{\dagger}, z\right)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)}
\end{aligned}
$$

This relation is called the dependent-independent anti-correlation. As shown in 'Likely histograms', above, the strength of the dependent-independent anticorrelation depends on the relative space of the histogram with respect to the independent analogue, spaceRelative $\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)(A)$.

Second, conjecture that the negative logarithm of the iso-abstract conditional multinomial probability of the histogram, $A$, with respect to the independent analogue or naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$, varies with the negative logarithm of the lifted iso-abstract conditional multinomial probability of the derived, $A * T$, with respect to the lifted independent analogue or abstract, $(A * T)^{\mathrm{X}}$,

$$
\begin{array}{r}
-\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}} * T^{\dagger}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}} * T^{\dagger}, z\right)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)} \sim \\
-\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}}, z\right)(A * T)}{\sum Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}}, z\right)\left(B^{\prime}\right): B^{\prime} \in \operatorname{isowl}(U)(T, A)}
\end{array}
$$

where the lifted integral iso-abstracts is abbreviated

$$
\text { isowl }(U)(T, A):=\left\{B * T: B \in Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right\}
$$

This correlation is called the underlying-lifted correlation. Lifting the isoabstracts is functional,

$$
\left\{\left(A * T,(A * T)^{\mathrm{x}}\right): A \in \mathcal{A}_{U, V, z}\right\} \in \mathcal{A}_{U, W, z} \rightarrow \mathcal{A}_{U, W, z}
$$

and

$$
\left\{\left(A * T, Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right): A \in \mathcal{A}_{U, V, z}\right\} \quad \in \quad \mathcal{A}_{U, W, z} \rightarrow \mathrm{P}\left(\mathcal{A}_{U, V, z}\right)
$$

so the underlying-lifted correlation is expected to be positive.
Third, conjecture that, in the case where the abstract is integral, $(A * T)^{\mathrm{X}} \in$ $\mathcal{A}_{\mathrm{i}}$, the denominator of the lifted iso-abstract conditional multinomial probability is dominated by the abstract term, $Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)\left((A * T)^{\mathrm{X}}\right)$, and similar terms, and so the negative logarithm of the lifted iso-abstract conditional multinomial probability with respect to the lifted independent analogue or abstract, $(A * T)^{\mathrm{X}}$, varies with the negative logarithm of the relative multinomial probability with respect to the abstract, $(A * T)^{\mathrm{X}}$, which is the relative space with respect to the abstract, which is the derived alignment,

$$
\begin{aligned}
&-\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}}, z\right)(A * T)}{\sum Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)\left(B^{\prime}\right): B^{\prime} \in \operatorname{isowl}(U)(T, A)} \\
& \sim-\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)(A * T)}{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}}, z\right)\left((A * T)^{\mathrm{X}}\right)} \\
&=\operatorname{spaceRelative}\left((A * T)^{\mathrm{X}}\right)(A * T) \\
&=\operatorname{algn}(A * T)
\end{aligned}
$$

This correlation is called the conditional-relative correlation. The strength of the conditional-relative correlation increases with the derived iso-independence of the integral lifted iso-abstracts,

$$
\frac{\left|\left\{B * T: B \in Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right\}\right|}{\left|Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right|}
$$

As the derived iso-independence increases, the lifted abstract-independent, $A^{\mathrm{U}(T)^{\prime}}$, tends to the abstract, $(A * T)^{\mathrm{X}}$, and the lifted abstract-independent term, $Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)\left(A^{\mathrm{U}(T)^{\prime}}\right)$, tends to equal the abstract term, $Q_{\mathrm{m}, U}((A *$ $\left.T)^{\mathrm{X}}, z\right)\left((A * T)^{\mathrm{X}}\right)$, in the case where both are integral, $A^{\mathrm{U}(T)^{\prime}},(A * T)^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$. In the limit, the lifted iso-abstract conditional multinomial probability, with respect to the independent-analogue, $(A * T)^{\mathrm{X}}$, equals the iso-independent conditional multinomial probability, with respect to the independent, $(A * T)^{\mathrm{X}}$, of the layer above, which is where the substrate histogram is the derived histogram, $A * T$,

$$
\begin{aligned}
& -\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)(A * T)}{\sum Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)\left(B^{\prime}\right): B^{\prime} \in \operatorname{isowl}(U)(T, A)} \\
& \quad \sim-\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)(A * T)}{\sum Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}}, z\right)(B): B \in Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)}
\end{aligned}
$$

The corresponding iso-independent conditional multinomial probability, with respect to the dependent, $(A * T)^{\mathrm{Y}}$, of the derived layer is shown in section
'Aligned induction', above, to vary with the alignment of the derived layer's substrate histogram, $A * T$,

$$
\begin{aligned}
&-\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}}, z\right)(A * T)}{\sum Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)(B): B \in Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)} \\
& \sim \ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{Y}}, z\right)(A * T)}{\sum Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{Y}}, z\right)(B): B \in Y_{U, i, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)} \\
& \sim \operatorname{algn}(A * T)
\end{aligned}
$$

That is, in the case where the derived iso-independence is high, abstract induction may be viewed as aligned non-modelled induction of the derived.

In abstract induction, where (i) the history probability function is iso-abstract historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{\mathrm{o}}}$, given some substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, if it is the case that (ii) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{0}$, and such that (iii) the scaled estimate distribution histogram is integral, $\tilde{E}_{0, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the log likelihood of the iso-abstract conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the relative space of the sample with respect to the naturalised abstract,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \text { spaceRelative }\left(\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}} * T_{\mathrm{o}}^{\dagger}\right)\left(A_{\mathrm{o}}\right)
$$

and varies with the derived alignment,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

The derived alignment of the maximum likelihood estimate is greater than or equal to that of the sample,

$$
\operatorname{algn}\left(Z_{\mathrm{o}} * \tilde{E}_{\mathrm{o}} * T\right) \geq \operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

In section 'Classical modelled induction', above, it is shown that the isoderived conditional stuffed historical probability distribution at the maximum likelihood estimate, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)$, can be related to queries on the maximum likelihood estimate of the distribution histogram, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, in the special case where the sample histogram is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$. The given substrate transform must be such that its contraction has underlying variables that are a subset of the query variables, und $\left(T_{\mathrm{o}}^{\%}\right) \subseteq K$. In the case where the query histogram consists of one effective state, $Q=\left\{\left(S_{Q}, 1\right)\right\}$, the
application of the query in terms of a modified sample histogram is

$$
\begin{aligned}
& \left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)= \\
& \quad\left\{\left(N,\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{Q, N}\right)\right)^{1 / z_{\mathrm{o}}}\right): N \in\left(V_{\mathrm{o}} \backslash K\right)^{\mathrm{CS}}\right. \\
& \left.\quad A_{Q, N}=A_{\mathrm{o}}-\left(A_{\mathrm{o}} * C_{Q}\right)+\left(\left(A_{\mathrm{o}} * C_{Q}\right) \% K *\{N\}^{\mathrm{U}}\right)\right\}^{\wedge}
\end{aligned}
$$

where $\left\{R_{Q}\right\}=\left(Q * T_{\mathrm{o}}^{\%}\right)^{\mathrm{FS}}, C_{Q}=T_{\mathrm{o}}^{-1}\left(R_{Q}\right)$ and his $=$ histogram $\in \mathcal{T} \rightarrow \mathcal{A}$. If the sample histogram is completely effective, $A_{\mathrm{o}}^{\mathrm{F}}=V_{0}^{\mathrm{C}}$, the modified sample histogram, $A_{Q, N}$, can be drawn from the distribution, $\hat{Q_{\mathrm{h}, \mathrm{d}, T_{\mathrm{o}}, U}}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{Q, N}\right)>$ 0 , because its derived is equal to the known derived, $A_{Q, N} * T_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}}$. That is, the modified sample histogram is in the iso-deriveds, $A_{Q, N} \in D_{U, i, T_{0}, z_{0}}^{-1}\left(A_{\mathrm{o}} *\right.$ $T_{\mathrm{o}}$ ).

However, in the case of abstract induction, where the abstract is necessary, although the modified sample histogram is in the iso-abstracts, $A_{Q, N} \in$ $Y_{U, i, T_{\mathrm{o}}, \mathrm{W}, z}^{-1}\left(\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}\right)$, the modified derived, $\hat{A}_{Q, N} * T_{\mathrm{o}}$, is not necessarily equal to that of the distribution, $\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}$. That is, in some cases $\hat{A}_{Q, N} * T_{\mathrm{o}} \neq \hat{E}_{\mathrm{h}} * T_{\mathrm{o}}$. Only the modified abstract is necessary, $\left(\hat{A}_{Q, N} * T_{\mathrm{o}}\right)^{\mathrm{X}}=\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$. Furthermore, even if the sample is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, the maximum likelihood estimate of the distribution histogram, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{W}(T)}$, is not necessarily equal to the sample, $\tilde{E}_{\mathrm{o}} \neq \hat{A}_{\mathrm{o}}$. So it cannot be assumed that application of the query via the model of the sample is equal to the query via the model of the distribution, $\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right) \neq$ $\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * E_{\mathrm{h}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)$. Nor can the query via the model of the sample, $\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)$, be expressed in terms of the iso-abstract conditional stuffed historical probability distribution at the scaled naturalised sample, $\hat{Q}_{\mathrm{h}, \mathrm{w}, T_{o}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)$.

Consider the constraints that may be added to abstract induction to increase the resemblance to classical modelled induction, so that queries via the model of the sample are more approximate to queries via the model of the distribution, $\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right) \approx\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) *\right.$ $\left.E_{\mathrm{h}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)$.

The set of law-like iso-deriveds are a subset of the set of entity-like isoabstracts, $D_{U, T, z}^{-1}(A * T) \subseteq Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$, so conjecture that the logarithm of the fraction of the sum of the iso-abstract multinomial probabilities, with respect to the naturalisation, $A * T * T^{\dagger}$, that are iso-derived varies as the
relative space of the naturalisation with respect to the naturalised abstract,

$$
\begin{aligned}
& \ln \frac{\sum Q_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)}{}(B): B \in D_{U, \mathrm{i}, T, z}^{-1}(A * T) \\
& \sum Q_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \\
& \sim \quad-\operatorname{spaceRelative}\left(A * T * T^{\dagger}\right)\left((A * T)^{\mathrm{x}} * T^{\dagger}\right) \\
& \sim \text { spaceRelative }\left((A * T)^{\mathrm{x}} * T^{\dagger}\right)\left(A * T * T^{\dagger}\right)
\end{aligned}
$$

If the relative space is high, the elements of the iso-abstracts which are not iso-deriveds and so do not have the same derived as the naturalisation, $A$ * $T * T^{\dagger} * T=A * T$, have low multinomial probability with respect to the naturalisation,
$\sum\left(Q_{\mathrm{m}, U}\left(A * T * T^{\dagger}, z\right)(B): B \in Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \backslash D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right) \approx 0$
If the sample is known to be naturalised, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, then as the relative space of the sample with respect to the naturalised sample abstract, spaceRelative $\left(\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}} * T_{\mathrm{o}}^{\dagger}\right)\left(A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}\right)$, increases, the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, which is the abstract-dependent, $\hat{A}_{\mathrm{o}}^{\mathrm{W}\left(T_{\mathrm{o}}\right)}$, tends to the deriveddependent which equals the naturalisation, $\hat{A}_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, and away from the naturalised abstract, $\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}} * T_{\mathrm{o}}^{\dagger}$. Thus, the maximum likelihood estimate is more classical if the sample is known to be naturalised and the relative space is high.

The relative space of the histogram with respect to the naturalised abstract varies with the lifted relative space, which equals the derived alignment,

$$
\begin{aligned}
\text { spaceRelative }\left((A * T)^{\mathrm{X}} *\right. & \left.T^{\dagger}\right) \\
& (A) \\
& \sim \operatorname{spaceRelative}\left((A * T)^{\mathrm{x}} * T^{\dagger} * T\right)(A * T) \\
& =\operatorname{spaceRelative}\left((A * T)^{\mathrm{X}}\right)(A * T) \\
& =\operatorname{algn}(A * T)
\end{aligned}
$$

depending on the underlying-lifted correlation and the conditional-relative correlation.

The conditional-relative correlation improves as the derived iso-independence increases and the lifted abstract-independent, $A^{\mathrm{U}(T)^{\prime}}$, tends to the abstract, $(A * T)^{\mathrm{X}}$. In the case where the formal is independent, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, the possible derived volume equals the derived volume, $w^{\prime}=w$ where $w^{\prime}=\left|T^{-1}\right|$ and $w=\left|W^{\mathrm{C}}\right|$. As shown in 'Deltas and Perturbations', above, any subset of the integral congruent deltas $Q_{A} \subset \mathcal{A}_{\mathrm{i}} \times \mathcal{A}_{\mathrm{i}}$ which conserves iso-independence,
$\forall(D, I) \in Q_{A}\left(A-D+I \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right)$, is a linear sum of circuit deltas, where the circuit deltas are defined as the subset of iso-independent deltas having size less than or equal to two, $C_{A}=\left\{(D, I):(D, I) \in Q_{A}\right.$, $\left.\operatorname{size}(I) \leq 2\right\}$. The set of lifted iso-independent deltas, $\forall\left(D^{\prime}, I^{\prime}\right) \in Q_{A^{\prime}}\left(A * T-D^{\prime}+I^{\prime} \in\right.$ $\left.\left\{B * T: B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right\}\right)$, must be smaller than the set of derived iso-independent deltas, $\forall\left(D^{\prime}, I^{\prime}\right) \in Q_{A * T}\left(A * T-D^{\prime}+I^{\prime} \in Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right)$, if the possible derived volume is less than the derived volume, $w^{\prime}<w \Longrightarrow$ $\left|Q_{A^{\prime}}\right|<\left|Q_{A * T}\right|$, because circuit deltas cannot be constructed on impossible states. Therefore in the case of independent formal, where the possible derived volume equals the derived volume, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}} \Longrightarrow w^{\prime}=w$, the derived iso-independence is greater than would otherwise be the case, and the lifted abstract-independent approximates to the abstract, $A^{\mathrm{U}(T)^{\prime}} \approx(A * T)^{\mathrm{X}}$.

If the sample is known to have independent formal, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, the correlation between the relative space of the histogram with respect to the naturalised abstract and the derived alignment,

$$
\text { spaceRelative }\left(\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}} * T_{\mathrm{o}}^{\dagger}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

is higher than would be the case if there was formal alignment, $\operatorname{algn}\left(A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right)>$ 0 .

So the maximum likelihood estimate is more classical and less formal if (i) the sample is naturalised, (ii) the sample has independent formal and (iii) the derived alignment is high.

In abstract induction, where (i) the history probability function is iso-abstract historically distributed, $P=P_{U, X, H_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}}}$, given some substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, if it is the case that (ii) the sample is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, (iii) the sample formal is independent, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, (iv) the derived alignment is high, $\operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right) \gg 0$, (v) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{0}$, and such that (vi) the scaled estimate distribution histogram is integral, $\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the log likelihood of the iso-abstract conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the log likelihood of the iso-derived conditional stuffed historical probability distribution at the naturalisation,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

the formal alignment of the maximum likelihood estimate is small,

$$
\operatorname{algn}\left(Z_{\mathrm{o}} * \tilde{E}_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right) \approx 0
$$

and the derived of the maximum likelihood estimate approximates to the normalised sample derived,

$$
\tilde{E}_{\mathrm{o}} * T_{\mathrm{o}} \approx \hat{A}_{\mathrm{o}} * T_{\mathrm{o}}
$$

In this case queries via the model of the sample approximate to queries via the model of the distribution,

$$
\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right) \approx\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * E_{\mathrm{h}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)
$$

That is, at high derived alignments where the sample is known to be natural and the sample formal is known to be independent, abstract induction has similar properties to non-formal classical modelled induction.

If the relative entropy is high, entropy $\operatorname{Cross}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)>\ln \left|T_{\mathrm{o}}^{-1}\right|$, the sum sensitivity of the iso-derived conditional stuffed historical probability distribution at the naturalisation varies with the derived entropy,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

Note, however, that because the abstract induction is more derived alignedlike than classical modelled induction,

$$
\frac{\left|\left\{B * T: B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right\}\right|}{\left|Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|} \geq \frac{1}{\left|Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{x}}\right)\right|}
$$

the sum sensitivity of the iso-abstract conditional stuffed historical probability distribution at the maximum likelihood estimate may be expected rather to vary against the derived alignment,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\right.\right. & \left.\left.\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \\
& \sim z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)-z_{\mathrm{o}} \times \operatorname{entropy}\left(\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}\right) \\
& \approx-\operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
\end{aligned}
$$

So the log likelihood of the iso-abstract conditional stuffed historical probability distribution at the maximum likelihood estimate varies against the sum sensitivity of the iso-abstract conditional stuffed historical probability distribution at the maximum likelihood estimate,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) & \sim \operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right) \\
& \sim-\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)
\end{aligned}
$$

In the case of high relative entropy, the sum sensitivity of the iso-derived conditional stuffed historical probability distribution is conjectured to vary
with the unknown-known multinomial probability distribution sum sensitivity difference,

```
\(\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim\)
    \(\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\right)\right)-\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, z_{\mathrm{o}}\right)\right)\right)\)
```

so the sum sensitivity of the iso-abstract conditional stuffed historical probability distribution is also conjectured to vary with the unknown-known multinomial probability distribution sum sensitivity difference,

```
sum(sensitivity}(U)(\mp@subsup{\hat{Q}}{\textrm{h},\textrm{w},\mp@subsup{T}{\textrm{o}}{\prime},U}{}(\mp@subsup{\tilde{E}}{\textrm{o},\mp@subsup{z}{\textrm{h}}{}}{},\mp@subsup{z}{\textrm{o}}{})))
    sum(sensitivity (U)(\mp@subsup{\hat{Q}}{\textrm{m},U}{}(\mp@subsup{A}{\textrm{o}}{},\mp@subsup{z}{\textrm{o}}{})))-\operatorname{sum}(\operatorname{sensitivity}(U)(\mp@subsup{\hat{Q}}{\textrm{m},U}{}(\mp@subsup{A}{\textrm{o}}{}*\mp@subsup{T}{\textrm{o}}{},\mp@subsup{z}{\textrm{o}}{})))
```

the sum sensitivity of the iso-abstract conditional stuffed historical probability distribution at the maximum likelihood estimate is less than or equal to the sum sensitivity of the stuffed historical probability distribution at the maximum likelihood estimate,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\right.\right. & \left.\left.\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \\
\leq & \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)
\end{aligned}
$$

and the log likelihood of the iso-abstract conditional stuffed historical probability distribution at the maximum likelihood estimate is greater than or equal to the log likelihood of the stuffed historical probability distribution at the maximum likelihood estimate,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z\right)\left(A_{\mathrm{o}}\right) \geq \ln \hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z\right)\left(A_{\mathrm{o}}\right)
$$

In the case where (i) the sample is natural, (ii) the sample formal is independent, and (iii) the relative entropy is high, as the derived alignment increases (a) the non-formal classical log-likelihood increases and (b) the underlyingderived sum sensitivity difference decreases.

If, in addition, the size is less than the volume, $z_{\mathrm{o}}<v_{\mathrm{o}}$, but the sample approximates to the naturalisation, $A_{\mathrm{o}} \approx A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, then the log likelihood varies against the specialising derived substrate history coder space,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\operatorname{space}\left(C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)\left(H_{\mathrm{o}}\right)
$$

where
$C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)=\operatorname{coderHistorySubstrateDerivedSpecialising}\left(U, X, T, D_{\mathrm{S}}, D_{\mathrm{X}}\right)$

So the sum sensitivity varies against the log-likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

the sensitivity to model also varies against the log likelihood,
$-\ln \mid \max \left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{w}, T, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right.\right.$,

$$
\left.\left.A_{\mathrm{o}}^{\mathrm{x}} * T=\left(A_{\mathrm{o}}^{\mathrm{X}} * T\right)^{\mathrm{X}}, A_{\mathrm{o}} \approx A_{\mathrm{o}} * T * T^{\dagger}\right\}\right) \mid \sim
$$

$$
-\ln \hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

and the log-likelihood varies with its degree of structure with respect to the expanded specialising derived history coder, $C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}$,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{structure}(U, X)\left(P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{\mathrm{o}}}, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)
$$

Note that, although the added constraint of known natural sample, $A_{\mathrm{o}}=$ $A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, can increase the resemblance to classical induction, the induction remains abstract induction because the condition of necessary abstract has not changed and so neither the iso-set, $Y_{U, i, T o, \mathrm{~W}, z_{\mathrm{o}}}^{-1}\left(\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}\right)$, nor the iso-derivedence have changed. That is, the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, does not move away from the abstract-dependent, $\hat{A}_{\mathrm{o}}^{\mathrm{W}\left(T_{\mathrm{o}}\right)}$, to the derived-dependent, $\hat{A}_{o}^{\mathrm{D}\left(T_{\mathrm{o}}\right)}$, but rather both the maximum likelihood estimate and the abstract-dependent move together towards the derived-dependent, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{W}\left(T_{\mathrm{o}}\right)} \approx \hat{A}_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)}$.

Note also that the assumption of high derived alignment, $\operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right) \gg 0$, is not well defined, although there is an upper bound, $\operatorname{algnMax}(U)\left(W_{\mathrm{o}}, z_{\mathrm{o}}\right)$. A more formal method of expression would be to say that the correlation between the iso-abstract conditional stuffed historical probability distribution and the iso-derived conditional stuffed historical probability distribution is itself correlated to the derived alignment,

$$
\left[\ln \hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right] \sim \operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

More formal still would be to define this relation in terms of the correlations of functions of the sized cardinal substrate histograms, $\mathcal{A}_{z}$, given the renormalised geometry-weighted probability function, $\operatorname{corr}(z) \in\left(\mathcal{A}_{z} \rightarrow \mathbf{R}\right) \times\left(\mathcal{A}_{z} \rightarrow\right.$ $\mathbf{R}) \rightarrow \mathbf{R}$, as in section 'Substrate structures alignment', above.

In the discussion above, the model, $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, is known, and the abstract, $\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, is both necessary and known. Optimisation can be done to find the maximum likelihood estimate of the distribution histogram for known model,

$$
\left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \mathrm{w}, T_{\mathrm{o}}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}\right\}\right)
$$

Just as in the discussion above of classical modelled induction, consider the case where the abstract, $\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, is still necessary but the model, $T_{\mathrm{o}}$, is unknown and so the abstract is unknown. Again, the maximum likelihood estimate for the pair $\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right)$ can be defined as an optimisation of the multinomial probability conditional on the iso-abstracts where both the distribution histogram and transform are treated as arguments to a likelihood function,

$$
\begin{aligned}
& \left\{\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right)\right\} \\
& =\operatorname{maxd}\left(\left\{\left((E, T), \frac{Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in Y_{U, i, T, \mathrm{~W}, z_{\mathrm{o}}}^{-1}\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{x}}\right)} Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)(B)}\right):\right.\right. \\
& \left.\left.\quad E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}, T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
\end{aligned}
$$

It is conjectured that in abstract induction there are some cases in which there is a unique solution for the pair ( $\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}$ ). This is because in entity-like induction, but not law-like induction, the denominator does not necessarily reduce to equal the numerator, so avoiding degeneracy. In the case where there is a unique solution then the maximisation can be rewritten in terms of the abstract-dependent,

$$
\left\{\tilde{T}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(T, \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}^{\mathrm{W}(T)}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in Y_{U, i, T, \mathrm{~W}, z_{\mathrm{o}}}^{-1}\left(\left(A_{\circ} * T\right)^{\mathrm{x}}\right)} Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}^{\mathrm{W}(T)}, z_{\mathrm{o}}\right)(B)}\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

The maximum likelihood estimate for the model, $\tilde{T}_{\mathrm{o}}$, is sometimes not computable because the abstract-dependent, $A_{\mathrm{o}}^{\mathrm{W}\left(\tilde{T}_{\mathrm{o}}\right)}$, is sometimes not computable. A finite approximation to arbitrary accuracy for the abstract-dependent, $A_{k}^{\mathrm{W}(T)} \approx$ $A^{\mathrm{W}(T)}$, is computable. However, even an approximation is not tractable. The abstract function, $Y_{U, \mathrm{i}, T, \mathrm{~W}, z} \in \mathcal{A}_{U, \mathrm{i}, V, z}: \rightarrow \mathcal{A}_{U, W, z}$, is intractable because its computation requires the intractable computation of its domain of the substrate histograms, $\mathcal{A}_{U, \mathrm{i}, V, z}$.

In abstract induction, where the history probability function is iso-abstract historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{\mathrm{o}}}$, given some unknown substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, in some cases the maximum likelihood estimate of the model, $\tilde{T}_{\mathrm{o}}$, at the maximum likelihood estimate of the distribution, $\tilde{E}_{\mathrm{o}}$, is non-trivial,

$$
\tilde{T}_{\mathrm{o}} \notin\left\{T_{\mathrm{s}}, T_{\mathrm{u}}\right\}
$$

Consider how an approximation to the optimisation may be made more tractable. It is conjectured in section 'Likely histograms', above, that the
log-likelihood with respect to the dependent-analogue varies with the relative space with respect to the independent-analogue,

$$
\begin{array}{r}
\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{W}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{W}(T)}, z\right)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)} \\
\quad \text { spaceRelative }\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)(A)
\end{array}
$$

and conjectured further in section 'Transform alignment', above, that the relative space with respect to the naturalised abstract varies with the derived alignment,

$$
\text { spaceRelative }\left((A * T)^{\mathrm{X}} * T^{\dagger}\right)(A) \sim \operatorname{algn}(A * T)
$$

This correlation was decomposed in the discussion above into three separate correlations, (i) the dependent-independent anti-correlation, (ii) the underlying-lifted correlation and (iii) the conditional-relative correlation. Now consider how the optimisation of the terms of these relations may form the definition of induction assumptions.

The maximum likelihood estimate for the unknown model, $\tilde{T}_{\mathrm{o}}$, with respect to the dependent-analogue is

$$
\begin{aligned}
& \left\{\tilde{T}_{\mathrm{o}}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(T, \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}^{\mathrm{W}(T)}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}^{\mathrm{W}(T)}, z_{\mathrm{o}}\right)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z_{\mathrm{o}}}^{-1}\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}\right)}\right):\right.\right. \\
& \left.\left.\quad T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
\end{aligned}
$$

First, given the dependent-independent anti-correlation, assume that the maximum likelihood estimate of the iso-abstract conditional multinomial probability with respect to the dependent-analogue or abstract-dependent, $A_{\mathrm{o}}^{\mathrm{W}(T)}$, is also the minimum likelihood estimate of the iso-abstract conditional multinomial probability with respect to the independent-analogue or naturalised abstract, $\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}} * T^{\dagger}$,

$$
\begin{aligned}
& \left\{\tilde{T}_{\mathrm{o}}\right\}= \\
& \quad \operatorname{mind}\left(\left\{\left(T, \frac{Q_{\mathrm{m}, U}\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{x}} * T^{\dagger}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum Q_{\mathrm{m}, U}\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}} * T^{\dagger}, z_{\mathrm{o}}\right)(B): B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z_{\mathrm{o}}}^{-1}\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}\right)}\right):\right.\right.
\end{aligned}
$$

$$
\left.\left.T \in \mathcal{T}_{U, V_{o}}\right\}\right)
$$

This assumption is the iso-abstract dependent-independent anti-optimisation assumption. It relies on the monotonicity of the dependent-independent anticorrelation.

Second, given the underlying-lifted correlation, assume that the minimum likelihood estimate of the iso-abstract conditional multinomial probability with respect to the independent-analogue or naturalised abstract, $\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}} * T^{\dagger}$, is also the minimum likelihood estimate of the lifted iso-abstract conditional multinomial probability with respect to the lifted independent-analogue or abstract, $\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}$,

$$
\left\{\tilde{T}_{o}\right\}=
$$

$$
\operatorname{mind}\left(\left\{\left(T, \frac{Q_{\mathrm{m}, U}\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{x}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}} * T\right)}{\sum Q_{\mathrm{m}, U}\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}, z_{\mathrm{o}}\right)\left(B^{\prime}\right): B^{\prime} \in \operatorname{isowl}(U)\left(T, A_{\mathrm{o}}\right)}\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

where the lifted integral iso-abstracts is abbreviated

$$
\text { isowl }(U)(T, A):=\left\{B * T: B \in Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right\}
$$

This assumption is the iso-abstract underlying-lifted optimisation assumption. It relies on the monotonicity of the underlying-lifted correlation.

Third, given the conditional-relative correlation, assume that the minimum likelihood estimate of the lifted iso-abstract conditional multinomial probability with respect to the lifted independent-analogue or abstract, $\left(A_{\mathrm{o}} * T\right)^{\mathrm{x}}$, is also the minimum likelihood estimate of the relative multinomial probability with respect to the lifted independent-analogue or abstract, $\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}$,

$$
\left\{\tilde{T}_{\mathrm{o}}\right\}=\operatorname{mind}\left(\left\{\left(T, \frac{Q_{\mathrm{m}, U}\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{x}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}} * T\right)}{Q_{\mathrm{m}, U}\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}, z_{\mathrm{o}}\right)\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}\right)}\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

The negative logarithm of the relative multinomial probability is the relative space of the derived with respect to the abstract, which is the derived alignment,

$$
\begin{aligned}
-\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}}, z\right)(A * T)}{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)\left((A * T)^{\mathrm{X}}\right)} & =\operatorname{spaceRelative}\left((A * T)^{\mathrm{X}}\right)(A * T) \\
& =\operatorname{algn}(A * T)
\end{aligned}
$$

So the third assumption is that the minimum likelihood estimate of the lifted iso-abstract conditional multinomial probability with respect to the abstract, $\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}$, is also the maximum likelihood estimate with respect to the derived alignment,

$$
\left\{\tilde{T}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(T, \operatorname{algn}\left(A_{\mathrm{o}} * T\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

This assumption is the iso-abstract conditional-relative optimisation assumption. It relies on the monotonicity of the conditional-relative correlation.

A finite approximation to arbitrary accuracy of the derived alignment, $\operatorname{algn}\left(A_{0} *\right.$ $T$ ), is computable by means of an approximation to the gamma function. The computation of the derived alignment is tractable given limits on the derived volume, $\left|T^{-1}\right|$. So the optimisation of maximum likelihood estimate of the model, $\tilde{T}_{\mathrm{o}}$, at least for a limited subset of the substrate transforms, is tractable.

In abstract induction, where (i) the history probability function is iso-abstract historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{\mathrm{o}}}$, given some unknown substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, if it is the case that (ii) the isoabstract dependent-independent anti-optimisation assumption is true, (iii) the iso-abstract underlying-lifted optimisation assumption is true, and (iv) the iso-abstract conditional-relative optimisation assumption is true, then the maximum likelihood estimate of the model, $\tilde{T}_{\mathrm{o}}$, at the maximum likelihood estimate of the distribution, $\tilde{E}_{\mathrm{o}}$, is

$$
\left\{\tilde{T}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(T, \operatorname{algn}\left(A_{\mathrm{o}} * T\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

It is shown in the known transform case above that the maximum likelihood estimate is more classical and less formal if (i) the sample is naturalised, (ii) the sample has independent formal and (iii) the derived alignment is high. This is the case for unknown transform too. In fact, if the three iso-abstract optimisation assumptions are true, then the maximum likelihood estimate for the model, $\tilde{T}_{\mathrm{o}}$, occurs at the maximisation of the derived alignment, implying that the derived alignment is as high as possible, $\forall T \in \mathcal{T}_{U, V_{\mathrm{o}}}\left(\left(A_{\mathrm{o}}=\right.\right.$ $\left.\left.A_{\mathrm{o}} * T * T^{\dagger}\right) \wedge\left(A_{\mathrm{o}}^{\mathrm{X}} * T=\left(A_{\mathrm{o}}^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \Longrightarrow \operatorname{algn}\left(A_{\mathrm{o}} * \tilde{T}_{\mathrm{o}}\right) \geq \operatorname{algn}\left(A_{\mathrm{o}} * T\right)\right)$.

In abstract induction, where (i) the history probability function is iso-abstract historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{\mathrm{o}}}$, given some unknown substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, if it is the case that (ii) the isoabstract dependent-independent anti-optimisation assumption is true, (iii) the iso-abstract underlying-lifted optimisation assumption is true, (iv) the isoabstract conditional-relative optimisation assumption is true, (v) the sample is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, (vi) the sample formal is independent, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}_{\sim}}=\left(A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, then (a) the maximum likelihood estimate of the model, $\tilde{T}_{\mathrm{o}}$, at the maximum likelihood estimate of the distribution, $\tilde{E}_{\mathrm{O}}$, is

$$
\left.\left.\left.\begin{array}{rl}
\left\{\tilde{T}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(T, \operatorname{algn}\left(A_{\mathrm{o}} * T\right)\right):\right.\right. & T
\end{array} \quad \in \mathcal{T}_{U, V_{\mathrm{o}}}, \quad A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger}, A_{\mathrm{o}}^{\mathrm{x}} * T=\left(A_{\mathrm{o}}^{\mathrm{x}} * T\right)^{\mathrm{x}}\right\}\right)\right) ~ \$
$$

(b) the log likelihood of the iso-abstract conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the derived alignment,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{w}, \tilde{T}_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

(c) the log likelihood of the iso-abstract conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the log likelihood of the iso-derived conditional stuffed historical probability distribution at the naturalisation,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{w}, \tilde{T}_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

(d) the formal alignment of the maximum likelihood estimate is small,

$$
\operatorname{algn}\left(Z_{\mathrm{o}} * \tilde{E}_{\mathrm{o}}^{\mathrm{X}} * \tilde{T}_{\mathrm{o}}\right) \approx 0
$$

and (e) the derived of the maximum likelihood estimate approximates to the normalised sample derived,

$$
\tilde{E}_{\mathrm{o}} * \tilde{T}_{\mathrm{o}} \approx \hat{A}_{\mathrm{o}} * T_{\mathrm{o}}
$$

In this case queries via the model of the sample approximate to queries via the model of the distribution,
$\left(Q * \tilde{T}_{\mathrm{o}}^{\%} * \operatorname{his}\left(\tilde{T}_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right) \approx\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * E_{\mathrm{h}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)$
If, in addition, (vii) the component size cardinality relative entropy of the maximum likelihood estimate for the model is high, entropy $\operatorname{Cross}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} *\right.$ $\left.T_{\mathrm{o}}\right)>\ln \left|T_{\mathrm{o}}^{-1}\right|$, then the sum sensitivity varies against the log-likelihood,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{w}, \tilde{T}_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) & \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \\
& \sim-\operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
\end{aligned}
$$

If, further, (viii) the size is less than the volume, $z_{0}<v_{\mathrm{o}}$, but the sample approximates to the naturalisation, $A_{\mathrm{o}} \approx A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, then the sensitivity to model also varies against the log likelihood,
$-\ln \mid \max \left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{w}, T, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right.\right.$,

$$
\begin{aligned}
A_{\mathrm{o}}^{\mathrm{X}} * T=\left(A_{\mathrm{o}}^{\mathrm{X}} * T\right)^{\mathrm{X}}, A_{\mathrm{o}} \approx & \left.\left.A_{\mathrm{o}} * T * T^{\dagger}\right\}\right) \mid \sim \\
& -\ln \hat{Q}_{\mathrm{h}, \mathrm{w}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
\end{aligned}
$$

or
$-\ln \mid \max \left(\left\{\left(T, \operatorname{algn}\left(A_{\mathrm{o}} * T\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right.\right.$,
$\left.\left.A_{\mathrm{o}}^{\mathrm{X}} * T=\left(A_{\mathrm{o}}^{\mathrm{X}} * T\right)^{\mathrm{X}}, A_{\mathrm{o}} \approx A_{\mathrm{o}} * T * T^{\dagger}\right\}\right) \mid \sim$
$-\operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)$
So (a) by weakening the induction condition from law-like necessary derived to entity-like necessary abstract and (b) by strengthening the constraints on the sample to be natural and have independent formal, it is found that in some cases the abstract induction maximum likelihood estimate of the model is non-trivial, $\tilde{T}_{\mathrm{o}} \notin\left\{T_{\mathrm{s}}, T_{\mathrm{u}}\right\}$, but retains properties of classical induction such as allowing query via the model, minimising sensitivity to the unknown underlying and minimising sensitivity to the model. Furthermore, the optimisation is tractable depending on the limits on the searched subset of the substrate transforms.

### 5.9 Aligned modelled induction

The case of classical modelled induction, where the derived is necessary, may be termed law-like because the set of iso-deriveds is law-like. All drawn histories $H \in \mathcal{H}_{U, X}$, where $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, T_{\mathrm{o}}}(H)>0$, are such that their normalised derived histograms are fixed, $\hat{A}_{H} * T_{\mathrm{o}}=\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}$. That is, in law-like induction the relationship between the derived variables is unchanging,

$$
\forall R_{1}, R_{2} \in\left(A_{H} * T_{\mathrm{o}}\right)^{\mathrm{FS}}\left(\frac{\left(A_{H} * T_{\mathrm{o}}\right)_{R_{2}}}{\left(A_{H} * T_{\mathrm{o}}\right)_{R_{1}}}=\frac{\left(E_{\mathrm{h}} * T_{\mathrm{o}}\right)_{R_{2}}}{\left(E_{\mathrm{h}} * T_{\mathrm{o}}\right)_{R_{1}}}\right)
$$

Idealisation induction is also law-like because the derived is still necessary, $\hat{A}_{H} * T_{\mathrm{o}}=\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}$ where $P_{U, X, H_{\mathrm{h}}, \dagger, T_{\mathrm{o}}}(H)>0$. In fact, idealisation induction is stricter because it also imposes the constraint that the independent components be necessary, $\forall C \in T_{\mathrm{o}}^{\mathrm{P}}\left(\left(A_{H} * C^{\mathrm{U}}\right)^{\mathrm{X} \wedge}=\left(E_{\mathrm{o}} * C^{\mathrm{U}}\right)^{\mathrm{X} \wedge}\right)$.

However, as is shown above, in the case where the model, $T_{\mathrm{o}}$, is unknown, neither of the law-like induction types, necessary derived and necessary idealisation, have a singular solution for the maximum likelihood estimate of the distribution-model pair, $\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right)$. It is necessary to relax the condition to possible derived and possible idealisation to obtain a singular solution.

Also discussed above is the case of abstract induction. This case, where the abstract is necessary, may be termed entity-like because the set of isoabstracts is entity-like. All drawn histories $H \in \mathcal{H}_{U, X}$, where $P_{U, X, H_{\mathrm{h}}, \mathrm{w}, T_{\mathrm{o}}}(H)>$

0 , are such that their normalised abstract histograms are fixed, $\left(\hat{A}_{H} * T_{\mathrm{o}}\right)^{\mathrm{X}}=$ $\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$. If the model is a substrate transform, $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, then necessary abstract is equivalent to necessary derived variables, $\left(\hat{A}_{H} * T_{\mathrm{o}}\right)^{\mathrm{X}}=$ $\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}} \Longleftrightarrow \forall P \in W_{\mathrm{o}}\left(\hat{A}_{H} * P^{\mathrm{T}}=\hat{E}_{\mathrm{h}} * P^{\mathrm{T}}\right)$. In entity-like induction the relations between the derived variables are not necessary, but only relations between the values within each derived variable separately are necessary,

$$
\begin{aligned}
& \forall P \in W_{\mathrm{o}} \forall u_{1}, u_{2} \in P \\
& \qquad\left(\frac{\left(A_{H} * T_{\mathrm{o}}\right) \%\{P\}\left(\left\{\left(P, u_{2}\right)\right\}\right)}{\left(A_{H} * T_{\mathrm{o}}\right) \%\{P\}\left(\left\{\left(P, u_{1}\right)\right\}\right)}=\frac{\left(E_{\mathrm{h}} * T_{\mathrm{o}}\right) \%\{P\}\left(\left\{\left(P, u_{2}\right)\right\}\right)}{\left(E_{\mathrm{h}} * T_{\mathrm{o}}\right) \%\{P\}\left(\left\{\left(P, u_{1}\right)\right\}\right)}\right)
\end{aligned}
$$

That is, the derived variables are separately necessary. In entity-like induction it is sometimes the case that the sample derived is not equal to the distribution derived, $\left(\hat{A}_{H} * T_{\mathrm{o}}\right)^{\mathrm{X}}=\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}} \Longleftarrow \hat{A}_{H} * T_{\mathrm{o}}=\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}$.

In the case of unknown model, $T_{\mathrm{o}}$, abstract induction has a singular solution for the maximum likelihood estimate of the distribution-model pair, $\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right)$. Abstract induction is not law-like but only entity-like, so it is sometimes the case that the estimated derived does not equal the estimated distribution derived, $\hat{A}_{H} * \tilde{T}_{\mathrm{o}} \neq \hat{E}_{\mathrm{h}} * \tilde{T}_{\mathrm{o}}$.

However, in the case where (i) the sample is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, and (ii) the sample formal is independent, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, then the estimated derived alignment is maximised, $\forall T \in \mathcal{T}_{U, V_{\mathrm{o}}}\left(\left(A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger}\right) \wedge\left(A_{\mathrm{o}}^{\mathrm{X}} * T=\right.\right.$ $\left.\left.\left(A_{\mathrm{o}}^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \Longrightarrow \operatorname{algn}\left(A_{\mathrm{o}} * \tilde{T}_{\mathrm{o}}\right) \geq \operatorname{algn}\left(A_{\mathrm{o}} * T\right)\right)$, and, as derived alignment, $\operatorname{algn}\left(A_{\mathrm{o}} * \tilde{T}_{\mathrm{o}}\right)$, increases, abstract induction tends to classical induction, where the normalised sample derived approximates to the derived of the maximum likelihood estimate, $\hat{A}_{\mathrm{o}} * \tilde{T}_{\mathrm{o}} \approx \tilde{E}_{\mathrm{o}} * \tilde{T}_{\mathrm{o}}$. Moreover, the computation of the maximum likelihood estimate of the model, $\tilde{T}_{\mathrm{o}}$, may be made tractable if limits are imposed on the optimisation.

Although abstract induction can provide a non-trivial solution for the maximum likelihood estimate for the model, $\tilde{T}_{\mathrm{o}}$, and constrained abstract induction can do so such that the maximum likelihood estimate for the distribution histogram, $\tilde{E}_{\mathrm{o}}$, is approximately classical, $\tilde{E}_{\mathrm{o}} \approx \hat{A}_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)}$, abstract induction is neutral with respect to formal alignment. That is, the set of iso-abstracts is conditional on neither the formal, $A^{\mathrm{X}} * T$, nor the formal independent, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, so the abstract dependent, $A^{\mathrm{W}(T)}$, is neutral with respect to the formal and the formal independent, and nothing can be said of its formal alignment, $\operatorname{algn}\left(A^{\mathrm{W}(T) \mathrm{x}} * T\right)$. Indeed in some cases the abstract dependent may be purely formal, $A^{\mathrm{W}(T)} * T=A^{\mathrm{W}(T) \mathrm{X}} * T \Longrightarrow \operatorname{algn}\left(A^{\mathrm{W}(T)} * T\right)=\operatorname{algn}\left(A^{\mathrm{W}(T) \mathrm{X}} * T\right)$.

So, in some cases, the model estimate, $\tilde{T}_{\mathrm{o}}$, can be tautological or otherwise overlapping, $\operatorname{overlap}\left(\tilde{T}_{\mathrm{o}}\right) \Longrightarrow A_{\mathrm{o}}^{\mathrm{X}} * \tilde{T}_{\mathrm{o}} \neq\left(A_{\mathrm{o}}^{\mathrm{X}} * \tilde{T}_{\mathrm{o}}\right)^{\mathrm{X}} \Longrightarrow \operatorname{algn}\left(A_{\mathrm{o}}^{\mathrm{X}} * \tilde{T}_{\mathrm{o}}\right)>0$. Even in the case of constrained abstract induction where the sample formal is known to be independent, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, the other members of the iso-abstracts may have formal alignment, $\forall B \in Y_{U, T_{\mathrm{o}}, \mathrm{W}, z_{0}}^{-1}\left(\left(A_{\mathrm{o}} *\right.\right.$ $\left.\left.T_{\mathrm{o}}\right)^{\mathrm{X}}\right)\left(\operatorname{algn}\left(B^{\mathrm{X}} * T_{\mathrm{o}}\right) \geq 0\right)$, and the abstract-dependent may have formal alignment, $\operatorname{algn}\left(A_{\mathrm{o}}^{\mathrm{W}\left(T_{\mathrm{o}}\right) \mathrm{X}} * T_{\mathrm{o}}\right) \geq 0$. To address this, consider strengthening abstract induction to partition induction where the condition of necessary formal independent, $\left(A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, is added to the condition of necessary abstract, $\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$.

The partition-independent, $A^{\mathrm{P}(T)} \in \mathcal{A}_{U, V, z}$, is defined in section 'Likely histograms', above, as

$$
\left\{A^{\mathrm{P}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isop}(U)(T, A)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

where the integral iso-partition-independents is abbreviated

$$
\operatorname{isop}(U)(T, A):=Y_{U, i, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}}\right) \cap Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)
$$

and the iso-partition-independents is such that

$$
\begin{aligned}
& Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \\
& \quad=\left\{B: B \in \mathcal{A}_{U, V, z},\left(B^{\mathrm{x}} * T\right)^{\mathrm{x}}=\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}},(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}\right\}
\end{aligned}
$$

The corresponding dependent analogue is the partition-dependent, $A^{\mathrm{R}(T)} \in$ $\mathcal{A}_{U, V, z}$, defined
$\left\{A^{\mathrm{R}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \operatorname{isop}(U)(T, A)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)$
In partition induction the history probability function, $P$, is historically distributed but constrained such that all drawn histories, $P(H)>0$, have (i) an formal independent probability histogram equal to the formal independent distribution probability histogram, $\left(\hat{A}_{H}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}=\left(\hat{E}_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, and (ii) an abstract probability histogram equal to the abstract distribution probability histogram, $\left(\hat{A}_{H} * T_{\mathrm{o}}\right)^{\mathrm{X}}=\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$. In the case of known transform, $T_{\mathrm{o}}$, the maximum likelihood estimate for the distribution histogram is the partition-dependent, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{R}\left(T_{\mathrm{o}}\right)}$. Partition induction is entity-like because the iso-partition-independents is a subset of the iso-abstracts, so the derived variables are separately necessary,

$$
\begin{aligned}
& \forall P \in W_{\mathrm{o}} \forall u_{1}, u_{2} \in P \\
& \qquad\left(\frac{\left(A_{H} * T_{\mathrm{o}}\right) \%\{P\}\left(\left\{\left(P, u_{2}\right)\right\}\right)}{\left(A_{H} * T_{\mathrm{o}}\right) \%\{P\}\left(\left\{\left(P, u_{1}\right)\right\}\right)}=\frac{\left(E_{\mathrm{h}} * T_{\mathrm{o}}\right) \%\{P\}\left(\left\{\left(P, u_{2}\right)\right\}\right)}{\left(E_{\mathrm{h}} * T_{\mathrm{o}}\right) \%\{P\}\left(\left\{\left(P, u_{1}\right)\right\}\right)}\right)
\end{aligned}
$$

although the iso-abstractence is lower,

$$
\frac{\left|Y_{U, i, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}\right) \cap Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|} \leq 1
$$

and so partition induction may be less entity-like than abstract induction.
Now, in addition, formal variables are separately necessary,

$$
\begin{aligned}
& \forall P \in W_{\mathrm{o}} \forall u_{1}, u_{2} \in P \\
& \qquad \quad\left(\frac{\left(A_{H}^{\mathrm{X}} * T_{\mathrm{o}}\right) \%\{P\}\left(\left\{\left(P, u_{2}\right)\right\}\right)}{\left(A_{H}^{\mathrm{X}} * T_{\mathrm{o}}\right) \%\{P\}\left(\left\{\left(P, u_{1}\right)\right\}\right)}=\frac{\left(E_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}}\right) \%\{P\}\left(\left\{\left(P, u_{2}\right)\right\}\right)}{\left(E_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}}\right) \%\{P\}\left(\left\{\left(P, u_{1}\right)\right\}\right)}\right)
\end{aligned}
$$

That is, the stricter condition of partition induction requires that the partition derived variables are necessary with respect to both the histogram and its independent. If the model is a substrate transform, $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, then (i) necessary abstract is equivalent to necessary derived variables, $\left(\hat{A}_{H} * T_{\mathrm{o}}\right)^{\mathrm{X}}=$ $\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}} \Longleftrightarrow \forall P \in W_{\mathrm{o}}\left(\hat{A}_{H} * P^{\mathrm{T}}=\hat{E}_{\mathrm{h}} * P^{\mathrm{T}}\right)$, and (ii) necessary formal independent is equivalent to necessary formal variables, $\left(\hat{A}_{H}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}=$ $\left(\hat{E}_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}} \Longleftrightarrow \forall P \in W_{\mathrm{o}}\left(\hat{A}_{H}^{\mathrm{X}} * P^{\mathrm{T}}=\hat{E}_{\mathrm{h}}^{\mathrm{X}} * P^{\mathrm{T}}\right)$.

Also, partition induction may be more law-like than abstract induction if the iso-derivedence is greater,

$$
\begin{array}{r}
\frac{\left|Y_{U, i, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \cap D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}{\left|\left(Y_{U, \mathrm{i}, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}}\right) \cup D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right) \cap Y_{U, \mathbf{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}> \\
\qquad \frac{\left|D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right|}{\left|Y_{U, \mathbf{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
\end{array}
$$

depending on the relative intersection cardinalities.
It is conjectured in 'Transform alignment', above, that the formal alignment of the independent analogue of the iso-partition-independents, $\operatorname{algn}\left(A^{\mathrm{P}(T) \mathrm{X}} *\right.$ $T$ ), is less than or equal to the formal alignment, $\operatorname{algn}\left(A^{\mathrm{X}} * T\right)$, which in turn is less than or equal to the dependent analogue formal alignment, $\operatorname{algn}\left(A^{\mathrm{R}(T) \mathrm{X}} * T\right)$,

$$
\operatorname{algn}\left(A^{\mathrm{P}(T) \mathrm{X}} * T\right) \leq \operatorname{algn}\left(A^{\mathrm{X}} * T\right) \leq \operatorname{algn}\left(A^{\mathrm{R}(T) \mathrm{X}} * T\right)
$$

That is, the formal alignment of the maximum likelihood estimate of partition induction, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{R}\left(T_{\mathrm{o}}\right)}$, is greater than or equal to the sample formal
alignment, $\operatorname{algn}\left(Z_{\mathrm{o}} * \tilde{E}_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right) \geq \operatorname{algn}\left(A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right)$. So in some cases even if the sample is not purely formal, $A_{\mathrm{o}} * T_{\mathrm{o}} \neq A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}$, the distribution histogram estimate may be purely formal, $A_{\mathrm{o}}^{\mathrm{R}\left(T_{\mathrm{o}}\right)} * T_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{R}\left(T_{\mathrm{o}}\right) \mathrm{X}} * T_{\mathrm{o}}$.

If there is no knowledge regarding formal alignment, partition induction may be preferable to abstract induction because of its possibly higher degree of law-likeness or iso-derivedence. In this case the partition induction maximum likelihood estimate approximates more closely to classical, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{R}\left(T_{\mathrm{o}}\right)} \approx \hat{A}_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)}$, than abstract induction.

If, however, the distribution histogram is known to have small formal alignment, $\operatorname{algn}\left(Z_{\mathrm{o}} * \hat{E}_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right) \approx 0$, then, even if the sample formal is independent, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, the distribution formal estimate is unconstrained,

$$
\operatorname{algn}\left(Z_{\mathrm{o}} * \tilde{E}_{\mathrm{o}}^{\mathrm{x}} * T_{\mathrm{o}}\right) \geq \operatorname{algn}\left(A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right)=0
$$

Of course, this is also the case if the distribution formal is known to be $i n-$ dependent, $E_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(E_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}} \Longrightarrow \operatorname{algn}\left(Z_{\mathrm{o}} * \hat{E}_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right)=0$.

Clearly, in the case of small or zero distribution formal alignment, the partition induction condition is insufficient. Now consider further strengthening the condition of necessary formal independent, $\left(\hat{A}_{H}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}=\left(\hat{E}_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, to necessary formal, where the history probability function, $P$, is historically distributed but constrained such that all drawn histories, $P(H)>0$, have a formal probability histogram equal to the formal distribution probability histogram, $\hat{A}_{H}^{\mathrm{X}} * T_{\mathrm{o}}=\hat{E}_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}}$.

In aligned modelled induction, also called transform induction, the condition is necessary transform independent, $\hat{A}_{H}^{\mathrm{X}\left(T_{\mathrm{o}}\right)}=\hat{E}_{0}^{\mathrm{X}\left(T_{\mathrm{o}}\right)}$, or necessary formal and necessary abstract, $\left(\hat{A}_{H}^{\mathrm{X}} * T_{\mathrm{o}},\left(\hat{A}_{H} * T_{\mathrm{o}}\right)^{\mathrm{X}}\right)=\left(\hat{E}_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}},\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}\right)$. The corresponding iso-set is the iso-transform-independents, which is the intersection of the iso-abstracts and the iso-formals, which in turn is a subset of the iso-partition-independents which in turn is a subset of the iso-abstracts,

$$
\begin{aligned}
Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) & =Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \cap Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \\
& \subseteq Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \cap Y_{U, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{x}} * T\right)^{\mathrm{X}}\right) \\
& \subseteq Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)
\end{aligned}
$$

The transform-independent, $A^{\mathrm{X}(T)} \in \mathcal{A}_{U, V, z}$, is defined in section 'Likely histograms', above, as

$$
\left\{A^{\mathrm{X}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

where the integral iso-transform-independents is abbreviated

$$
\begin{aligned}
\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A) & =Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \\
& =\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{x}} * T=A^{\mathrm{x}} * T,(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}\right\}
\end{aligned}
$$

The corresponding dependent analogue is the transform-dependent, $A^{\mathrm{Y}(T)} \in$ $\mathcal{A}_{U, V, z}$, defined

$$
\left\{A^{\mathrm{Y}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

In 'Transform alignment', above, it is conjectured that the partition-dependent formal alignment is greater than or equal to the formal alignment, which in turn is greater than or equal to the transform-dependent formal alignment

$$
\operatorname{algn}\left(A^{\mathrm{R}(T) \mathrm{X}} * T\right) \geq \operatorname{algn}\left(A^{\mathrm{X}} * T\right) \geq \operatorname{algn}\left(A^{\mathrm{Y}(T) \mathrm{X}} * T\right)
$$

So if the sample formal alignment is small, the transform-dependent formal alignment is also small,

$$
\operatorname{algn}\left(A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right) \approx 0 \Longrightarrow \operatorname{algn}\left(A_{\mathrm{o}}^{\mathrm{Y}\left(T_{\mathrm{o}}\right) \mathrm{X}} * T_{\mathrm{o}}\right) \approx 0
$$

whereas the partition-dependent formal alignment remains unconstrained,

$$
\operatorname{algn}\left(A_{\mathrm{o}}^{\mathrm{R}\left(T_{\mathrm{o}}\right) \mathrm{X}} * T_{\mathrm{o}}\right) \geq \operatorname{algn}\left(A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right) \approx 0
$$

Therefore if it is known that the distribution histogram formal alignment is $\operatorname{small}, \operatorname{algn}\left(Z_{\mathrm{o}} * \hat{E}_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right) \approx 0$, then, although partition induction is stricter than abstract induction, partition induction is still insufficiently constrained compared to transform induction. Furthermore, if the formal is necessarily independent, $\forall H \in \mathcal{H}_{U, X}\left(P(H)>0 \Longrightarrow A_{H}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{H}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}\right)$, then this additional condition may be obtained in transform induction by constraining the sample to have independent formal, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, because the iso-transform-independents necessarily have the same formal,

$$
\begin{aligned}
& A^{\mathrm{x}} * T=\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}} \Longrightarrow \\
& \quad \forall B \in Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \\
& \quad\left(B^{\mathrm{X}} * T=A^{\mathrm{x}} * T=\left(A^{\mathrm{x}} * T\right)^{\mathrm{x}}=\left(B^{\mathrm{x}} * T\right)^{\mathrm{x}}\right)
\end{aligned}
$$

Just as for partition induction, in transform induction the derived variables and formal variables are separately necessary. If the model is a substrate transform, $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, then

$$
\forall P \in W_{\mathrm{o}}\left(\left(\hat{A}_{H} * P^{\mathrm{T}}=\hat{E}_{\mathrm{h}} * P^{\mathrm{T}}\right) \wedge\left(\hat{A}_{H}^{\mathrm{X}} * P^{\mathrm{T}}=\hat{E}_{\mathrm{h}}^{\mathrm{X}} * P^{\mathrm{T}}\right)\right)
$$

If the iso-derivedence of the integral iso-transform-independents is greater than the iso-derivedence of the integral iso-partition-independents,

$$
\begin{gathered}
\frac{\left|Y_{U, i, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}{\left|\left(Y_{U, \mathrm{i}, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cup D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right) \cap Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}> \\
\frac{\left|Y_{U, \mathrm{i}, T, \mathrm{~V}, \mathbf{x}, z}^{-1}\left(\left(A^{\mathrm{x}} * T\right)^{\mathrm{X}}\right) \cap D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}{\left|\left(Y_{U, \mathrm{i}, T, \mathrm{~V}, \mathrm{x}, z}^{-1}\left(\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}\right) \cup D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right) \cap Y_{U, \mathbf{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
\end{gathered}
$$

then transform induction is more law-like than partition induction, and so is more classical.

Like abstract induction and partition induction, in the case of unknown model, $T_{\mathrm{o}}$, transform induction has a unique solution for the maximum likelihood estimate for the pair $\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right)$.

If, in addition, the sample is considered to be special by assuming it is ideal, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, the dependent analogue, $A_{\mathrm{o}}^{\mathrm{Y}\left(T_{\mathrm{o}}\right)}$, is closer to the derived dependent, $A_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)}$, and therefore more law-like. This is analogous to the special case in abstract induction where the sample is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$.

Furthermore, if the sample is assumed to be such that the formal equals the abstract, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, then the model estimate optimisation can be lifted into the derived variables, and so made tractable and thence practicable. This is analogous to the special case in abstract induction where the sample has independent formal, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$.

First, however, consider the case where the given substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, is known.

In aligned modelled induction, while the distribution probability histogram, $\hat{E}_{\mathrm{h}}$, remains unknown, the formal distribution probability histogram, $\hat{E}_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}}$, and the abstract distribution probability histogram, $\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, are necessary. That is, the history probability function, $P$, is historically distributed but constrained such that all drawn histories have (i) a formal probability histogram equal to the formal distribution probability histogram, $\hat{A}_{H}^{\mathrm{X}} * T_{\mathrm{o}}=\hat{E}_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}}$, and (ii) an abstract probability histogram equal to the abstract distribution probability histogram, $\left(\hat{A}_{H} * T_{\mathrm{o}}\right)^{\mathrm{X}}=\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$. Define the iso-transformindependent historically distributed history probability function $P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{\mathrm{o}}} \in$

$$
\begin{aligned}
& \left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}, \\
& P_{U, X, H_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}}:=}^{\left(\bigcup \left\{\left\{(H, 1): H \subseteq H_{\mathrm{h}} \% V_{H},|H|=z_{H},\right.\right.\right.} \\
& \qquad \begin{array}{l}
\left.\hat{A}_{H}^{\mathrm{X}} * T_{\mathrm{o}}=\hat{E}_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}},\left(\hat{A}_{H} * T_{\mathrm{o}}\right)^{\mathrm{x}}=\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{x}}\right\}^{\wedge} \\
\qquad \\
\left.\left.\quad V_{H} \subseteq V_{\mathrm{h}}, z_{H} \in\left\{1 \ldots z_{\mathrm{h}}\right\}\right\}\right)^{\wedge} \cup \\
\left\{(H, 0): H \in \mathcal{H}_{U, X}, \hat{A}_{H}^{\mathrm{x}} * T_{\mathrm{o}} \neq \hat{E}_{\mathrm{h}}^{\mathrm{x}} * T_{\mathrm{o}} \vee\left(\hat{A}_{H} * T_{\mathrm{o}}\right)^{\mathrm{x}} \neq\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{x}}\right\} \cup \\
\left\{(H, 0): H \in \mathcal{H}_{U, X}, H \nsubseteq H_{\mathrm{h}} \% V_{H}\right\} \cup\{(\emptyset, 0)\}
\end{array}
\end{aligned}
$$

For drawn histories the formal probability histogram and abstract probability histogram are necessary, $\forall H \in \mathcal{H}_{U, X}\left(P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{\mathrm{o}}}(H)>0 \Longrightarrow \hat{A}_{H}^{\mathrm{X}} * T_{\mathrm{o}}=\right.$ $\left.\hat{E}_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}} \wedge\left(\hat{A}_{H} * T_{\mathrm{o}}\right)^{\mathrm{X}}=\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}\right)$. Not all sizes and sets of variables are necessarily drawable. That is, in some cases, $\exists z \in\left\{1 \ldots z_{\mathrm{h}}\right\} \exists V \subseteq V_{\mathrm{h}} \forall H \in$ $\mathcal{H}_{U, X}\left(\left(z_{H}=z\right) \wedge\left(V_{H}=V\right) \Longrightarrow P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{\mathrm{o}}}(H)=0\right)$. The distribution history can always be drawn, so the probability function is not a weak probability function, $\sum_{H \in \mathcal{H}_{U, X}} P_{U, X, H_{\mathrm{h}}, y, T_{o}}(H)=1$.

In aligned modelled induction the history probability function is iso-transformindependent historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{\mathrm{o}}}$.

Given a drawn history $H \in \mathcal{H}_{U, X}$, where $P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{\mathrm{o}}}(H)>0$, the iso-transform-independent probability of histogram $A_{H}=\operatorname{histogram}(H)+V_{H}^{\mathrm{CZ}} \in$ $\mathcal{A}_{U, \mathrm{i}, V_{H}, z_{H}}$ is now conditional,

$$
\begin{aligned}
& \frac{Q_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i},, T_{\mathrm{o}}, z_{H}}(A)} Q_{\mathrm{h}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)(B)}= \\
& \frac{\sum P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}}{\sum P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, V_{G}=V_{H},|G|=z_{H}}
\end{aligned}
$$

where the integral iso-transform-independents is abbreviated

$$
\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)=Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)
$$

and the set of integral iso-transform-independents is the intersection of the iso-formals and iso-abstracts

$$
\begin{aligned}
& Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \\
& \quad=Y_{U, 1, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{x}} * T\right) \cap Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \\
& \quad=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{X}} * T=A^{\mathrm{x}} * T,(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}\right\}
\end{aligned}
$$

The iso-transform-independent historical probability may be expressed in terms of a histogram distribution which is not explicitly conditional on the necessary formal and necessary abstract, $\left(\hat{E}_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}},\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}\right)$,

$$
\hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{H}, z_{H}\right)\left(A_{H}\right) \propto \sum\left(P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{\mathrm{o}}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}\right)
$$

where the iso-derived conditional stuffed historical probability distribution is defined

$$
\begin{aligned}
\hat{Q}_{\mathrm{h}, \mathrm{y}, T, U} & (E, z) \\
:= & \left\{\left(A, \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} Q_{\mathrm{h}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \leq E\right\}^{\wedge} \cup \\
& \left\{(A, 0): A \in \mathcal{A}_{U, \mathrm{i}, \mathrm{i}, \mathrm{Z}, z}, A \not \leq E\right\}
\end{aligned}
$$

which is defined if $z \leq \operatorname{size}(E)$. In the case where all the formal-abstract pairs are possible,

$$
\forall A^{\prime} \in \operatorname{ran}\left(Y_{U, \mathbf{i}, T, z}\right) \exists A \in \mathcal{A}_{U, \mathrm{i}, V, z}\left(\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)=A^{\prime}\right) \wedge(A \leq E)\right)
$$

the normalisation of the iso-transform-independent conditional stuffed historical probability distribution is a fraction $1 /\left|\operatorname{ran}\left(Y_{U, i, T, z}\right)\right|$,

$$
\begin{aligned}
& \hat{Q}_{\mathrm{h}, \mathrm{y}, T, U}(E, z) \\
& \quad=\left\{\left(A, \frac{1}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, T, z}\right)\right|} \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} Q_{\mathrm{h}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
\end{aligned}
$$

In the case of a full functional transform, $T_{\mathrm{f}}=\left\{\{w\}^{\mathrm{CS}\{ \} V \mathrm{~T}}: w \in V\right\}^{\mathrm{T}}$, the iso-transform-independents equals the iso-independents, $\mathcal{A}_{U \text { i, }, \mathrm{y}, T_{\mathrm{f}}, z}(A)=$ $Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, and so the case is the same as for aligned non-modelled induction, (i) the maximum likelihood estimate varies with the sample probability histogram, $\tilde{E}_{\mathrm{o}} \sim \hat{A}_{\mathrm{o}}$, and against the independent sample probability histogram, $\tilde{E}_{\mathrm{o}} \nsim \hat{A}_{\mathrm{o}}^{\mathrm{X}}$, and (ii) the sum sensitivity varies with the sample alignment, $\operatorname{algn}\left(A_{\mathrm{o}}\right)$, at low alignments and against the sample alignment, $-\operatorname{algn}\left(A_{\mathrm{o}}\right)$, at high alignments.

At the other extreme of a unary transform, $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$, the iso-transformindependents equals the substrate histograms, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}(A)=\mathcal{A}_{U, \mathrm{i}, V, z}$, and so the case is the same as for classical non-modelled induction, (i) the maximum likelihood estimate equals the sample probability histogram, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, and (ii) the sum sensitivity varies with the negative scaled sample entropy, $-z_{\mathrm{o}} \times$ entropy $\left(A_{\mathrm{o}}\right)$.

The iso-transform-independent conditional generalised multinomial probability distribution is defined

$$
\begin{aligned}
& \hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}(E, z) \\
&:=\left\{\left(A, \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, y, T, z}(A)} Q_{\mathrm{m}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A^{\mathrm{F}} \leq E^{\mathrm{F}}\right\}^{\wedge} \cup \\
&\left\{(A, 0): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A^{\mathrm{F}} \not \leq E^{\mathrm{F}}\right\}
\end{aligned}
$$

which is defined if $\operatorname{size}(E)>0$.
The case where all the formal-abstract pairs are possible is weaker than for historical,

$$
\forall A^{\prime} \in \operatorname{ran}\left(Y_{U, \mathbf{i}, T, z}\right) \exists A \in \mathcal{A}_{U, \mathrm{i}, V, z}\left(\left(\left(A^{\mathrm{X}} * T,(A * T)^{\mathrm{X}}\right)=A^{\prime}\right) \wedge\left(A^{\mathrm{F}} \leq E^{\mathrm{F}}\right)\right)
$$

In this case the iso-transform-independent conditional generalised multinomial probability distribution is

$$
\begin{aligned}
& \hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}(E, z) \\
& \quad=\left\{\left(A, \frac{1}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, T, z}\right)\right|} \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \mathcal{A}_{U, i, \mathrm{i}, T, z}(A)} Q_{\mathrm{m}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}
\end{aligned}
$$

Assume that the distribution history size, $z_{\mathrm{h}}$, is large with respect to the sample size $z_{0}=\operatorname{size}\left(A_{\mathrm{o}}\right)$, so that, in the limit, the iso-transform-independent conditional stuffed historical probability, $\hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$, approximates to the iso-transform-independent conditional multinomial probability, $\hat{Q}_{\mathrm{m}, \mathrm{y}, T_{\mathrm{o}}, U}\left(E_{\mathrm{h}} \% V_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)$. That is, if $z_{\mathrm{o}} \ll z_{\mathrm{h}}$ then

$$
\hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \approx \hat{Q}_{\mathrm{m}, \mathrm{y}, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

The iso-transform-independent multinomial parameterised probability density function, $\operatorname{mytppdf}(T, z) \in \operatorname{ppdfs}(v, v)$, and iso-transform-independent multinomial likelihood function, $\operatorname{mytlf}(T, z) \in \operatorname{lfs}(v, v)$, corresponding to the iso-transform-independent multinomial probability distribution, $\hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}$, are not given explicitly here, but are such that

$$
\operatorname{mytppdf}(T, z)\left(\hat{E}^{\mathbb{\square}}\right)\left(A^{\mathbb{\square}}\right)=\operatorname{mytlf}(T, z)\left(A^{\rrbracket}\right)\left(\hat{E}^{\mathbb{\rrbracket}}\right)=\hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}(E, z)(A)
$$

Now in the case of aligned modelled induction where the transform, $T_{\mathrm{o}}$, is known, the real maximum likelihood estimate $\tilde{E}_{\mathrm{o}}^{\prime} \in \mathbf{R}_{(0,1)}^{v_{0}}$ for the parameter of the iso-transform-independent multinomial parameterised probability density function is

$$
\left\{\tilde{E}_{\mathrm{o}}^{\prime}\right\}=\operatorname{maxd}\left(\operatorname{mytlf}\left(T_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}^{\square}\right)\right)
$$

which is such that $\forall i \in\left\{1 \ldots v_{\mathrm{o}}\right\}\left(\partial_{i}\left(\operatorname{mytlf}\left(T_{\mathrm{o}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}^{\square}\right)\right)\left(\tilde{E}_{\mathrm{o}}^{\prime}\right)=0\right)$. The maximum likelihood estimate $\tilde{E}_{\mathrm{o}}^{\prime}$ is only defined in the case where the sample histogram is completely effective, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}} \Longrightarrow \hat{A}_{\mathrm{o}}^{\square} \in \mathbf{R}_{(0,1)}^{v_{\mathrm{o}}}$, because the binomial likelihood function is only defined for the open set. That is, $\mathrm{d}\left(\mathrm{blf}\left(z_{0}\right)(0)\right)$ is undefined and so the derivative of the iso-transform-independent multinomial parameterised probability density function is undefined where there are ineffective states.

In the case of completely effective sample histogram, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$, the maximisation for known transform, $T_{\mathrm{o}}$, of the iso-transform-independent conditional generalised multinomial probability parameterised by the complete congruent histograms of unit size is a singleton of the rational maximum likelihood estimate

$$
\left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \mathrm{y}, T_{\mathrm{o}}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{o}, 1}\right\}\right)
$$

The real maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}^{\prime}$, is not necessarily a rational coordinate, $\mathbf{R}_{(0,1)}^{v_{0}} \supset \mathbf{Q}_{(0,1)}^{v_{0}}$, and so the rational maximum likelihood estimate is not necessarily equal to the real maximum likelihood estimate. However, it is conjectured that the maximisation of the distribution approximates to the maximisation of the likelihood function,

$$
\tilde{E}_{\mathrm{o}}^{\square} \approx \tilde{E}_{\mathrm{o}}^{\prime}
$$

In the case where the sample histogram is not completely effective, $A_{\mathrm{o}}^{\mathrm{F}}<V_{\mathrm{o}}^{\mathrm{C}}$, the maximisation of the iso-transform-independent conditional generalised multinomial probability distribution for known transform is well defined, unlike the parameterised probability density function, but is not necessarily a singleton

$$
\left|\max \left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \mathrm{y}, T_{\mathrm{o}}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{o}, 1}\right\}\right)\right| \geq 1
$$

In the case where the maximisation of the iso-transform-independent conditional generalised multinomial probability distribution is a singleton, it is equal to the normalised transform-dependent, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{Y}\left(T_{\mathrm{o}}\right)}$, where the transformdependent $A^{\mathrm{Y}(T)} \in \mathcal{A}_{U, V, z}$ is defined in 'Likely histograms', above, as the maximum likelihood estimate of the distribution histogram of the multinomial probability of the histogram, $A$, conditional that it is an iso-transformindependent,

$$
\begin{aligned}
& \left\{A^{\mathrm{Y}(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The transform-dependent, $A^{\mathrm{Y}(T)}$, is sometimes not computable. The finite approximation to the transform-dependent is

$$
\begin{aligned}
& \left\{A_{k}^{\mathrm{Y}(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D / Z_{k}, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)}\right): D \in \mathcal{A}_{U, \mathrm{i}, V, k z}\right\}\right)
\end{aligned}
$$

The approximation, $A_{k}^{\mathrm{Y}(T)} \approx A^{\mathrm{Y}(T)}$, improves as the scaling factor, $k$, increases.

Unlike in classical non-modelled induction, where the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, is equal to the sample probability histogram, $\hat{A}_{\mathrm{o}}$, in aligned modelled induction the maximum likelihood estimate is not necessarily equal to the sample probability histogram. It is only in the case where the sample histogram equals the transform-independent that the maximum likelihood estimate is necessarily equal to the sample probability histogram,

$$
A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{X}\left(T_{\mathrm{o}}\right)} \Longrightarrow A_{\mathrm{o}}^{\mathrm{Y}\left(T_{\mathrm{o}}\right)}=A_{\mathrm{o}} \Longrightarrow \tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

where the transform-independent $A^{\mathrm{X}(T)} \in \mathcal{A}_{U, V, z}$ is defined in 'Likely histograms', above, as the maximum likelihood estimate for the distribution histogram of the sum of the generalised multinomial probabilities of the integral iso-transform-independents of the histogram, $A$,

$$
\left\{A^{\mathrm{X}(T)}\right\}=\operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
$$

Otherwise, the overall maximum likelihood estimate, which is the transformdependent, is near the histogram, $\tilde{E}_{\mathrm{o}} \sim \hat{A}_{\mathrm{o}}$, only in as much as it is far from the transform-independent, $\tilde{E}_{\mathrm{o}} \nsim \hat{A}_{\mathrm{o}}^{\mathrm{X}\left(T_{\mathrm{o}}\right)}$.

The requirement that the distribution history itself be drawable, $P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{\mathrm{o}}}\left(H_{\mathrm{h}}\right)>$ 0 , has been ignored so far. This requirement modifies the maximisation to add the constraint that the maximum likelihood estimate be an iso-transformindependent, $\left(\left(\tilde{E}_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}}\right),\left(\tilde{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}\right)=\left(\left(\hat{A}_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right),\left(\hat{A}_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}\right)$,

$$
\begin{aligned}
& \left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \mathrm{y}, T_{\mathrm{o}}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1},\right.\right. \\
& \left.\left.\qquad E^{\mathrm{X}} * T_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{x}} * T_{\mathrm{o}},\left(E * T_{\mathrm{o}}\right)^{\mathrm{x}}=\left(\hat{A}_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{x}}\right\}\right)
\end{aligned}
$$

So, strictly speaking, the maximum likelihood estimate is only approximately equal to the normalised transform-dependent, $\tilde{E}_{\mathrm{o}} \approx \hat{A}_{\mathrm{o}}^{\mathrm{Y}\left(T_{\mathrm{o}}\right)}$, if the transformdependent is not an iso-transform-independent, $A_{\mathrm{o}}^{\mathrm{Y}\left(T_{\mathrm{o}}\right)} \notin \mathcal{A}_{U, \mathrm{y}, T_{\mathrm{o}}, z_{0}}\left(A_{\mathrm{o}}\right)$. In
the special case, however, where the sample histogram equals the transformindependent, the maximum likelihood estimate is exactly equal to the normalised transform-dependent, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{X}\left(T_{\mathrm{o}}\right)} \Longrightarrow \tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{Y}\left(T_{\mathrm{o}}\right)}=\hat{A}_{\mathrm{o}}$.

In aligned modelled induction, also known as transform induction, where (i) the history probability function is iso-transform-independent historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{\mathrm{o}}}$, given some substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, if it is the case that (ii) the sample histogram equals the transform-independent, $A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{X}\left(T_{\mathrm{o}}\right)}$, then the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, of the unknown distribution probability histogram, $\hat{E}_{\mathrm{o}}$, in the iso-transform-independent conditional stuffed historical probability distribution, $\hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(E_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is

$$
\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

The set of iso-transform-independents is a subset of the iso-abstracts, $Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \subseteq Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$, so transform induction is entity-like. The iso-abstractence or degree of entity-likeness is

$$
\frac{\left|Y_{U, i, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|} \leq 1
$$

If the set of iso-transform-independents is a proper subset of the iso-abstracts, then transform induction is less entity-like than abstract induction.

The set of iso-transform-independents is not a subset of the iso-deriveds, $Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \nsubseteq D_{U, T, z}^{-1}(A * T)$, so transform induction is not law-like, unlike classical modelled induction or idealisation induction. However, transform induction may be more law-like than abstract induction if the iso-derivedence or degree of law-likeness is greater,

$$
\begin{array}{r}
\frac{\left|Y_{U, \mathrm{i}, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}{\left|\left(Y_{U, \mathrm{i}, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cup D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right) \cap Y_{U, \mathrm{i}, T, \mathrm{w}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}> \\
\frac{\left|D_{U, \mathrm{i}, T, z}^{-1}(A * T)\right|}{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
\end{array}
$$

which depends on the relative intersection cardinalities. That is, transform induction is sometimes less entity-like and more law-like than abstract induction.

Constraints on the sample can make the denominator, $\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(B)$ :
$B \in Y_{U, 1, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)$, more approximate to the iso-derived denominator, $\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{D}(T)}, z\right)(B): B \in D_{U, i, T, z}^{-1}(A * T)$. In this way transform induction can sometimes approximate to classical modelled induction, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{Y}\left(T_{\mathrm{o}}\right)} \approx \hat{A}_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)}$.

The degree to which the iso-transform-independents is said to be alignedlike, or the iso-independence, is

$$
\begin{aligned}
& \frac{\left|Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|}{\left|Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}= \\
& \quad \frac{\left|Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|}{\left|\left(Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right) \cap Y_{U, \mathrm{i}, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)\right|}
\end{aligned}
$$

In some cases the iso-independence of the iso-idealisations is greater than or equal to the iso-independence of the iso-transform-independents,

$$
\frac{\left|Y_{U, \mathrm{i}, T, \mathrm{t}, z}^{-1}\left(A * T * T^{\dagger A}\right)\right|}{\left|Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|} \geq \frac{\left|Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|}{\left|Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cup Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right)\right|}
$$

and so transform induction is sometimes less aligned-like than idealisation induction. However, the derived iso-independence of the integral lifted iso-transform-independents is necessarily greater than or equal to the derived iso-independence of any law-like iso-set,

$$
\frac{\left|\left\{B * T: B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right\}\right|}{\left|Y_{U, \mathbf{i}, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|} \geq \frac{1}{\left|Y_{U, \mathbf{i}, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
$$

and so transform induction may be said to be more derived aligned-like than either classical modelled induction or idealisation induction. However, the derived iso-independence of the integral lifted iso-transform-independents is less than or equal to the derived iso-independence of the integral lifted isoabstracts,

$$
\begin{aligned}
& \frac{\left|\left\{B * T: B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right\}\right|}{\left|Y_{U, \mathrm{i}, W, z}^{-\mathrm{i}}\left((A * T)^{\mathrm{X}}\right)\right|} \leq \\
& \frac{\left|\left\{B * T: B \in Y_{U, \mathrm{i}, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right\}\right|}{\left|Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
\end{aligned}
$$

So transform induction is less derived aligned-like than abstract induction.

As the iso-independence increases, the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, which equals the transform-dependent, $\hat{A}_{\mathrm{o}}^{\mathrm{Y}\left(T_{\mathrm{o}}\right)}$, tends to the dependent, $\hat{A}_{\mathrm{o}}^{\mathrm{Y}}$, which is independent of the model, $T_{\mathrm{o}}$, because the independent analogue, $\hat{A}_{\mathrm{o}}^{\mathrm{X}\left(T_{\mathrm{o}}\right)}$, tends to the independent, $A_{\mathrm{o}}^{\mathrm{X}}$, which is also independent of the model, as the transform tends to full functional. As the derived iso-independence increases, however, the lifted independent analogue, $A_{\mathrm{o}}^{\mathrm{X}\left(T_{\mathrm{o}}\right)^{\prime}}$, tends to the $a b$ stract, $\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, which is not independent of the model, $T_{\mathrm{o}}$.

The finite set of integral iso-formals of $A^{\mathrm{X}} * T$ is

$$
Y_{U, i, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B^{\mathrm{X}} * T=A^{\mathrm{X}} * T\right\}
$$

The iso-independents are a subset of the iso-formals,

$$
Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right) \subseteq Y_{U, i, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right)
$$

so the iso-independent multinomial probability is at least the iso-formal multinomial probability,

$$
\frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} Q_{\mathrm{m}, U}(E, z)(B)} \geq \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in Y_{U, i, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{x}} * T\right)} Q_{\mathrm{m}, U}(E, z)(B)}
$$

That is, necessary formal, $\hat{A}_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\hat{E}_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}$, is a weaker condition on the drawable histories than necessary independent, $\hat{A}_{\mathrm{o}}^{\mathrm{X}}=\hat{E}_{\mathrm{o}}^{\mathrm{X}}$.

The finite set of integral iso-abstracts of $(A * T)^{\mathrm{X}}$ is

$$
Y_{U, i, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z, z},(B * T)^{\mathrm{x}}=(A * T)^{\mathrm{x}}\right\}
$$

In general, the iso-independents are neither a subset nor a superset of the iso-abstracts.

In the case of a full functional transform, $T_{\mathrm{f}}=\left\{\{w\}^{\mathrm{Cs}\{ \} V \mathrm{~T}}: w \in V\right\}^{\mathrm{T}}$, both the iso-formals and the iso-abstracts equal the iso-independents, $Y_{U, \mathrm{i}, T_{\mathrm{f}}, \mathrm{V}, z}^{-1}\left(A^{\mathrm{X}} *\right.$ $\left.T_{\mathrm{f}}\right)=Y_{U, \mathrm{i}, T_{\mathrm{f}}, \mathrm{W}, z}^{-1}\left(\left(A * T_{\mathrm{f}}\right)^{\mathrm{X}}\right)=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, and so the case is the same as for aligned non-modelled induction. At the other extreme of a unary transform, $T_{\mathrm{u}}=\left\{V^{\mathrm{CS}}\right\}^{\mathrm{T}}$, both the iso-formals and the iso-abstracts equal the substrate histograms, $Y_{U, i, T \mathrm{u}, \mathrm{V}, z}^{-1}\left(A^{\mathrm{X}} * T_{\mathrm{u}}\right)=Y_{U, \mathrm{i}, T_{\mathrm{u}}, \mathrm{W}, z}^{-1}\left(\left(A * T_{\mathrm{u}}\right)^{\mathrm{X}}\right)=\mathcal{A}_{U, \mathrm{i}, V, z}$, and so the case is the same as for classical non-modelled induction.

This suggests that, in the case of necessary formal, $\hat{A}_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\hat{E}_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}$, and necessary abstract, $\left(\hat{A}_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}=\left(\hat{E}_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, as the transform, $T_{\mathrm{o}}$, ranges
from full functional, $T_{\mathrm{f}}$, to unary, $T_{\mathrm{u}}$, the condition weakens from necessary independent aligned induction to unconditional classical induction, and so (i) the maximum likelihood estimate tends to the sample probability histogram, $\tilde{E}_{\mathrm{o}} \rightarrow \hat{A}_{\mathrm{o}}$, (ii) the maximum likelihood alignment tends to that of the sample histogram, $\operatorname{algn}\left(Z_{\mathrm{o}} * \tilde{E}_{\mathrm{o}}\right) \rightarrow \operatorname{algn}\left(A_{\mathrm{o}}\right)$, and (iii) at low alignments the sum sensitivity tends to vary less with the sample alignment and more with the negative scaled sample entropy, $\operatorname{algn}\left(A_{\mathrm{o}}\right) \rightarrow-z_{\mathrm{o}} \times$ entropy $\left(A_{\mathrm{o}}\right)$.

In general, the iso-independents are neither a subset nor a superset of the iso-transform-independents, so the iso-independent multinomial probability,

$$
\frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} Q_{\mathrm{m}, U}(E, z)(B)}
$$

is not bounded by the iso-transform-independent multinomial probability,

$$
\frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \mathcal{A}_{U, i, y, T, z}(A)} Q_{\mathrm{m}, U}(E, z)(B)}
$$

That is, necessary formal and necessary abstract, $\hat{A}_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\hat{E}_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}} \wedge\left(\hat{A}_{\mathrm{o}} *\right.$ $\left.T_{\mathrm{o}}\right)^{\mathrm{X}}=\left(\hat{E}_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, is not necessarily a weaker condition on the drawable histories than necessary independent, $\hat{A}_{\mathrm{o}}^{\mathrm{X}}=\hat{E}_{\mathrm{o}}^{\mathrm{X}}$.

In the case of a full functional transform, $T_{\mathrm{f}}$, the iso-transform-independents equals the iso-independents, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{f}}, z}(A)=Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)$, and so the case is the same as for aligned non-modelled induction. In the case of unary transform, $T_{\mathrm{u}}$, the iso-transform-independents equals the substrate histograms, $\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{u}}, z}(A)=\mathcal{A}_{U, \mathrm{i}, V, z}$, and so the case is the same as for classical nonmodelled induction.

The sample histogram is in the intersection of the iso-independents and the iso-transform-independents,

$$
A \in Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{x}}\right) \cap Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{x}}\right)\right)
$$

so the iso-independence is non-zero,

$$
\frac{\left|Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cap Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}{\left|Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right) \cup Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|}>0
$$

and the iso-independent multinomial probability is correlated with the iso-transform-independent multinomial probability

$$
\frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in Y_{U, i, V, z}^{-1}\left(A^{\mathrm{x}}\right)} Q_{\mathrm{m}, U}(E, z)(B)} \sim \frac{Q_{\mathrm{m}, U}(E, z)(A)}{\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} Q_{\mathrm{m}, U}(E, z)(B)}
$$

In the case still of necessary formal and necessary abstract, but where the transform is constrained to be such that the formal independent equals the abstract, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$, then the independent is an iso-abstract,

$$
\left(A^{\mathrm{X}} * T\right)^{\mathrm{x}}=(A * T)^{\mathrm{x}} \quad \Longrightarrow \quad A^{\mathrm{X}} \in Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)
$$

If, in addition, the independent is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, then both the sample histogram and the independent sample histogram are in the intersection of the iso-independents and the iso-transform-independents,

$$
\left\{A, A^{\mathrm{x}}\right\} \subseteq Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right) \cap Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{X}}\right)\right)
$$

so the iso-independence may be expected to be higher, and the correlation between the iso-independent multinomial probability and the iso-transformindependent multinomial probability may be expected to be stronger.

This is also the case where the constraints on the transform are stricter. For example, if the formal equals the abstract, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}} \Longrightarrow$ $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$.

If the formal histogram equals the abstract histogram then the lifted iso-transform-independents contains the abstract histogram

$$
(A * T)^{\mathrm{x}}=A^{\mathrm{x}} * T \in\left\{B * T: B \in Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{x}}\right)\right)\right\}
$$

In this case, if the abstract is also integral, $(A * T)^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, the derived isoindependence of the iso-transform-independents,

$$
\frac{\left|\left\{B * T: B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right\}\right|}{\left|Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
$$

is greater than would otherwise be the case because the abstract is in the intersection, $(A * T)^{\mathrm{X}} \in\left\{B * T: B \in Y_{U, \mathbf{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right\} \cap Y_{U, \mathbf{i}, W, z}^{-1}((A *$ $T)^{\mathrm{X}}$ ).

Note that it is only in the subset where the formal histogram equals the $a b-$ stract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, that the lifted iso-transform-independent relation is functional

$$
\begin{aligned}
& \left\{\left(A * T,\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{X}}\right)\right): A \in \mathcal{A}_{U, V, z}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{x}}\right\} \\
\in & \mathcal{A}_{U, W, z} \rightarrow\left(\mathcal{A}_{U, W, z} \times \mathcal{A}_{U, W, z}\right)
\end{aligned}
$$

and

$$
\begin{aligned}
& \left\{\left(A * T, Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right): A \in \mathcal{A}_{U, V, z}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{x}}\right\} \\
\in & \mathcal{A}_{U, W, z} \rightarrow \mathrm{P}\left(\mathcal{A}_{U, \mathrm{i}, V, z}\right)
\end{aligned}
$$

Similarly it is only in the subset where the formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, that the formal domained relation of the iso-transform-independents is functional

$$
\begin{aligned}
& \left\{\left(A^{\mathrm{X}} * T,\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right): A \in \mathcal{A}_{U, V, z}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}\right\} \\
\in & \mathcal{A}_{U, W, z} \rightarrow\left(\mathcal{A}_{U, W, z} \times \mathcal{A}_{U, W, z}\right)
\end{aligned}
$$

and

$$
\begin{aligned}
& \left\{\left(A^{\mathrm{x}} * T, Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{x}}\right)\right)\right): A \in \mathcal{A}_{U, V, z}, A^{\mathrm{x}} * T=(A * T)^{\mathrm{x}}\right\} \\
\in & \mathcal{A}_{U, W, z} \rightarrow \mathrm{P}\left(\mathcal{A}_{U, \mathrm{i}, V, z}\right)
\end{aligned}
$$

Given the known substrate transform, $T_{\mathrm{o}}$, consider the maximum likelihood estimate of the iso-transform-independent conditional generalised multinomial probability distribution, $\hat{Q}_{\mathrm{m}, \mathrm{y}, T_{\mathrm{o}}, U}$.

The independent-analogue or transform-independent, $A^{\mathrm{X}(T)}$, is the maximum likelihood estimate of the distribution histogram of the multinomial probability of membership of the iso-transform-independents,

$$
\begin{aligned}
\left\{A^{\mathrm{X}(T)}\right\} & = \\
& \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right)\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The lifted independent-analogue or the lifted transform-independent, $A^{\mathrm{X}(T)^{\prime}}$, is defined

$$
\begin{aligned}
& \left\{A^{\mathrm{X}(T)^{\prime}}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D, \sum\left(Q_{\mathrm{m}, U}(D, z)\left(B^{\prime}\right): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right)\right): D \in \mathcal{A}_{U, W, z}\right\}\right)
\end{aligned}
$$

where the lifted integral iso-transform-independents is abbreviated

$$
\mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)=\left\{B * T: B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right\}
$$

The corresponding dependent-analogue or transform-dependent, $A^{\mathrm{Y}(T)}$, is the maximum likelihood estimate of the distribution histogram of the multino-
mial probability of the histogram, $A$, conditional that it is an iso-transformindependent,

$$
\begin{aligned}
& \left\{\left(A^{\mathrm{Y}(T)}, \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)}\right)\right\}= \\
& \max \left(\left\{\left(D, \frac{Q_{\mathrm{m}, U}(D, z)(A)}{\sum Q_{\mathrm{m}, U}(D, z)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)}\right): D \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

In section 'Likely histograms', above, the logarithm of the maximum conditional probability with respect to the dependent-analogue is conjectured to vary with the relative space with respect to the independent-analogue. In the case of iso-transform-independent conditional,

$$
\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \sim
$$

where the distribution-relative multinomial space is defined, in section 'Likely histograms', above, as

$$
\text { spaceRelative }(E)(A):=-\ln \frac{\operatorname{mpdf}(U)(E, z)(A)}{\operatorname{mpdf}(U)(E, z)(E)}
$$

The set of iso-transform-independents is entity-like, not law-like, so the derived, $A * T$, and the transform-dependent derived, $A^{\mathrm{Y}(T)} * T$, are not necessarily equal to each other and nor are they necessarily equal to the transformindependent derived, $A^{\mathrm{X}(T)} * T$. In section 'Transform alignment', above, it is conjectured that the relation between the relative spaces,

$$
\begin{aligned}
0 & =\text { spaceRelative }\left(A^{\mathrm{X}(T)}\right)\left(A^{\mathrm{X}(T)}\right) \\
& \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)(A) \\
& \leq \operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)\left(A^{\mathrm{Y}(T)}\right)
\end{aligned}
$$

can be lifted and so the dependent analogue derived alignment is conjectured to be greater than or equal to the derived alignment which in turn is greater than or equal to the independent analogue derived alignment,

$$
\operatorname{algn}\left(A^{\mathrm{X}(T)} * T\right) \leq \operatorname{algn}(A * T) \leq \operatorname{algn}\left(A^{\mathrm{Y}(T)} * T\right)
$$

The transform-dependent varies with the histogram, $A^{\mathrm{Y}(T)} \sim A$, so conjecture that the log-likelihood varies with the derived alignment,

$$
\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \sim \operatorname{algn}(A * T)
$$

The derivation of this correlation can be seen more clearly in terms of a decomposition into three separate correlations. First, conjecture that the logarithm of the iso-transform-independent conditional multinomial probability of the histogram, $A$, with respect to the dependent analogue or transformdependent, $A^{\mathrm{Y}(T)}$, varies against the logarithm of the iso-transform-independent conditional multinomial probability with respect to the independent analogue or transform-independent, $A^{\mathrm{X}(T)}$,

$$
\begin{aligned}
& \ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \sim \\
& \quad-\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)}
\end{aligned}
$$

This relation is called the dependent-independent anti-correlation. As shown in 'Likely histograms', above, the strength of the dependent-independent anticorrelation depends on the relative space of the histogram with respect to the independent analogue, spaceRelative $\left(A^{\mathrm{X}(T)}\right)(A)$.

Second, conjecture that the negative logarithm of the iso-transform-independent conditional multinomial probability of the histogram, $A$, with respect to the independent analogue or transform-independent, $A^{\mathrm{X}(T)}$, varies with the negative logarithm of the lifted iso-transform-independent conditional multinomial probability of the derived, $A * T$, with respect to the lifted independent analogue or transform-independent derived, $A^{\mathrm{X}(T)} * T$,

$$
\begin{aligned}
& -\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)}, z\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \sim \\
& \quad-\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)} * T, z\right)(A * T)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)} * T, z\right)\left(B^{\prime}\right): B^{\prime} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)}
\end{aligned}
$$

This correlation is called the underlying-lifted correlation. As mentioned above in this section, lifting the iso-transform-independents is not functional,
$\left\{\left(A * T,\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right): A \in \mathcal{A}_{U, V, z}\right\} \notin \mathcal{A}_{U, W, z} \rightarrow\left(\mathcal{A}_{U, W, z} \times \mathcal{A}_{U, W, z}\right)$
unless the formal histogram equals the abstract histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$. The underlying-lifted correlation is expected to be weaker if the lift is not functional.

Third, conjecture that, in the case where the lifted transform-independent is integral, $A^{\mathrm{X}(T)^{\prime}} \in \mathcal{A}_{\mathrm{i}}$, the denominator of the lifted iso-transform-independent
conditional multinomial probability is dominated by the lifted transformindependent term, $Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)} * T, z\right)\left(A^{\mathrm{X}(T)^{\prime}}\right)$, and similar terms, and so the negative logarithm of the lifted iso-transform-independent conditional multinomial probability with respect to the lifted independent analogue or transform-independent derived, $A^{\mathrm{X}(T)} * T$, varies with the negative logarithm of the ratio of (i) the multinomial probability of the derived, $A * T$, with respect to the transform-independent derived, $A^{\mathrm{X}(T)} * T$, and (ii) the multinomial probability of the lifted transform-independent, $A^{\mathrm{X}(T)^{\prime}}$, with respect to the transform-independent derived, $A^{\mathrm{X}(T)} * T$, which approximates to the relative space with respect to the abstract, $(A * T)^{\mathrm{X}}$, which is the derived alignment,

$$
\begin{aligned}
&-\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)} * T, z\right)(A * T)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)} * T, z\right)\left(B^{\prime}\right): B^{\prime} \in} \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A) \\
& \sim-\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)} * T, z\right)(A * T)}{Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)} * T, z\right)\left(A^{\left.\mathrm{X}(T)^{\prime}\right)}\right.} \\
& \approx-\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)(A * T)}{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)\left((A * T)^{\mathrm{X}}\right)} \\
&=\operatorname{spaceRelative}\left((A * T)^{\mathrm{X}}\right)(A * T) \\
&=\operatorname{algn}(A * T)
\end{aligned}
$$

This correlation is called the conditional-relative correlation. The strength of the conditional-relative correlation increases with the derived iso-independence of the integral lifted iso-transform-independents,

$$
\frac{\left|\left\{B * T: B \in Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right\}\right|}{\left|Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
$$

Insofar as the transform-independent derived approximates to the abstract, $A^{\mathrm{X}(T)} * T \approx(A * T)^{\mathrm{X}}$, as the derived iso-independence increases, the lifted transform-independent, $A^{\mathrm{X}(T)^{\prime}}$, tends to the abstract, $(A * T)^{\mathrm{X}}$, and the lifted transform-independent term, $Q_{\mathrm{m}, U}\left(A^{\mathrm{X}(T)} * T, z\right)\left(A^{\mathrm{X}(T)^{\prime}}\right)$, tends to the abstract term, $Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)\left((A * T)^{\mathrm{X}}\right)$, in the case where both are integral, $A^{\mathrm{X}(T)^{\prime}},(A * T)^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$.

In transform induction, where (i) the history probability function is iso-transform-independent historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{o}}$, given some substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{0}}$, if it is the case that (ii) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{0}$, and such that (iii) the scaled estimate distribution histogram is integral, $\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then the log likelihood of the iso-transform-independent
conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the relative space of the sample with respect to the transform-independent,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{spaceRelative}\left(A_{\mathrm{o}}^{\mathrm{X}\left(T_{\mathrm{o}}\right)}\right)\left(A_{\mathrm{o}}\right)
$$

and varies with the derived alignment,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

The derived alignment of the maximum likelihood estimate is greater than or equal to that of the sample,

$$
\operatorname{algn}\left(Z_{\mathrm{o}} * \tilde{E}_{\mathrm{o}} * T\right) \geq \operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

In section 'Classical modelled induction', above, it is shown that the isoderived conditional stuffed historical probability distribution at the maximum likelihood estimate, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{o}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)$, can be related to queries on the maximum likelihood estimate of the distribution histogram, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}$, in the special case where the sample histogram is natural, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$. The given substrate transform must be such that its contraction has underlying variables that are a subset of the query variables, und $\left(T_{\mathrm{o}}^{\%}\right) \subseteq K$. In the case where the query histogram consists of one effective state, $Q=\left\{\left(S_{Q}, 1\right)\right\}$, the application of the query in terms of a modified sample histogram is

$$
\begin{aligned}
& \left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)= \\
& \quad\left\{\left(N,\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{Q, N}\right)\right)^{1 / z_{\mathrm{o}}}\right): N \in\left(V_{\mathrm{o}} \backslash K\right)^{\mathrm{CS}}\right. \\
& \left.\quad A_{Q, N}=A_{\mathrm{o}}-\left(A_{\mathrm{o}} * C_{Q}\right)+\left(\left(A_{\mathrm{o}} * C_{Q}\right) \% K *\{N\}^{\mathrm{U}}\right)\right\}^{\wedge}
\end{aligned}
$$

where $\left\{R_{Q}\right\}=\left(Q * T_{\mathrm{o}}^{\%}\right)^{\mathrm{FS}}, C_{Q}=T_{\mathrm{o}}^{-1}\left(R_{Q}\right)$ and his $=$ histogram $\in \mathcal{T} \rightarrow \mathcal{A}$. If the sample histogram is completely effective, $A_{\mathrm{o}}^{\mathrm{F}}=V_{\mathrm{o}}^{\mathrm{C}}$, the modified sample histogram, $A_{Q, N}$, can be drawn from the distribution, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{o}, U}\left(A_{o, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{Q, N}\right)>$ 0 , because its derived is equal to the known derived, $A_{Q, N} * T_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}}$. That is, the modified sample histogram is in the iso-deriveds, $A_{Q, N} \in D_{U, \mathrm{i}, T_{0}, z_{0}}^{-1}\left(A_{\mathrm{o}} *\right.$ $T_{\mathrm{o}}$ ).

However, in the case of transform induction, where the transform-independent is necessary, the modified sample histogram is not necessarily in the iso-transform-independents, $A_{Q, N} \notin Y_{U, i, T_{\mathrm{o}}, z}^{-1}\left(\left(A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}},\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}\right)\right)$. Although the modified sample histogram is necessarily an iso-abstract, $\left(A_{Q, N} * T_{\mathrm{o}}\right)^{\mathrm{X}}=$ $\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, in some cases the modified sample histogram is not an iso-formal,
$A_{Q, N}^{\mathrm{X}} * T_{\mathrm{o}} \neq A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}$. Even if the modified derived is an iso-transformindependent, the modified derived, $\hat{A}_{Q, N} * T_{\mathrm{o}}$, is not necessarily equal to that of the distribution, $\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}$. That is, in some cases $\hat{A}_{Q, N} * T_{\mathrm{o}} \neq$ $\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}$. So it cannot be assumed that application of the query via the model of the sample is equal to the query via the model of the distribution, $\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right) \neq\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * E_{\mathrm{h}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)$. Nor can the query via the model of the sample, $\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)$, be expressed in terms of the iso-transform-independent conditional stuffed historical probability distribution at the scaled sample, $\hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)$.

Consider the constraints that may be added to transform induction to increase the resemblance to classical modelled induction, so that queries via the model of the sample are more approximate to queries via the model of the distribution, $\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right) \approx\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) *\right.$ $\left.E_{\mathrm{h}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)$.

In abstract induction, above, it is conjectured that, because the law-like isoderiveds are a subset of the set of entity-like iso-abstracts, $D_{U, T, z}^{-1}(A * T) \subseteq$ $Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$, the maximum likelihood estimate is more classical if (i) the sample is known to be equal to the independent analogue, or naturalisation, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, and (ii) the relative space of the sample with respect to the naturalised sample abstract, spaceRelative $\left(\left(A_{0} * T_{\mathrm{o}}\right)^{\mathrm{X}} * T_{\mathrm{o}}^{\dagger}\right)\left(A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}\right)$, is high.

For transform induction, however, the set of iso-deriveds is not necessarily a subset of the entity-like iso-transform-independents, $\mid D_{U,, T, z}^{-1}(A * T) \backslash$ $Y_{U, i, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right) \mid \geq 0\right.$. The set of iso-liftisations is a law-like subset of the iso-transform-independents,
$Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap D_{U, T, z}^{-1}(A * T) \subseteq Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{X}} * T\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{X}}\right)$
but the independent analogue, which is the liftisation, $A^{\mathrm{K}(T)}$, is sometimes not computable. So consider instead the set of iso-idealisations which is a further law-like subset of the iso-transform-independents,

$$
\begin{aligned}
Y_{U, T, \mathrm{t}, z}^{-1}\left(A * T * T^{\dagger A}\right) & =C_{U, T, \mathrm{x}, z}^{-1}\left(\left\{\left(A * C^{\mathrm{U}}\right)^{\mathrm{x} \wedge}: C \in T^{\mathrm{P}}\right\}\right) \cap D_{U, T, z}^{-1}(A * T) \\
& \subseteq Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{x}} * T\right) \cap D_{U, T, z}^{-1}(A * T) \\
& \subseteq Y_{U, T, \mathrm{~V}, z}^{-1}\left(A^{\mathrm{x}} * T\right) \cap Y_{U, T, \mathrm{~W}, z}^{-1}\left((A * T)^{\mathrm{x}}\right)
\end{aligned}
$$

Conjecture that the logarithm of the fraction of the sum of the iso-transformindependent multinomial probabilities, with respect to the idealisation, $A * T *$
$T^{\dagger A}$, that are iso-idealisations varies as the relative space of the idealisation with respect to the transform-independent,

$$
\begin{aligned}
&\left.\ln \frac{\sum Q_{\mathrm{m}, U}\left(A * T * T^{\dagger A}, z\right)(B): B \in Y_{U,,, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)}{\sum Q_{\mathrm{m}, U}\left(A * T * T^{\dagger A}\right.}, z\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A) \\
& \sim \quad-\operatorname{spaceRelative}\left(A * T * T^{\dagger A}\right)\left(A^{\mathrm{X}(T)}\right) \\
& \sim \operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)\left(A * T * T^{\dagger A}\right)
\end{aligned}
$$

If the relative space is high, the elements of the iso-transform-independents which are not iso-idealisations and which sometimes do not have the same derived as the idealisation, $A * T * T^{\dagger A} * T=A * T$, have low multinomial probability with respect to the idealisation,
$\sum\left(Q_{\mathrm{m}, U}\left(A * T * T^{\dagger A}, z\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A) \backslash Y_{U, \mathrm{i}, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right)\right) \approx 0$
If the sample is known to be ideal, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, then with the increase of the relative space of the sample with respect to the transform-independent, spaceRelative $\left(A_{\mathrm{o}}^{\mathrm{X}\left(T_{\mathrm{o}}\right)}\right)\left(A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}\right)$, the maximum likelihood estimate, $\tilde{E}_{\mathrm{o}}$, which is the transform-dependent, $\hat{A}_{\mathrm{o}}^{\mathrm{Y}\left(T_{\mathrm{o}}\right)}$, tends to the idealisation-dependent which equals the idealisation, $\hat{A}_{\mathrm{o}}^{\dagger\left(T_{\mathrm{o}}\right)}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, and away from the transform-independent, $\hat{A}_{\mathrm{o}}^{\mathrm{X}\left(T_{\mathrm{o}}\right)}$. Consequently, ideal sample increases the correlation between the log likelihood of the iso-transform-independent conditional stuffed historical probability distribution at the maximum likelihood estimate and the log likelihood of the iso-idealisation conditional stuffed historical probability distribution at the idealisation,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \ln \hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

Thus, the maximum likelihood estimate is more classical if the sample is known to be ideal and the relative space is high. That is, transform induction is analogous to abstract induction in this respect except that the stricter ideal sample, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, is required instead of natural sample, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$.

Even if the sample is ideal, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, the maximum likelihood estimate of the distribution histogram, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{Y}(T)}$, is not necessarily equal to the sample, $\tilde{E}_{\mathrm{o}} \neq \hat{A}_{\mathrm{o}}$. So it still cannot be assumed that application of the query via the model of the sample is equal to the query via the model of the distribution, $\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right) \neq$ $\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * E_{\mathrm{h}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)$. Nor can the query via the model of the sample, $\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)$, be expressed in terms of the
iso-transform-independent conditional stuffed historical probability distribution at the scaled idealised sample, $\hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)$.

The relative space of the histogram with respect to the independent analogue, or transform-independent, $A^{\mathrm{X}(T)}$, varies with the lifted relative space, which varies with the derived alignment,

$$
\begin{aligned}
\text { spaceRelative }\left(A^{\mathrm{X}(T)}\right)(A) & \sim \operatorname{spaceRelative}\left(A^{\mathrm{X}(T)} * T\right)(A * T) \\
& \approx \operatorname{spaceRelative}\left((A * T)^{\mathrm{X}}\right)(A * T) \\
& =\operatorname{algn}(A * T)
\end{aligned}
$$

depending on the underlying-lifted correlation and the conditional-relative correlation.

The conditional-relative correlation improves as the derived iso-independence increases and the lifted transform-independent, $A^{\mathrm{X}(T)^{\prime}}$, tends to the abstract, $(A * T)^{\mathrm{X}}$. As shown in 'Deltas and Perturbations' and 'Abstract induction', above, in the case where the formal is independent, $A^{\mathrm{X}} * T=\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}$, the possible derived volume equals the derived volume, $w^{\prime}=w$ where $w^{\prime}=\left|T^{-1}\right|$ and $w=\left|W^{\mathrm{C}}\right|$. In this case the derived iso-independence is greater than it would be otherwise, improving the approximation of the lifted transformindependent to the abstract, $A^{\mathrm{X}(T)^{\prime}} \approx(A * T)^{\mathrm{X}}$.

In the stricter case where the formal equals the abstract, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, the lifted iso-transform-independents contains the abstract histogram

$$
(A * T)^{\mathrm{X}} \in Y_{U, W, z}^{-1}\left((A * T)^{\mathrm{x}}\right) \cap\left\{B * T: B \in Y_{U, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)\right\}
$$

and again the derived iso-independence is greater than it would be otherwise, strengthening the conditional-relative correlation.

Incidentally, the case where the formal equals the abstract, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, implies that the formal independent equals the abstract, $\left(A^{\mathrm{X}} * T\right)^{\mathrm{X}}=(A * T)^{\mathrm{X}}$, which implies that the independent is an iso-transform-independent,

$$
A^{\mathrm{X}} \in Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right) \cap Y_{U, \mathrm{i}, T, z}^{-1}\left(\left(\left(A^{\mathrm{X}} * T\right),(A * T)^{\mathrm{X}}\right)\right)
$$

and so the underlying iso-independence is also greater than it would be otherwise.

Furthermore, in the case where the formal histogram equals the abstract
histogram, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$, the lifted iso-transform-independent relation is functional

$$
\begin{aligned}
& \left\{\left(A * T,\left(\left(A^{\mathrm{x}} * T\right),(A * T)^{\mathrm{x}}\right)\right): A \in \mathcal{A}_{U, V, z}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{x}}\right\} \\
\in & \mathcal{A}_{U, W, z} \rightarrow\left(\mathcal{A}_{U, W, z} \times \mathcal{A}_{U, W, z}\right)
\end{aligned}
$$

and so the underlying-lifted correlation is also strengthened.
In the case where the formal histogram equals the abstract histogram, the independent analogue, or transform-independent, equals the computable naturalised abstract,

$$
A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}} \quad \Longrightarrow \quad A^{\mathrm{X}(T)}=(A * T)^{\mathrm{X}} * T^{\dagger}
$$

So the three correlations now simplify. First, the dependent-independent anti-correlation between the logarithm of the iso-transform-independent conditional multinomial probability of the histogram, $A$, with respect to the dependent analogue or transform-dependent, $A^{\mathrm{Y}(T)}$, and the logarithm of the iso-transform-independent conditional multinomial probability with respect to the naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$, is,

$$
\begin{aligned}
& \ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \sim \\
& \quad-\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}} * T^{\dagger}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}} * T^{\dagger}, z\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)}
\end{aligned}
$$

Second, the underlying-lifted correlation between the negative logarithm of the iso-transform-independent conditional multinomial probability of the histogram, $A$, with respect to the naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$, and the negative logarithm of the lifted iso-transform-independent conditional multinomial probability of the derived, $A * T$, with respect to the abstract, $(A * T)^{\mathrm{X}}$, is,

$$
\begin{aligned}
&-\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}} * T^{\dagger}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}} * T^{\dagger}, z\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \sim \\
&-\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}}, z\right)(A * T)}{\sum Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)\left(B^{\prime}\right): B^{\prime} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)}
\end{aligned}
$$

Third, the conditional-relative correlation between the negative logarithm of the lifted iso-transform-independent conditional multinomial probability with respect to the abstract, $(A * T)^{\mathrm{X}}$, and the negative logarithm of the relative
multinomial probability with respect to the abstract, $(A * T)^{\mathrm{X}}$, which is the derived alignment, is,

$$
\begin{aligned}
&-\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)(A * T)}{\sum Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)\left(B^{\prime}\right): B^{\prime} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)} \\
& \sim-\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)(A * T)}{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}}, z\right)\left(A^{\left.\mathrm{X}(T)^{\prime}\right)}\right.} \\
& \approx-\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}}, z\right)(A * T)}{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}}, z\right)\left((A * T)^{\mathrm{X}}\right)} \\
&=\operatorname{spaceRelative}\left((A * T)^{\mathrm{X}}\right)(A * T) \\
&=\operatorname{algn}(A * T)
\end{aligned}
$$

That is, if the sample is known to have formal-abstract equivalence, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=$ $\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, the correlation between the relative space of the histogram with respect to the naturalised abstract and the derived alignment,

$$
\text { spaceRelative }\left(\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}} * T_{\mathrm{o}}^{\dagger}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

is higher than would otherwise be the case. So the correlation between the logarithm of the iso-transform-independent conditional multinomial probability with respect to the transform-dependent, and the derived alignment,

$$
\ln \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}^{\mathrm{Y}\left(T_{\mathrm{o}}\right)}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}^{\mathrm{Y}\left(T_{\mathrm{o}}\right)}, z_{\mathrm{o}}\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{o}}, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)} \sim \operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

is also higher. Consequently, formal-abstract equivalence increases the correlation between the log likelihood of the iso-transform-independent conditional stuffed historical probability distribution at the maximum likelihood estimate and the derived alignment,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

Sample formal-abstract equivalence, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, implies stricter conditions for transform induction, (i) necessary formal, $\hat{A}_{H}^{\mathrm{X}} * T_{\mathrm{o}}=\hat{E}_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}}$, and necessary independence of formal, $\hat{A}_{H}^{\mathrm{X}} * T_{\mathrm{o}}=\left(\hat{A}_{H}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, and (ii) necessary abstract, $\left(\hat{A}_{H} * T_{\mathrm{o}}\right)^{\mathrm{X}}=\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, and necessary abstraction of independent, $\left(\hat{A}_{H}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}=\left(\hat{A}_{H} * T_{\mathrm{o}}\right)^{\mathrm{X}}$. Sample formal-abstract equivalence also implies (i) necessary independence of distribution formal, $\hat{E}_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(\hat{E}_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, and (ii) necessary abstraction of distribution independent, $\left(\hat{E}_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}=\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$.

If the sample is known to be both (i) ideal, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, and (ii)
formal-abstract equivalent, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, then the logarithm of the fraction of the sum of the iso-transform-independent multinomial probabilities, with respect to the idealisation, that are iso-idealisations also varies with the derived alignment,

$$
\begin{aligned}
& \ln \frac{\sum Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)(B): B \in Y_{U, \mathrm{i}, T_{\mathrm{o}}, \mathrm{t}, z_{\mathrm{o}}}^{-1}}{}\left(A_{\mathrm{o}}\right) \\
& \sum Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T_{\mathrm{o}}, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right) \\
& \sim \operatorname{spaceRelative}\left(\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{x}} * T_{\mathrm{o}}^{\dagger}\right)\left(A_{\mathrm{o}}\right) \\
& \sim \operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
\end{aligned}
$$

So the maximum likelihood estimate becomes more classical as the derived alignment increases. As the derived alignment increases the more the query via the model of the sample approximates to the query via the model of the distribution, $\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right) \approx\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) *\right.$ $\left.E_{\mathrm{h}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)$.

Now transform induction is analogous to abstract induction except that (i) the stricter ideal sample, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, is required instead of natural sample, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, and (ii) the stricter sample formal-abstract equality, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, is required instead of independent sample formal, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$.

The set of iso-idealisations is a subset of the intersection of the iso-independents and iso-deriveds, $Y_{U, T, \uparrow, z}^{-1}\left(A * T * T^{\dagger A}\right) \subseteq Y_{U, V, z}^{-1}\left(A^{\mathrm{X}}\right) \cap D_{U, T, z}^{-1}(A * T)$. In section 'Idealisation induction', above, it is shown that the cardinality of the iso-independents varies with the alignment,

$$
\ln \left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right| \sim \operatorname{algn}(A)
$$

At high alignments, the iso-independence of the iso-idealisations, $\mid Y_{U, i, T, \uparrow, z}^{-1}(A *$ $\left.T * T^{\dagger A}\right)\left|/\left|Y_{U, i, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right|\right.$, decreases, and the iso-derivedence, $| Y_{U, \mathrm{i}, T, \dagger, z}^{-1}(A * T *$ $\left.T^{\dagger A}\right)\left|/\left|D_{U, i, T, z}^{-1}(A * T)\right|\right.$, increases. So the iso-idealisation log likelihood varies with the iso-derived log likelihood,

$$
\ln \hat{Q}_{\mathrm{m}, \mathrm{t}, T, U}(A, z)(A) \sim \ln \hat{Q}_{\mathrm{m}, \mathrm{~d}, T, U}(A, z)(A)
$$

The iso-idealisation conditional multinomial distribution sum sensitivity varies with the iso-independent sum sensitivity,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \uparrow, T, U}(A, z)\right)\right) \sim \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{y}, U}(A, z)\right)\right)
$$

and the iso-derived sum sensitivity,
$\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \dagger, T, U}(A, z)\right)\right) \sim \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{d}, T, U}(A, z)\right)\right)$

It is conjectured above that at intermediate alignments, $0 \ll \operatorname{algn}(A) \ll$ $\operatorname{algnMax}(U)(V, z)$, the iso-independent sum sensitivity is constant and the iso-idealisation sum sensitivity varies only with the iso-derived sum sensitivity,
$\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \dagger, T, U}(A, z)\right)\right) \sim \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, \mathrm{d}, T, U}(A, z)\right)\right)$
In transform induction, where (i) the history probability function is iso-transform-independent historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{\mathrm{o}}}$, given some substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{o}}$, if it is the case that (ii) the sample is ideal, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, (iii) the sample formal equals the sample abstract, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, (iv) the alignment is at least intermediate, $\operatorname{algn}\left(A_{\mathrm{o}}\right)>\operatorname{algnMax}(U)\left(V_{\mathrm{o}}, z_{\mathrm{o}}\right) / 2$, (v) the derived alignment is high, $\operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right) \gg 0$, (vi) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{\mathrm{o}}$, and such that (vii) the scaled estimate distribution histogram is integral, $\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then (a) the log likelihood of the iso-transform-independent conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the log likelihood of the iso-idealisation conditional stuffed historical probability distribution at the idealisation which, in turn, varies with the log likelihood of the iso-derived conditional stuffed historical probability distribution at the sample,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) & \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{t}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \\
& \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
\end{aligned}
$$

(b) so the log likelihood varies with the size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) & \sim \\
\left(z_{\mathrm{o}}+v_{\mathrm{o}}\right) \times \operatorname{entropy}\left(A_{\mathrm{o}}\right. & \left.* T_{\mathrm{o}}+V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right) \\
& -z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)-v_{\mathrm{o}} \times \operatorname{entropy}\left(V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)
\end{aligned}
$$

(c) the formal alignment of the maximum likelihood estimate is zero,

$$
\begin{aligned}
\tilde{E}_{\mathrm{o}}^{\mathrm{x}} * T_{\mathrm{o}} & =\hat{A}_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}} \\
& =\left(\hat{A}_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{x}} \\
& =\left(\tilde{E}_{\mathrm{o}}^{\mathrm{x}} * T_{\mathrm{o}}\right)^{\mathrm{X}}
\end{aligned}
$$

and (d) the maximum likelihood estimate derived approximates to the normalised sample derived,

$$
\tilde{E}_{\mathrm{o}} * T_{\mathrm{o}} \approx \hat{A}_{\mathrm{o}} * T_{\mathrm{o}}
$$

In this case queries via the model of the sample approximate to queries via the model of the distribution,

$$
\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right) \approx\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * E_{\mathrm{h}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)
$$

That is, at high derived alignments, and intermediate or high underlying alignment, where the sample is known to be ideal and the sample formal is known to be equal to the sample abstract, aligned modelled induction has similar properties to classical modelled induction.

If the relative entropy is high, entropy $\operatorname{Cross}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)>\ln \left|T_{\mathrm{o}}^{-1}\right|$, the sum sensitivity of the iso-derived conditional stuffed historical probability distribution at the naturalisation varies with the derived entropy,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

Note, however, that because the transform induction is more derived alignedlike than classical modelled induction,

$$
\frac{\left|\left\{B * T: B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)\right\}\right|}{\left|Y_{U, \mathrm{i}, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|} \geq \frac{1}{\left|Y_{U, i, W, z}^{-1}\left((A * T)^{\mathrm{X}}\right)\right|}
$$

the sum sensitivity of the iso-transform-independent conditional stuffed historical probability distribution at the maximum likelihood estimate may be expected rather to vary against the derived alignment,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\right.\right. & \left.\left.\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \\
& \sim z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)-z_{\mathrm{o}} \times \operatorname{entropy}\left(\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{x}}\right) \\
& \approx-\operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
\end{aligned}
$$

So the sum sensitivity of the iso-transform-independent conditional stuffed historical probability distribution at the maximum likelihood estimate varies against the log likelihood of the iso-transform-independent conditional stuffed historical probability distribution at the maximum likelihood estimate,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) & \sim-\operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right) \\
& \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
\end{aligned}
$$

In the case of high relative entropy the sum sensitivity of the iso-derived conditional stuffed historical probability distribution is conjectured to vary with the unknown-known multinomial probability distribution sum sensitivity difference,

```
sum(sensitivity }(U)(\mp@subsup{\hat{Q}}{\textrm{h},\textrm{d},\mp@subsup{T}{\textrm{o}}{\prime},U}{}(\mp@subsup{A}{\textrm{o},\mp@subsup{z}{\textrm{h}}{}}{},\mp@subsup{z}{\textrm{o}}{})))
    \operatorname{sum}(\operatorname{sensitivity}(U)(\mp@subsup{\hat{Q}}{\textrm{m},U}{}(\mp@subsup{A}{\textrm{o}}{},\mp@subsup{z}{\textrm{o}}{})))-\operatorname{sum}(\operatorname{sensitivity}(U)(\mp@subsup{\hat{Q}}{\textrm{m},U}{}(\mp@subsup{A}{\textrm{o}}{}*\mp@subsup{T}{\textrm{o}}{},\mp@subsup{z}{\textrm{o}}{})))
```

so the sum sensitivity of the iso-transform-independent conditional stuffed historical probability distribution is also conjectured to vary with the unknownknown multinomial probability distribution sum sensitivity difference,

$$
\begin{aligned}
& \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim \\
& \quad \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}\left(A_{\mathrm{o}}, z_{\mathrm{o}}\right)\right)\right)-\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{m}, U}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, z_{\mathrm{o}}\right)\right)\right)
\end{aligned}
$$

the sum sensitivity of the iso-transform-independent conditional stuffed historical probability distribution at the maximum likelihood estimate is less than or equal to the sum sensitivity of the stuffed historical probability distribution at the maximum likelihood estimate,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\right.\right. & \left.\left.\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \\
\leq & \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right)
\end{aligned}
$$

and the log likelihood of the iso-transform-independent conditional stuffed historical probability distribution at the maximum likelihood estimate is greater than or equal to the log likelihood of the stuffed historical probability distribution at the maximum likelihood estimate,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z\right)\left(A_{\mathrm{o}}\right) \geq \ln \hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z\right)\left(A_{\mathrm{o}}\right)
$$

That is, in the case where (i) the sample is ideal, (ii) the sample formal equals the sample abstract, and (iii) the relative entropy is high, as the derived alignment increases, (a) the log-likelihood increases and (b) the underlying-derived sum sensitivity difference decreases.

If, in addition, the size is less than the volume, $z_{\mathrm{o}}<v_{\mathrm{o}}$, then the log likelihood varies with the scaled component size cardinality relative entropy,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim z_{\mathrm{o}} \times \text { entropyRelative }\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)
$$

and varies against the specialising derived substrate history coder space,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\operatorname{space}\left(C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)\left(H_{\mathrm{o}}\right)
$$

where
$C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}(T)=\operatorname{coderHistorySubstrateDerivedSpecialising}\left(U, X, T, D_{\mathrm{S}}, D_{\mathrm{X}}\right)$
Note that this correlation is conjectured to be weaker than that of classical modelled induction,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\operatorname{space}\left(C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)\left(H_{\mathrm{o}}\right)
$$

because the expected component entropy of the idealisation is less than or equal to that of the naturalisation.

Also note that, in the case where the size is less than the volume, $z_{0}<v_{0}$, the integral idealisation can be exactly equal to the sample, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, but the integral naturalisation cannot, $A_{\mathrm{o}} \approx A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$.

The iso-transform-independent conditional stuffed historical probability distribution log-likelihood is maximised and the specialising derived substrate history coder space is minimised by varying the transform such that (i) the derived entropy is low, (ii) the possible derived volume is small, (iii) the underlying components have high entropy and (iv) high counts are in low cardinality components and high cardinality components have low counts.

In the high relative entropy case, entropy $\operatorname{Cross}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)>\ln \left|T_{\mathrm{o}}^{-1}\right|$, the sum sensitivity varies against the log-likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

In the case where the size is less than the volume, $z_{0}<v_{\mathrm{o}}$, the sensitivity to model also varies against the log likelihood,
$-\ln \mid \max \left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{y}, T, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{o}}\right.\right.$,

$$
\begin{aligned}
\left.\left.A_{\mathrm{o}}^{\mathrm{X}} * T=\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}, A_{\mathrm{o}} \approx A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}}\right\}\right) \mid & \sim \\
& -\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}} U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
\end{aligned}
$$

and the log-likelihood varies with its degree of structure with respect to the expanded specialising derived history coder, $C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}$,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{structure}(U, X)\left(P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{\mathrm{o}}}, C_{\mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)
$$

Although (i) it cannot be assumed that the application of the query via the model of the sample is equal to the query via the model of the distribution, $\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right) \neq\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * E_{\mathrm{h}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)$, and (ii) the query via the model of the sample, $\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash\right.$ $K$ ), cannot be expressed in terms of the iso-transform-independent conditional stuffed historical probability distribution at the scaled ideal sample, $\hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)$, in the case where the sample is ideal and the sample formal equals the sample abstract the maximum likelihood estimate approximates to the normalised sample derived,

$$
\tilde{E}_{\mathrm{o}} * T_{\mathrm{o}} \approx \hat{A}_{\mathrm{o}} * T_{\mathrm{o}}
$$

and so queries via the model of the sample approximate to queries via the model of the distribution,

$$
\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right) \approx\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * E_{\mathrm{h}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)
$$

So it may be conjectured that (a) the query sensitivity to the distribution histogram varies as the iso-transform-independent sum sensitivity divided by the size

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}}
$$

(b) although the query application via the model is sometimes not equal to the estimated transformed conditional product, the query sensitivity to the distribution histogram is sometimes lower,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname { s e n s i t i v i t y } ( U ) \left(\hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}( \right.\right. & \left.\left.\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}} \\
& \leq \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}}
\end{aligned}
$$

and (c) the model likelihood of the distribution histogram is sometimes higher,

$$
\hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z\right)\left(A_{Q, N}\right) \geq \hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z\right)\left(A_{Q, N}\right)
$$

In other words, querying via the known derived of the model sometimes reduces the sensitivity to the unknown and increases the likelihood at the cost of modifying the query. Note that the degree to which this is case is lower in aligned modelled induction than it is in classical modelled induction.

Note that, although the added constraint of known ideal sample, $A_{\mathrm{o}}=$ $A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, can increase the resemblance to classical induction, the induction remains transform induction because the condition of necessary formal and necessary abstract has not changed and so neither the iso-set, $Y_{U, i, T_{\mathrm{o}}, z_{\mathrm{o}}}^{-1}\left(\left(\left(A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right),\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}\right)\right)$, nor the iso-derivedence have changed. That is, the maximum likelihood estimate, $\tilde{E}_{\mathrm{O}}$, does not move away from the transform-dependent, $\hat{A}_{\mathrm{o}}^{\mathrm{Y}\left(T_{\mathrm{o}}\right)}$, to the idealisation-dependent, $\hat{A}_{\mathrm{o}}^{\dagger\left(T_{\mathrm{o}}\right)}$, but rather both the maximum likelihood estimate and the transform-dependent move together towards the idealisation-dependent, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{Y}\left(T_{\mathrm{o}}\right)} \approx \hat{A}_{\mathrm{o}}^{\dagger\left(T_{\mathrm{o}}\right)}$, and so both the maximum likelihood estimate the transform-dependent move together towards the derived-dependent, $\tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}^{\mathrm{Y}\left(T_{\mathrm{o}}\right)} \approx \hat{A}_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)}$.

Note also that the assumption of high derived alignment, $\operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right) \gg 0$, is not well defined, although there is an upper bound, $\operatorname{algnMax}(U)\left(W_{\mathrm{o}}, z_{\mathrm{o}}\right)$. A more formal method of expression would be to say that the correlation between the iso-transform-independent conditional stuffed historical probability
distribution and the iso-derived conditional stuffed historical probability distribution is itself correlated to the derived alignment,

$$
\left[\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right] \sim \operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

More formal still would be to define this relation in terms of the correlations of functions of the sized cardinal substrate histograms, $\mathcal{A}_{z}$, given the renormalised geometry-weighted probability function, $\operatorname{corr}(z) \in\left(\mathcal{A}_{z} \rightarrow \mathbf{R}\right) \times\left(\mathcal{A}_{z} \rightarrow\right.$ $\mathbf{R}) \rightarrow \mathbf{R}$, as in section 'Substrate structures alignment', above.

Similarly, the assumption of intermediate underlying alignment, $0 \ll \operatorname{algn}\left(A_{\mathrm{o}}\right) \ll$ $\operatorname{algnMax}(U)\left(V_{\mathrm{o}}, z_{\mathrm{o}}\right)$, is also ill-defined. Note, however, that the two assumptions are linked. Intermediate underlying alignment tends to imply at least intermediate derived alignment, $0 \ll \operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)<\operatorname{algnMax}(U)\left(W_{\mathrm{o}}, z_{\mathrm{o}}\right)$, because the formal alignment is zero, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$. The relation is stronger as the transform tends to full functional.

In the discussion above, the model, $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, is known, and both the formal, $\hat{E}_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}}$, and the abstract, $\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, are necessary and known. Optimisation can be done to find the maximum likelihood estimate of the distribution histogram for known model,

$$
\left\{\tilde{E}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(E, \hat{Q}_{\mathrm{m}, \mathrm{y}, T_{\mathrm{o}}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): E \in \mathcal{A}_{U, V_{o}, 1}\right\}\right)
$$

Just as in the discussion above of classical modelled induction, consider the case where both the formal, $\hat{E}_{\mathrm{h}}^{\mathrm{X}} * T_{\mathrm{o}}$, and the abstract, $\left(\hat{E}_{\mathrm{h}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, are still necessary but the model, $T_{\mathrm{o}}$, is unknown and so both the formal and the abstract are unknown. Again, the maximum likelihood estimate for the pair ( $\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}$ ) can be defined as an optimisation of the multinomial probability conditional on the iso-transform-independents where both the distribution histogram and transform are treated as arguments to a likelihood function,

$$
\begin{aligned}
& \left\{\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right)\right\} \\
& \qquad=\operatorname{maxd}\left(\left\{\left((E, T), \frac{Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in \mathcal{A}_{U, i, \mathrm{y}, T, z_{o}}\left(A_{\mathrm{o}}\right)} Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)(B)}\right)\right.\right. \\
& \left.\left.\quad E \in \mathcal{A}_{U, V_{o}, 1}, T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
\end{aligned}
$$

It is conjectured that in transform induction there are some cases in which there is a unique solution for the pair ( $\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}$ ). This is because in entity-like induction, but not law-like induction, the denominator does not necessarily reduce to equal the numerator, so avoiding degeneracy. In the case where
there is a unique solution then the maximisation can be rewritten in terms of the transform-dependent,

$$
\left\{\tilde{T}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(T, \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}^{\mathrm{Y}(T)}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\left.\sum_{B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z_{\mathrm{o}}\left(A_{\mathrm{o}}\right)} Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}^{\mathrm{Y}}(T)\right.}, z_{\mathrm{o}}\right)(B)}\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

The maximum likelihood estimate for the model, $\tilde{T}_{\mathrm{o}}$, is sometimes not computable because the transform-dependent, $A_{\mathrm{o}}^{\mathrm{Y}\left(\tilde{T}_{\mathrm{o}}\right)}$, is sometimes not computable. A finite approximation to arbitrary accuracy for the transformdependent, $A_{k}^{\mathrm{Y}(T)} \approx A^{\mathrm{Y}(T)}$, is computable. However, even an approximation is not tractable. The formal-abstract pair valued function, $Y_{U, \mathbf{i}, T, z} \in$ $\mathcal{A}_{U, \mathrm{i}, V, z}: \rightarrow\left(\mathcal{A}_{U, W, z} \times \mathcal{A}_{U, W, z}\right)$, is intractable because its computation requires the intractable computation of its domain of the substrate histograms, $\mathcal{A}_{U, \mathrm{i}, V, z}$.

In transform induction, where the history probability function is iso-transformindependent historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{\mathrm{o}}}$, given some unknown substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{o}}$, in some cases the maximum likelihood estimate of the model, $\tilde{T}_{\mathrm{o}}$, at the maximum likelihood estimate of the distribution, $\tilde{E}_{\mathrm{o}}$, is non-trivial,

$$
\tilde{T}_{\mathrm{o}} \notin\left\{T_{\mathrm{s}}, T_{\mathrm{u}}\right\}
$$

Note that the optimisation is not the same as the optimisation of the iso-transform-independent conditional generalised multinomial probability,

$$
\operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{m}, \mathrm{y}, T, U}\left(A_{\mathrm{o}}^{\mathrm{Y}(T)}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

because the normalising factor, $1 /\left|\operatorname{ran}\left(Y_{U, \mathbf{i}, T, z_{0}}\right)\right|$, implies uniform possible induction rather than necessary induction. Recall that in classical induction the maximum likelihood estimate for the model in the necessary derived case is degenerate. Only in the uniform possible case are there non-trivial solutions. In abstract induction, however, there are non-trivial solutions where the condition is necessary abstract. In aligned induction, there are non-trivial solutions where the condition is necessary abstract and necessary formal.

Consider how an approximation to the optimisation may be made more tractable. It is conjectured in section 'Likely histograms', above, that the log-likelihood with respect to the dependent-analogue varies with the relative space with respect to the independent-analogue,

$$
\ln \frac{Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U}\left(A^{\mathrm{Y}(T)}, z\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z}(A)} \sim \operatorname{spaceRelative}\left(A^{\mathrm{X}(T)}\right)(A)
$$

and conjectured further in section 'Transform alignment', above, that the relative space with respect to the transform-independent varies with the derived alignment,

$$
\text { spaceRelative }\left(A^{\mathrm{X}(T)}\right)(A) \sim \operatorname{algn}(A * T)
$$

This correlation was decomposed in the discussion above into three separate correlations, (i) the dependent-independent anti-correlation, (ii) the underlying-lifted correlation and (iii) the conditional-relative correlation. Now consider how the optimisation of the terms of these relations may form the definition of induction assumptions.

The maximum likelihood estimate for the unknown model, $\tilde{T}_{\mathrm{o}}$, with respect to the dependent-analogue is

$$
\begin{aligned}
& \left\{\tilde{T}_{\mathrm{o}}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(T, \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}^{\mathrm{Y}(T)}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}^{\mathrm{Y}(T)}, z_{\mathrm{o}}\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)}\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
\end{aligned}
$$

First, given the dependent-independent anti-correlation, assume that the maximum likelihood estimate of the iso-transform-independent conditional multinomial probability with respect to the dependent-analogue or transform-dependent, $A_{\mathrm{o}}^{\mathrm{Y}(T)}$, is also the minimum likelihood estimate of the iso-transform-independent conditional multinomial probability with respect to the independent-analogue or transform-independent, $A_{\mathrm{o}}^{\mathrm{X}(T)}$,

$$
\begin{aligned}
& \left\{\tilde{T}_{\mathrm{o}}\right\}= \\
& \quad \operatorname{mind}\left(\left\{\left(T, \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}^{\mathrm{X}(T)}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}^{\mathrm{X}(T)}, z_{\mathrm{o}}\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)}\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
\end{aligned}
$$

This assumption is the iso-transform-independent dependent-independent antioptimisation assumption. It relies on the monotonicity of the dependentindependent anti-correlation.

Second, given the underlying-lifted correlation, assume that the minimum likelihood estimate of the iso-transform-independent conditional multinomial probability with respect to the independent-analogue or transform-independent, $A_{\mathrm{o}}^{\mathrm{X}(T)}$, is also the minimum likelihood estimate of the lifted iso-transformindependent conditional multinomial probability with respect to the lifted independent-analogue or transform-independent derived, $A_{\mathrm{o}}^{\mathrm{X}(T)} * T$,

$$
\left\{\tilde{T}_{0}\right\}=
$$

$$
\operatorname{mind}\left(\left\{\left(T, \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}^{\mathrm{X}(T)} * T, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}} * T\right)}{\sum Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}^{\mathrm{X}(T)} * T, z_{\mathrm{o}}\right)\left(B^{\prime}\right): B^{\prime} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z_{\mathrm{o}}}^{\prime}\left(A_{\mathrm{o}}\right)}\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

This assumption is the iso-transform-independent underlying-lifted optimisation assumption. It relies on the monotonicity of the underlying-lifted correlation.

Third, given the conditional-relative correlation, assume that the minimum likelihood estimate of the lifted iso-transform-independent conditional multinomial probability with respect to the lifted independent-analogue or transformindependent derived, $A_{\mathrm{o}}^{\mathrm{X}(T)} * T$, is also the minimum likelihood estimate of the relative multinomial probability with respect to the abstract, $\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}$,

$$
\left\{\tilde{T}_{\mathrm{o}}\right\}=\operatorname{mind}\left(\left\{\left(T, \frac{Q_{\mathrm{m}, U}\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{x}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}} * T\right)}{Q_{\mathrm{m}, U}\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}, z_{\mathrm{o}}\right)\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}\right)}\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

The negative logarithm of the relative multinomial probability is the relative space of the derived with respect to the abstract, which is the derived alignment,

$$
\begin{aligned}
-\ln \frac{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{x}}, z\right)(A * T)}{Q_{\mathrm{m}, U}\left((A * T)^{\mathrm{X}}, z\right)\left((A * T)^{\mathrm{X}}\right)} & =\operatorname{spaceRelative}\left((A * T)^{\mathrm{X}}\right)(A * T) \\
& =\operatorname{algn}(A * T)
\end{aligned}
$$

So the third assumption is that the minimum likelihood estimate of the lifted iso-transform-independent conditional multinomial probability with respect to the transform-independent derived, $A_{0}^{\mathrm{X}(T)} * T$, is also the maximum likelihood estimate for the derived alignment,

$$
\left\{\tilde{T}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(T, \operatorname{algn}\left(A_{\mathrm{o}} * T\right)\right): T \in \mathcal{T}_{U, V_{o}}\right\}\right)
$$

This assumption is the iso-transform-independent conditional-relative optimisation assumption. It relies on the monotonicity of the conditional-relative correlation.

A finite approximation to arbitrary accuracy of the derived alignment, $\operatorname{algn}\left(A_{0} *\right.$ $T$ ), is computable by means of an approximation to the gamma function. The computation of the derived alignment is tractable given limits on the derived volume, $\left|T^{-1}\right|$. So the optimisation of maximum likelihood estimate of the model, $\tilde{T}_{\mathrm{o}}$, at least for a limited subset of the substrate transforms, is tractable.

In transform induction, where (i) the history probability function is iso-transform-independent historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{o}}$, given some unknown substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{o}}$, if it is the case that (ii) the iso-transform-independent dependent-independent antioptimisation assumption is true, (iii) the iso-transform-independent underlyinglifted optimisation assumption is true, and (iv) the iso-transform-independent
conditional-relative optimisation assumption is true, then the maximum likelihood estimate of the model, $\tilde{T}_{\mathrm{o}}$, at the maximum likelihood estimate of the distribution, $\tilde{E}_{\mathrm{o}}$, is

$$
\left\{\tilde{T}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(T, \operatorname{algn}\left(A_{\mathrm{o}} * T\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

It is shown in the known transform case above that the maximum likelihood estimate is more classical and not formal if (i) the sample is idealised, (ii) the sample formal equals the sample abstract and (iii) the derived alignment is high. This is the case for unknown transform too. In fact, if the three iso-transform-independent optimisation assumptions are true, then the maximum likelihood estimate for the model, $\tilde{T}_{\mathrm{o}}$, occurs at the maximisation of the derived alignment, implying that the derived alignment is as high as possible, $\forall T \in \mathcal{T}_{U, V_{\mathrm{o}}}\left(\left(A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}}\right) \wedge\left(A_{\mathrm{o}}^{\mathrm{X}} * T=\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}\right) \Longrightarrow\right.$ $\left.\operatorname{algn}\left(A_{\mathrm{o}} * \tilde{T}_{\mathrm{o}}\right) \geq \operatorname{algn}\left(A_{\mathrm{o}} * T\right)\right)$.

Now the independent analogue, or transform-independent, equals the computable naturalised abstract,

$$
A^{\mathrm{x}} * T=(A * T)^{\mathrm{X}} \quad \Longrightarrow \quad A^{\mathrm{X}(T)}=(A * T)^{\mathrm{X}} * T^{\dagger}
$$

so the three optimisation assumptions are modified as follows:
The maximum likelihood estimate for the unknown model, $\tilde{T}_{\mathrm{o}}$, with respect to the dependent-analogue is

$$
\begin{aligned}
& \left\{\tilde{T}_{\mathrm{o}}\right\}= \\
& \qquad \operatorname{maxd}\left(\left\{\left(T, \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}^{\mathrm{Y}(T)}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}^{\mathrm{Y}(T)}, z_{\mathrm{o}}\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)}\right)\right.\right. \\
& \left.\left.\quad T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}}, A_{\mathrm{o}}^{\mathrm{X}} * T=\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}\right\}\right)
\end{aligned}
$$

First, given the dependent-independent anti-correlation, assume that the maximum likelihood estimate of the iso-transform-independent conditional multinomial probability with respect to the dependent-analogue or transform-dependent, $A_{\mathrm{o}}^{\mathrm{Y}(T)}$, is also the minimum likelihood estimate of the iso-transform-independent conditional multinomial probability with respect to the independent-analogue or naturalised abstract, $\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}} * T^{\dagger}$,

$$
\begin{aligned}
& \left\{\tilde{T}_{\mathrm{o}}\right\}= \\
& \quad \operatorname{mind}\left(\left\{\left(T, \frac{Q_{\mathrm{m}, U}\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}} * T^{\dagger}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum Q_{\mathrm{m}, U}\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{x}} * T^{\dagger}, z_{\mathrm{o}}\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)}\right)\right.\right. \\
& \left.\left.\quad T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}}, A_{\mathrm{o}}^{\mathrm{X}} * T=\left(A_{\mathrm{o}} * T\right)^{\mathrm{x}}\right\}\right)
\end{aligned}
$$

This assumption is the iso-transform-independent dependent-independent antioptimisation assumption. It relies on the monotonicity of the dependentindependent anti-correlation.

Second, given the underlying-lifted correlation, assume that the minimum likelihood estimate of the iso-transform-independent conditional multinomial probability with respect to the independent-analogue or transform-independent, $\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}} * T^{\dagger}$, is also the minimum likelihood estimate of the lifted iso-transform-independent conditional multinomial probability with respect to the lifted independent-analogue or abstract, $\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}$,

$$
\begin{aligned}
& \left\{\tilde{T}_{\mathrm{o}}\right\}= \\
& \quad \operatorname{mind}\left(\left\{\left(T, \frac{Q_{\mathrm{m}, U}\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{x}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}} * T\right)}{\sum Q_{\mathrm{m}, U}\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{x}}, z_{\mathrm{o}}\right)\left(B^{\prime}\right): B^{\prime} \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)}\right):\right.\right. \\
& \left.\left.\quad T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}}, A_{\mathrm{o}}^{\mathrm{X}} * T=\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}\right\}\right)
\end{aligned}
$$

This assumption is the iso-transform-independent underlying-lifted optimisation assumption. It relies on the monotonicity of the underlying-lifted correlation.

Third, given the conditional-relative correlation, assume that the minimum likelihood estimate of the lifted iso-transform-independent conditional multinomial probability with respect to the lifted independent-analogue or abstract, $\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}$, is also the minimum likelihood estimate of the relative multinomial probability with respect to the lifted independent-analogue or abstract, $\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}$,
$\left\{\tilde{T}_{0}\right\}=$

$$
\begin{aligned}
& \operatorname{mind}\left(\left\{\left(T, \frac{Q_{\mathrm{m}, U}\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{x}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}} * T\right)}{Q_{\mathrm{m}, U}\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}, z_{\mathrm{o}}\right)\left(\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}\right)}\right):\right.\right. \\
& \left.\left.\quad T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}}, A_{\mathrm{o}}^{\mathrm{X}} * T=\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}\right\}\right)
\end{aligned}
$$

So the third assumption is that the minimum likelihood estimate of the lifted iso-transform-independent conditional multinomial probability with respect to the abstract, $\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}$, is also the maximum likelihood estimate for the derived alignment,

$$
\begin{aligned}
&\left\{\tilde{T}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(T, \operatorname{algn}\left(A_{\mathrm{o}} * T\right)\right):\right.\right. \\
&\left.\left.T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}}, A_{\mathrm{o}}^{\mathrm{x}} * T=\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}\right\}\right)
\end{aligned}
$$

In transform induction, where (i) the history probability function is iso-transform-independent historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{\mathrm{o}}}$, given some
unknown substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{o}}$, if it is the case that (ii) the iso-transform-independent dependent-independent antioptimisation assumption is true, (iii) the iso-transform-independent underlyinglifted optimisation assumption is true, (iv) the iso-transform-independent conditional-relative optimisation assumption is true, (v) the sample is ideal, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, (vi) the sample formal equals the sample abstract, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, (vii) the alignment is at least intermediate, $\operatorname{algn}\left(A_{\mathrm{o}}\right)>$ $\operatorname{algnMax}(U)\left(V_{\mathrm{o}}, z_{\mathrm{o}}\right) / 2$, (viii) the distribution history size is large with respect to the sample size, $z_{\mathrm{h}} \gg z_{0}$, and such that (ix) the scaled estimate distribution histogram is integral, $\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}} \in \mathcal{A}_{\mathrm{i}}$, then (a) the maximum likelihood estimate of the model, $\tilde{T}_{\mathrm{o}}$, at the maximum likelihood estimate of the distribution, $\tilde{E}_{\mathrm{o}}$, is

$$
\begin{aligned}
& \left\{\tilde{T}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(T, \operatorname{algn}\left(A_{\mathrm{o}} * T\right)\right):\right.\right. \\
& \left.\left.\quad T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}}, A_{\mathrm{o}}^{\mathrm{X}} * T=\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}\right\}\right)
\end{aligned}
$$

(b) the log likelihood of the iso-transform-independent conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the derived alignment,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, \tilde{T}_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, \tilde{Z}_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

(c) the log likelihood of the iso-transform-independent conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the log likelihood of the iso-derived conditional stuffed historical probability distribution at the sample,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, \tilde{T}_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) & \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{t}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \\
& \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
\end{aligned}
$$

(d) so the log likelihood varies with the size-volume scaled component size cardinality sum relative entropy,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, \tilde{\mathcal{T}}_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) & \sim \\
\quad\left(z_{\mathrm{o}}+v_{\mathrm{o}}\right) \times \operatorname{entropy}\left(A_{\mathrm{o}}\right. & \left.* T_{\mathrm{o}}+V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right) \\
& -z_{\mathrm{o}} \times \operatorname{entropy}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)-v_{\mathrm{o}} \times \operatorname{entropy}\left(V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)
\end{aligned}
$$

(e) the formal alignment of the maximum likelihood estimate is zero,

$$
\begin{aligned}
\tilde{E}_{\mathrm{o}}^{\mathrm{x}} * \tilde{T}_{\mathrm{o}} & =\hat{A}_{\mathrm{o}}^{\mathrm{X}} * \tilde{T}_{\mathrm{o}} \\
& =\left(\tilde{A}_{\mathrm{o}}^{\mathrm{X}} * \tilde{T}_{\mathrm{o}}\right)^{\mathrm{x}} \\
& =\left(\tilde{E}_{\mathrm{o}}^{\mathrm{x}} * \tilde{T}_{\mathrm{o}}\right)^{\mathrm{X}}
\end{aligned}
$$

and (f) the derived of the maximum likelihood estimate approximates to the normalised sample derived,

$$
\tilde{E}_{\mathrm{o}} * \tilde{T}_{\mathrm{o}} \approx \hat{A}_{\mathrm{o}} * T_{\mathrm{o}}
$$

In this case queries via the model of the sample approximate to queries via the model of the distribution,

$$
\left(Q * \tilde{T}_{\mathrm{o}}^{\%} * \operatorname{his}\left(\tilde{T}_{\mathrm{o}}^{\%}\right) * A_{\mathrm{o}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right) \approx\left(Q * T_{\mathrm{o}}^{\%} * \operatorname{his}\left(T_{\mathrm{o}}^{\%}\right) * E_{\mathrm{h}}\right)^{\wedge} \%\left(V_{\mathrm{o}} \backslash K\right)
$$

That is, given unknown model where (i) the underlying alignment is intermediate, (ii) the sample is known to be ideal and (iii) the sample formal is known to be equal to the sample abstract, the maximisation of the derived alignment tends to make the properties of aligned modelled induction similar to those of classical modelled induction.

If, in addition, (x) the component size cardinality relative entropy of the maximum likelihood estimate for the model is high, entropy $\operatorname{Cross}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} *\right.$ $\left.T_{\mathrm{o}}\right)>\ln \left|T_{\mathrm{o}}^{-1}\right|$, then the sum sensitivity varies against the log-likelihood,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{y}, \tilde{T}_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) & \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \\
& \sim-\operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
\end{aligned}
$$

so the query sensitivity to the distribution histogram is sometimes lower,

$$
\begin{aligned}
\operatorname{sum}(\operatorname{sensitivity}(U)( & \hat{Q}_{\mathrm{h}, \mathrm{y}, \tilde{T}_{\mathrm{o}}, U}( \\
& \left.\left.\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}} \\
\leq & \operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) / z_{\mathrm{o}}
\end{aligned}
$$

and the model likelihood of the distribution histogram is sometimes higher,

$$
\hat{Q}_{\mathrm{h}, \mathrm{y}, \tilde{T}_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z\right)\left(A_{Q, N}\right) \geq \hat{Q}_{\mathrm{h}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z\right)\left(A_{Q, N}\right)
$$

If, further, (xi) the size is less than the volume, $z_{\mathrm{o}}<v_{\mathrm{o}}$, then the sensitivity to model also varies against the log likelihood,
$-\ln \mid \max \left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{y}, T, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right.\right.\right.$,

$$
\begin{aligned}
A_{\mathrm{o}}^{\mathrm{x}} * T=\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}, A_{\mathrm{o}}= & \left.\left.A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}}\right\}\right) \mid \\
& -\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
\end{aligned}
$$

or

$$
\begin{aligned}
-\ln \mid \max \left(\left\{\left(T, \operatorname{algn}\left(A_{\mathrm{o}} * T\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}},\right.\right. & \\
\left.\left.\qquad A_{\mathrm{o}}^{\mathrm{X}} * T=\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}, A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}}\right\}\right) \mid & \sim \\
& -\operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
\end{aligned}
$$

So (a) by weakening the induction condition from law-like necessary derived to entity-like necessary abstract, (b) by strengthening the induction condition with necessary formal and (c) by strengthening the constraints on the sample to be ideal and to have formal-abstract equivalence, it is found that in some cases the aligned modelled induction maximum likelihood estimate of the model is non-trivial, $\tilde{T}_{\mathrm{o}} \notin\left\{T_{\mathrm{s}}, T_{\mathrm{u}}\right\}$, but retains properties of classical modelled induction such as allowing query via the model, minimising sensitivity to the unknown underlying and minimising sensitivity to the model. Furthermore, the optimisation is tractable depending on the limits on the searched subset of the substrate transforms.

Now consider the definition of inducers in the light of the preceding discussion. The set of inducers is defined in section 'Tractable alignmentbounding', and reviewed in section 'Induction'. The inducers are computers $I_{z} \in \operatorname{inducers}(z) \subset$ computers such that (i) the domain is a set of substrate histograms which are at least a superset of the integral-independent substrate histograms, $\mathcal{A}_{z, \mathrm{xi}} \subseteq$ domain $\left(I_{z}\right) \subseteq \mathcal{A}_{z}$, (ii) the finite time and space application returns a rational-valued function of the substrate models set, $I_{z}^{*}(A) \in \mathcal{M}_{U_{A}, V_{A}} \rightarrow \mathbf{Q}$, and (iii) the maximum of the inducer application, $\operatorname{maxr} \circ I_{z}^{*}$, is positively correlated with the finite alignment-bounded iso-transform space ideal transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ I_{z}^{*}\right) \geq 0\right)
$$

where $\operatorname{cov}(z)(F, G):=\operatorname{covariance}\left(\hat{R}_{z}\right)(F, G)$ and the renormalised geometryweighted probability function is $\hat{R}_{z}=$ normalise $\left(\left\{\left(A, 1 /\left(\left|V_{A}\right|!\prod_{w \in V_{A}}\left|U_{A}(w)\right|!\right)\right)\right.\right.$ : $A \in \operatorname{dom}(F)\})$. The set of sized cardinal substrate histograms $\mathcal{A}_{z}$ is defined,

$$
\mathcal{A}_{z}=\left\{A: A \in \mathcal{A}_{\mathrm{c}} \cap \mathcal{A}_{\mathrm{i}}, \operatorname{size}(A)=z,\left|V_{A}\right| \leq z, A^{\mathrm{U}}=A^{\mathrm{XF}}=A^{\mathrm{C}}\right\}
$$

where $A^{\mathrm{CS}}=\operatorname{cartesian}\left(U_{A}\right)\left(V_{A}\right)$ and $U_{A}=\operatorname{implied}(\operatorname{implied}(A))$ and $V_{A}=$ $\operatorname{vars}(A)$. The set of integral-independent substrate histograms $\mathcal{A}_{z, \mathrm{xi}}$ is defined,

$$
\mathcal{A}_{z, \mathrm{xi}}=\left\{A: A \in \mathcal{A}_{z}, A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}\right\}
$$

The independent-sample-distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate ideal formal-abstract transform search set, also known as the alignment-bounded iso-transform space ideal transform search set, is defined $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}} \in \mathcal{A}_{z, \mathrm{xi}} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow\right.$
$\left.\ln \mathrm{Q}_{>0}\right)$ as

$$
\begin{aligned}
& X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)= \\
& \left\{\left(T,-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(A)}{\sum \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(B): B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)}\right)\right. \\
& \left.\quad T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}
\end{aligned}
$$

The maximum likelihood estimate for the model is,

$$
\begin{aligned}
\{\tilde{T}\}= & \operatorname{maxd}\left(X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)\right) \\
= & \operatorname{mind}\left(\left\{\left(T, e^{-x}\right):(T, x) \in X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}(A)\right\}\right) \\
= & \operatorname{mind}\left(\left\{\left(T, \frac{Q_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(A)}{\sum Q_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(B): B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)}\right):\right.\right. \\
& \left.\left.\quad T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}\right)
\end{aligned}
$$

This may be compared to the case in aligned modelled induction where the iso-transform-independent dependent-independent anti-optimisation assumption is true, the histogram is ideal, $A=A * T * T^{\dagger A}$, and the formal equals the abstract, $A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}$,

$$
\begin{aligned}
& \{\tilde{T}\}= \\
& \quad \operatorname{mind}\left(\left\{\left(T, \frac{Q_{\mathrm{m}, U_{A}}\left((A * T)^{\mathrm{x}} * T^{\dagger}, z\right)(A)}{\sum Q_{\mathrm{m}, U_{A}}\left((A * T)^{\mathrm{X}} * T^{\dagger}, z\right)(B): B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)}\right):\right.\right. \\
& \\
& \left.\left.\quad T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}\right)
\end{aligned}
$$

The independent-analogue is the naturalised abstract which equals the naturalised formal, $(A * T)^{\mathrm{X}} * T^{\dagger}=A^{\mathrm{X}} * T * T^{\dagger}$. As the transform, $T$, tends to full functional, $T_{\mathrm{f}}=\left\{\{w\}^{\mathrm{CS}\{ \} V_{A} \mathrm{~T}}: w \in V_{A}\right\}^{\mathrm{T}}$, the naturalised abstract tends to the independent, $\left(A * T_{\mathrm{f}}\right)^{\mathrm{X}} * T_{\mathrm{f}}^{\dagger}=A^{\mathrm{X}} * T_{\mathrm{f}} * T_{\mathrm{f}}^{\dagger}=A^{\mathrm{X}}$. This suggests a revised definition of inducers. The naturalised-abstract-sample-distributed iso-transform-independent conditional dependent multinomial space integralindependent substrate ideal formal-abstract transform search set, is defined $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{yx}, \mathrm{fa}, \mathrm{j}} \in \mathcal{A}_{z, \mathrm{xi}} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow \ln \mathrm{Q}_{>0}\right)$ as

$$
\begin{aligned}
& X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{yx}, \mathrm{fa}, \mathrm{j}}(A)= \\
& \begin{aligned}
\left\{\left(T,-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left((A * T)^{\mathrm{x}} * T^{\dagger}, z\right)(A)}{\sum \hat{Q}_{\mathrm{m}, U_{A}}\left((A * T)^{\mathrm{x}} * T^{\dagger}, z\right)(B): B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)}\right)\right.
\end{aligned} \\
& \left.\quad T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}
\end{aligned}
$$

Here the independent, $A^{\mathrm{X}}$, is replaced by the independent-analogue, which is the naturalised abstract, $(A * T)^{\mathrm{X}} * T^{\dagger}$, so the numerator is no longer constant,
$\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}}, z\right)(A)$, but depends on the model, $\hat{Q}_{\mathrm{m}, U_{A}}\left((A * T)^{\mathrm{X}} * T^{\dagger}, z\right)(A)$. In this revised definition of inducers, which is more consistent with ideal formalabstract aligned induction, the maximum of the inducer application, maxro $I_{z}^{*}$, is instead constrained to be positively correlated with the finite naturalised-abstract-sample-distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate ideal formal-abstract transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{yx}, \mathrm{f}, \mathrm{j},}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{x}, \mathrm{~T}, \mathrm{yx}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ I_{z}^{*}\right) \geq 0\right)
$$

In section 'Substrate structures alignment', above, it is conjectured that the alignment-bounded iso-transform space ideal transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}$, is correlated with the derived alignment integralindependent substrate ideal formal-abstract transform maximum function, $\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j},}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}\right) \geq 0\right)
$$

where the derived alignment integral-independent substrate ideal formal-abstract transform search set is defined,

$$
\begin{aligned}
X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}(A)= & \{(T, \operatorname{algn}(A * T)): \\
& \left.T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{x}} * T=(A * T)^{\mathrm{x}}, A=A * T * T^{\dagger A}\right\}
\end{aligned}
$$

As shown above, in 'Derived alignment and conditional probability', given the minimum alignment conjecture, the alignment-bounded lifted iso-transform space is bounded

$$
\begin{aligned}
& \leq\left(-\ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{x}} * T, z\right)(A * T)}{\sum \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{X}} * T, z\right)\left(B^{\prime}\right): B^{\prime} \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)}:\right. \\
& \left.\qquad A^{\mathrm{x}} \in \mathcal{A}_{\mathrm{i}}, A^{\mathrm{x}} * T=(A * T)^{\mathrm{x}}\right) \\
& \leq \operatorname{algn}(A * T)+\ln \left|\mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}^{\prime}(A)\right|
\end{aligned}
$$

The alignment-bounded iso-transform space is functionally related to the alignment-bounded lifted iso-transform space, although it is not always the case that the alignment-bounded iso-transform space is bounded by the derived alignment, algn $(A * T)$, so, strictly speaking, it is a misnomer. The correlation between the alignment-bounded iso-transform space ideal transform
maximum function, maxr $\circ X_{z, \mathrm{x}, \mathrm{T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}$, and the derived alignment integralindependent substrate ideal formal-abstract transform maximum function, $\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}$, is conjectured nonetheless.

Similarly, for the revised definition of inducers, conjecture that the naturalised-abstract-sample-distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate ideal formal-abstract transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{yx}, \mathrm{fa}, \mathrm{j}}$, is also correlated with the derived alignment integral-independent substrate ideal formal-abstract transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{f}, \mathrm{j},}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{yx}, \mathrm{f}, \mathrm{j},}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}\right) \geq 0\right)
$$

It is not obvious, however, whether this correlation is greater than that for the existing inducer definition,

$$
\begin{aligned}
\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{yx}, \mathrm{fa}, \mathrm{j}}\right. & \left.\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}\right) \geq \\
& \operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j},}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}\right)
\end{aligned}
$$

It is possible to go a step further and drop the iso-transform-independent dependent-independent anti-optimisation assumption. Now the maximum likelihood estimate for the unknown model, $\tilde{T}$, is with respect to the dependentanalogue, which is the transform-dependent, $A^{\mathrm{Y}(T)}$,

$$
\begin{aligned}
& \{\tilde{T}\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(T, \frac{Q_{\mathrm{m}, U_{A}}\left(A^{\mathrm{Y}(T)}, z\right)(A)}{\sum Q_{\mathrm{m}, U_{A}}\left(A^{\mathrm{Y}(T)}, z\right)(B): B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)}\right)\right.\right. \\
& \left.\left.\quad T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}\right)
\end{aligned}
$$

The corresponding transform-dependent-sample-distributed iso transform independent conditional dependent multinomial space integral-independent substrate ideal formal-abstract transform search set, is defined $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}} \in$ $\mathcal{A}_{z, \mathrm{xi}} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow \ln \mathrm{Q}_{>0}\right)$ as

$$
\begin{aligned}
& X_{z, \mathrm{xi}, T, \mathrm{yy}, \mathrm{fa}, \mathrm{j}}(A)= \\
& \qquad \begin{array}{l}
\left\{\left(T, \ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{Y}(T)}, z\right)(A)}{\sum \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{Y}(T)}, z\right)(B): B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)}\right)\right. \\
\left.\quad T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}
\end{array}
\end{aligned}
$$

In this further revision of the definition of inducers, the maximum of the inducer application, maxr $\circ I_{z}^{*}$, is constrained to be positively correlated
with the transform-dependent-sample-distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate ideal formal-abstract transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ I_{z}^{*}\right) \geq 0\right)
$$

Again, for the further revision of the definition of inducers, conjecture that the transform-dependent-sample-distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate ideal formal abstract transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}}$, is also correlated with the derived alignment integral-independent substrate ideal formalabstract transform maximum function, maxr $\circ X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{yy}, \mathrm{fa}, \mathrm{j},}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}\right) \geq 0\right)
$$

Conjecture, however, that the dependent-analogue correlation is less than that for the independent-analogue,

$$
\begin{aligned}
\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}},\right. & \left.\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}\right) \leq \\
& \operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{yx}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{a}, \mathrm{fa}, \mathrm{j}}^{\prime}\right)
\end{aligned}
$$

Note that the transform-dependent, $A^{\mathrm{Y}(T)}$, is sometimes not computable. The finite approximation to the transform-dependent is

$$
\begin{aligned}
& \left\{A_{k}^{\mathrm{Y}(T)}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(D / Z_{k}, \frac{Q_{\mathrm{m}, U_{A}}(D, z)(A)}{\sum Q_{\mathrm{m}, U_{A}}(D, z)(B): B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)}\right): D \in \mathcal{A}_{U_{A}, \mathrm{i}, V_{A}, k z}\right\}\right)
\end{aligned}
$$

A literal finite approximation for an inducer for the transform-dependent-sample-distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate ideal formal-abstract transform search set, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}}(A)$, requires the finite approximation to the transform-dependent, $A_{k}^{\mathrm{Y}(T)}$. Define the finite transform-dependent-sample-distributed iso-transformindependent conditional dependent multinomial space integral-independent substrate ideal formal-abstract transform search set,

$$
\begin{aligned}
& X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}, k}(A)= \\
& \qquad \begin{array}{l}
\left\{\left(T, \ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A_{k}^{\mathrm{Y}(T)}, z\right)(A)}{\sum \hat{Q}_{\mathrm{m}, U_{A}}\left(A_{k}^{\mathrm{Y}(T)}, z\right)(B): B \in \mathcal{A}_{U_{A}, \mathrm{i}, \mathrm{y}, T, z}(A)}\right)\right. \\
\left.\quad T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}
\end{array}
\end{aligned}
$$

Let the literal finite transform-dependent-sample-distributed iso-transformindependent conditional dependent multinomial space ideal formal-abstract
transform inducer $I_{z, \mathrm{yy}, \mathrm{l}, k} \in \operatorname{inducers}(z)$ be a literal implementation of the transform-dependent-sample-distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate ideal formal abstract transform search set, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}, k} \in \mathcal{A}_{z, \mathrm{xi}} \rightarrow\left(\mathcal{T}_{\mathrm{f}} \rightarrow \ln \mathrm{Q}_{>0}\right)$,

$$
\forall A \in \mathcal{A}_{z, \mathrm{xi}}\left(I_{z, \mathrm{yy}, \mathrm{l}, k}^{*}(A)=\left\{\left(T, I_{\approx \ln \mathbf{Q}}^{*}(y)\right):(T, y) \in X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}, k}(A)\right\}\right)
$$

In ideal formal-abstract transform induction the maximum likelihood estimate for the unknown model, $\tilde{T}_{\mathrm{o}}$, with respect to the dependent-analogue is

$$
\begin{aligned}
& \left\{\tilde{T}_{\mathrm{o}}\right\}= \\
& \qquad \operatorname{maxd}\left(\left\{\left(T, \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}^{\mathrm{Y}(T)}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum Q_{\mathrm{m}, U}\left(A_{\mathrm{o}}^{\mathrm{Y}(T)}, z_{\mathrm{o}}\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, T, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)}\right)\right.\right. \\
& \left.\left.\quad T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}}, A_{\mathrm{o}}^{\mathrm{X}} * T=\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}\right\}\right)
\end{aligned}
$$

The computation of the dependent-analogue, $A^{\mathrm{Y}(T)}$, is sometimes incomputable, but even with a computable approximation, $A_{k}^{\mathrm{Y}(T)}$, in the literal $f$ nite transform-dependent-sample-distributed iso-transform-independent conditional dependent multinomial space ideal formal-abstract transform inducer, $I_{z, \mathrm{yy}, 1, k}$,

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(I_{z_{\mathrm{o}}, \mathrm{yy}, 1, k}^{*}\left(A_{\mathrm{o}}\right)\right)
$$

in the case where $A_{\mathrm{o}} \in \mathcal{A}_{z_{0}, \mathrm{x}}$, the computation of the maximum likelihood estimate for the unknown model, $\tilde{T}_{\mathrm{o}}$, remains intractable.

The literal derived alignment integral-independent substrate ideal formal abstract transform inducer $I_{z, \mathrm{a}, 1}^{\prime} \in \operatorname{inducers}(z)$ is a literal finite approximation to the derived alignment integral-independent substrate ideal formal-abstract transform search set, $X_{z, \mathrm{xi}, \mathrm{T}, \mathrm{a}, \mathrm{f}, \mathrm{j}}^{\prime}(A)$,

$$
\begin{aligned}
I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}(A)= & \left\{\left(T, I_{\approx \ln \mathbf{Q}}^{*}(\operatorname{algn}(A * T))\right):\right. \\
& \left.T \in \mathcal{T}_{U_{A}, V_{A}}, A^{\mathrm{X}} * T=(A * T)^{\mathrm{X}}, A=A * T * T^{\dagger A}\right\}
\end{aligned}
$$

The induction correlation of the literal derived alignment inducer is conjectured to be positive, regardless of the definition of inducers,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime *}\right) \geq 0\right)
$$

and

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ I_{z, \mathrm{a}, 1}^{\prime *}\right) \geq 0\right)
$$

and

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{yy}, \mathrm{fa}, \mathrm{j},}, \operatorname{maxr} \circ I_{z, \mathrm{a}, \mathrm{l}}^{\prime}\right) \geq 0\right)
$$

Although the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$, is faster than the literal finite transform-dependent-sample-distributed iso-transform-independent conditional dependent multinomial space ideal formal-abstract transform inducer, $I_{z, \mathrm{yy}, \mathrm{l}, k}$, it is also intractable unless some limits are imposed on the substrate models.

Section 'Tractable alignment-bounding' discusses the various intractabilities and the classes of limits and constraints on the structures of more tractable inducers. There the tractable limited-models summed alignment valencydensity substrate aligned non-overlapping infinite-layer fud decomposition inducer is defined as an inducer,

$$
I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime} \in \operatorname{inducers}(z)
$$

Given non-independent substrate histogram $A \in \mathcal{A}_{z} \backslash\left\{A^{\mathrm{X}}\right\}$, the midising, idealising fud decomposition inducer is defined,

$$
\begin{aligned}
& I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}(A)= \\
& \quad\left\{\left(D, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algnValDensSum}\left(U_{A}\right)\left(A, D^{\mathrm{D}}\right)\right)\right):\right. \\
& \quad D \in \mathcal{D}_{\mathrm{F}, \infty, U_{A}, V_{A}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathbf{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right), \\
& \left.\quad \forall(C, F) \in \operatorname{cont}(D)\left(\operatorname{algn}\left(A * C * F^{\mathrm{T}}\right)>0\right)\right\}
\end{aligned}
$$

where (i) the limited-models fuds, $\mathcal{F}_{\mathrm{q}}$ is the intersection of limited-breadth, limited-layer, limited-underlying and limited-derived fuds, $\mathcal{F}_{\mathrm{q}}=\mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{d}} \cap$ $\mathcal{F}_{\mathrm{h}} \cap \mathcal{F}_{\mathrm{b}}$, (ii) cont $(D)=\operatorname{elements}(\operatorname{contingents}(D))$, (iii) ()$^{\mathrm{D}} \in \mathcal{D}_{\mathrm{F}} \rightarrow \mathcal{D}$, and (iv) the summed derived alignment valency density algnValDensSum $(U) \in$ $\mathcal{A} \times \mathcal{D} \rightarrow \mathbf{R}$ is defined as

$$
\begin{aligned}
& \operatorname{algnValDensSum}(U)(A, D):= \\
& \qquad \sum_{(C, T) \in \operatorname{cont}(D)} \operatorname{algn}(A * C * T) / \text { capacityValency }(U)\left((A * C * T)^{\mathrm{FS}}\right)
\end{aligned}
$$

The maximum of the fud decomposition, $\max \left(I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}(A)\right)$, is obtained by searching for the fud decomposition $D \in \mathcal{D}_{\mathrm{F}}$ which maximises the summed alignment valency-density,

$$
\operatorname{algnValDensSum}(U)\left(A, D^{\mathrm{D}}\right)=\sum_{(C, F) \in \operatorname{cont}(D)} \operatorname{algn}\left(A * C * F^{\mathrm{T}}\right) / w_{F}^{1 / m_{F}}
$$

where $W_{F}=\operatorname{der}(F), w_{F}=\left|W_{F}^{\mathrm{C}}\right|$ and $m_{F}=\left|W_{F}\right|$.
Section 'Tractable alignment-bounding' shows that the limited-models summed alignment valency-density substrate aligned non-overlapping infinite-layer fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is tractable in all respects. There is a summary of the removal of intractabilities in section 'Inducers'.

It is conjectured that the summed alignment valency-density decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is positively correlated with the literal derived alignment inducer, $I_{z, \mathrm{a}, 1}^{\prime}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{a}, 1}^{\prime *}, \operatorname{maxr} \circ I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}\right) \geq 0\right)
$$

So the summed alignment inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is also positively correlated with the literal finite transform-dependent-sample-distributed iso-transformindependent conditional dependent multinomial space ideal formal-abstract transform inducer, $I_{z, \mathrm{yy}, 1, k}$,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ I_{z, \mathrm{yy}, \mathrm{l}, k}^{*}, \operatorname{maxr} \circ I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}\right) \geq 0\right)
$$

and positively correlated with the finite transform-dependent-sample distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate ideal formal-abstract transform search set,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}, k}, \operatorname{maxr} \circ I_{z, \mathrm{~S}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}\right) \geq 0\right)
$$

Conjecture that, in the case where the model, $T_{\mathrm{o}}$, is unknown, the maximum likelihood estimate for the model for transform induction,

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(I_{z_{\mathrm{o}}, \mathrm{yy}, 1, k}^{*}\left(A_{\mathrm{o}}\right)\right)
$$

can be tractably approximated by the maximisation of the tractable limitedmodels summed alignment valency-density substrate aligned non-overlapping infinite-layer fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$,

$$
\tilde{T}_{\mathrm{o}} \approx D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}
$$

where

$$
D_{\mathrm{o}, \mathrm{Sd}} \in \operatorname{maxd}\left(I_{z_{\mathrm{o}}, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}\left(A_{\mathrm{o}}\right)\right)
$$

and $A_{\mathrm{o}} \neq A_{\mathrm{o}}^{\mathrm{X}}$. The tractable model, $D_{\mathrm{o}, \mathrm{Sd}}$, is defined explicitly,

$$
\begin{aligned}
& D_{\mathrm{o}, \mathrm{Sd}} \in \operatorname{maxd}\left(\left\{\left(D, I_{\approx \mathbf{R}}^{*}\left(\operatorname{algnValDensSum}(U)\left(A_{\mathrm{o}}, D^{\mathrm{D}}\right)\right)\right):\right.\right. \\
& \quad D \in \mathcal{D}_{\mathrm{F}, \infty, U, V_{\mathrm{o}}} \cap \operatorname{trees}\left(\mathcal{S} \times\left(\mathcal{F}_{\mathrm{n}} \cap \mathcal{F}_{\mathrm{q}}\right)\right), \\
& \left.\left.\forall(C, F) \in \operatorname{cont}(D)\left(\operatorname{algn}\left(A_{\mathrm{o}} * C * F^{\mathrm{T}}\right)>0\right)\right\}\right)
\end{aligned}
$$

The accuracy of the approximation can be defined as the ratio of the tractable model transform likelihood to the maximum model transform likelihood,

$$
0<\frac{\exp \left(X_{z_{\mathrm{o}}, \mathrm{xi}, \mathrm{~T}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}, k}\left(A_{\mathrm{o}}\right)\left(D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}\right)\right)}{\exp \left(X_{z_{\mathrm{o}}, \mathrm{xi}, \mathrm{~T}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}, k}\left(A_{\mathrm{o}}\right)\left(\tilde{T}_{\mathrm{o}}\right)\right)} \leq 1
$$

or, in terms of the literal inducer,

$$
0<\frac{I_{\text {exp }}^{*}\left(I_{z_{o}, y \mathrm{y}, \mathrm{l}, k}^{*}\left(A_{\mathrm{o}}\right)\left(D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}\right)\right)}{I_{\mathrm{exp}}^{*}\left(I_{z_{0}, \mathrm{yy}, \mathrm{l}, k}^{*}\left(A_{\mathrm{o}}\right)\left(\tilde{T}_{\mathrm{o}}\right)\right)} \leq 1
$$

The accuracy is defined explicitly,

$$
\begin{aligned}
& \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}, k}^{\mathrm{Y}\left(D_{\mathrm{osd}}^{\mathrm{T}}\right)}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum Q_{\mathrm{m}, U}\left(A_{\mathrm{o}, k}^{\mathrm{Y}\left(D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}\right)}, z_{\mathrm{o}}\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, D_{\mathrm{o}, \mathrm{Sd}}, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)} \\
& / \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}, k}^{\mathrm{Y}\left(\tilde{T}_{\mathrm{o}}\right)}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum Q_{\mathrm{m}, U}\left(A_{\mathrm{o}, k}^{\mathrm{Y}\left(\tilde{T}_{\mathrm{o}}\right)}, z_{\mathrm{o}}\right)(B): B \in \mathcal{A}_{U, \mathrm{i}, \mathrm{y}, \tilde{T}_{\mathrm{o}}, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)}
\end{aligned}
$$

The accuracy is computable, though not tractable and so not necessarily practicable.

In the case where (i) the iso-transform-independent dependent-independent anti-optimisation assumption is true, (ii) the iso-transform-independent underlying lifted optimisation assumption is true, and (iii) the iso-transformindependent conditional-relative optimisation assumption is true, then the maximum likelihood estimate for the model can be obtained from the literal derived alignment inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$,

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(I_{z_{0}, \mathrm{a}, \mathrm{l}}^{\prime *}\left(A_{\mathrm{o}}\right)\right)
$$

and a definition of accuracy can be made in terms of derived alignment,

$$
\frac{I_{\text {exp }}^{*}\left(I_{z_{0}^{\prime}, \mathrm{a}, 1}^{\prime *}\left(A_{\mathrm{o}}\right)\left(D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}\right)\right)}{I_{\text {exp }}^{*}\left(I_{z o, a, l}^{\prime *}\left(A_{\mathrm{o}}\right)\left(\tilde{T}_{\mathrm{o}}\right)\right)}=\frac{I_{\text {exp }}^{*}\left(I_{\mathrm{a}}^{*}\left(A_{\mathrm{o}} * D_{\mathrm{o}}^{\mathrm{T}}{ }_{\mathrm{odd}}\right)\right)}{I_{\text {exp }}^{*}\left(I_{\mathrm{a}}^{*}\left(A_{\mathrm{o}} * \tilde{T}_{\mathrm{o}}\right)\right)}
$$

In the case of integral independent, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, the exponential of the alignment is rational, $\exp (\operatorname{algn}(A)) \in \mathbf{Q}_{\geq 0}$, and there is no need for numeric approximation. In this case, the derived alignment accuracy is the exponential of the difference in derived alignments,

$$
0<\frac{\exp \left(\operatorname{algn}\left(A_{\mathrm{o}} * D_{\mathrm{o} \text { Sd }}^{\mathrm{T}}\right)\right)}{\exp \left(\operatorname{algn}\left(A_{\mathrm{o}} * \tilde{T}_{\mathrm{o}}\right)\right)} \leq 1
$$

This definition of accuracy is consistent with the gradient of the likelihood function at the mode, so the derived alignment accuracy varies against the sensitivity to model,

$$
\begin{aligned}
& \frac{\exp \left(\operatorname{algn}\left(A_{\mathrm{o}} * D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}\right)\right)}{\exp \left(\operatorname{algn}\left(A_{\mathrm{o}} * \tilde{T}_{\mathrm{o}}\right)\right)} \sim \\
& \quad-\left(-\ln \mid \max \left(\left\{\left(T, \operatorname{algn}\left(A_{\mathrm{o}} * T\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}},\right.\right.\right. \\
& \left.\left.\left.\quad A_{\mathrm{o}}^{\mathrm{X}} * T=\left(A_{\mathrm{o}} * T\right)^{\mathrm{X}}, A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}}\right\}\right) \mid\right)
\end{aligned}
$$

If the alignment is at least intermediate, $\operatorname{algn}\left(A_{\mathrm{o}}\right)>\operatorname{algnMax}(U)\left(V_{\mathrm{o}}, z_{\mathrm{o}}\right) / 2$, then the log likelihood of the iso-transform-independent conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the log likelihood of the iso-derived conditional stuffed historical probability distribution at the sample,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, \tilde{T}_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) & \sim \ln \hat{Q}_{\mathrm{h}, \uparrow, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \\
& \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
\end{aligned}
$$

If, in addition, the component size cardinality relative entropy of the maximum likelihood estimate for the model is high, entropyCross $\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} *\right.$ $\left.T_{\mathrm{o}}\right)>\ln \left|T_{\mathrm{o}}^{-1}\right|$, then the sum sensitivity varies against the log-likelihood,

$$
\begin{aligned}
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{y}, \tilde{T}_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) & \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \\
& \sim-\operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
\end{aligned}
$$

If, further, the size is less than the volume, $z_{0}<v_{0}$, then the sensitivity to model also varies against the log likelihood,
$-\ln \mid \max \left(\left\{\left(T, \operatorname{algn}\left(A_{\mathrm{o}} * T\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right.\right.$,

$$
\begin{aligned}
A_{\mathrm{o}}^{\mathrm{x}} * T=\left(A_{\mathrm{o}} * T\right)^{\mathrm{x}}, A_{\mathrm{o}}= & \left.\left.A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}}\right\}\right) \mid \\
& \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \\
& \sim-\operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
\end{aligned}
$$

So, although the maximum model derived alignment, $\operatorname{algn}\left(A_{\mathrm{o}} * \tilde{T}_{\mathrm{o}}\right)$, appears in the denominator of the derived alignment accuracy, the tractable model accuracy in fact varies with the derived alignment,

$$
\frac{\exp \left(\operatorname{algn}\left(A_{\mathrm{o}} * D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}\right)\right)}{\exp \left(\operatorname{algn}\left(A_{\mathrm{o}} * \tilde{T}_{\mathrm{o}}\right)\right)} \sim \operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

or

$$
\operatorname{algn}\left(A_{\mathrm{o}} * D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}\right)-\operatorname{algn}\left(A_{\mathrm{o}} * \tilde{T}_{\mathrm{o}}\right) \sim \operatorname{algn}\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)
$$

That is, although the model obtained from the tractable summed alignment valency-density inducer is merely an approximation, in the cases where the log-likelihood or derived alignment is high, and so both the sensitivity to model and the sensitivity to distribution are low, the approximation may be reasonably close nonetheless.

Consider the practicable model obtained by maximisation of the summed shuffle content alignment valency-density of the practicable highest-layer summed shuffle content alignment valency-density fud decomposition inducer,

$$
I_{z, \mathrm{Scs}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime} \in \operatorname{inducers}(z)
$$

Given substrate histogram $A \in \mathcal{A}_{z}$, the practicable fud decomposition inducer is defined in section 'Optimisation', above, as

$$
\begin{aligned}
& I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime *}(A)= \\
& \quad \operatorname{if}\left(Q \neq \emptyset,\left\{\left(D, I_{\text {Scsd }}^{*}((A, D))\right)\right\},\left\{\left(D_{\emptyset}, 0\right)\right\}\right): \\
& \quad Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{~d}}\right)\right),\{D\}=Q
\end{aligned}
$$

Let the practicable fud decomposition be

$$
D_{\mathrm{o}, \mathrm{Scsd}, P} \in \operatorname{maxd}\left(I_{z_{\mathrm{o}}, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime *}\left(A_{\mathrm{o}}\right)\right)
$$

The practicable fud decomposition inducer imposes a sequence on the search and other constraints that do not apply to the tractable summed alignment valency-density decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, so conjecture that the practicable derived alignment is less than or equal to the tractable derived alignment,

$$
\operatorname{algn}\left(A_{\mathrm{o}} * D_{\mathrm{o}, \mathrm{Scsd}, P}^{\mathrm{T}}\right) \leq \operatorname{algn}\left(A_{\mathrm{o}} * D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}\right)
$$

So conjecture, in the case where (i) the iso-transform-independent dependentindependent anti-optimisation assumption is true, (ii) the iso-transform independent underlying lifted optimisation assumption is true, and (iii) the iso-transform-independent conditional-relative optimisation assumption is true, that the derived alignment accuracy with respect to the practicable fud decomposition inducer is less than or equal to that of the tractable fud decomposition inducer,

$$
\frac{\exp \left(\operatorname{algn}\left(A_{\mathrm{o}} * D_{\mathrm{o}, \mathrm{Scsd}, P}^{\mathrm{T}}\right)\right)}{\exp \left(\operatorname{algn}\left(A_{\mathrm{o}} * \tilde{T}_{\mathrm{o}}\right)\right)} \leq \frac{\exp \left(\operatorname{algn}\left(A_{\mathrm{o}} * D_{\mathrm{o}}^{\mathrm{T}} \mathrm{Sd}\right)\right)}{\exp \left(\operatorname{algn}\left(A_{\mathrm{o}} * \tilde{T}_{\mathrm{o}}\right)\right)}
$$

and, in general, the accuracy is such that

$$
\frac{\exp \left(X_{z_{o}, \mathrm{xi}, \mathrm{~T}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}, k}\left(A_{\mathrm{o}}\right)\left(D_{\mathrm{o}, \mathrm{cssd}, P}^{\mathrm{T}}\right)\right)}{\exp \left(X_{z_{o}, \mathbf{x i}, \mathrm{~T}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}, k}\left(A_{\mathrm{o}}\right)\left(\tilde{T}_{\mathrm{o}}\right)\right)} \leq \frac{\exp \left(X_{z_{o}, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}, k}\left(A_{\mathrm{o}}\right)\left(D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}\right)\right)}{\exp \left(X_{z_{o}, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}, k}\left(A_{\mathrm{o}}\right)\left(\tilde{T}_{\mathrm{o}}\right)\right)}
$$

It is shown above in classical uniform possible modelled induction, where the history probability function is uniform possible iso-derived historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, T_{\mathrm{o}}}$, that, in the case where (i) the size is less than the volume, $z_{0}<v_{\mathrm{o}}$, but the sample approximates to the naturalisation, $A_{\mathrm{o}} \approx A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$, and (ii) the maximum likelihood estimate relative entropy is high, entropy $\operatorname{Cross}\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)>\ln \left|T_{\mathrm{o}}^{-1}\right|$, (a) the log likelihood of the iso-derived conditional stuffed historical probability distribution at the maximum likelihood estimate varies against the specialising derived substrate history coder space,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim-\operatorname{space}\left(C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)\right)\left(H_{\mathrm{o}}\right)
$$

(b) the sensitivity to distribution varies against the log likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

and (c) the sensitivity to model varies against the log likelihood,
$-\ln \left|\max \left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{d}, T, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}} \approx A_{\mathrm{o}} * T * T^{\dagger}\right\}\right)\right| \sim$

$$
-\ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

It is shown above in aligned modelled induction, where the history probability function is iso-transform-independent historically distributed, $P=$ $P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{\mathrm{o}}}$, that, in the case where (i) the sample is ideal, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$, (ii) the sample formal equals the sample abstract, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, (iii) the alignment is at least intermediate, $\operatorname{algn}\left(A_{\mathrm{o}}\right)>\operatorname{algnMax}(U)\left(V_{\mathrm{o}}, z_{\mathrm{o}}\right) / 2$, (iv) the size is less than the volume, $z_{\mathrm{o}}<v_{\mathrm{o}}$, and (v) the component size cardinality relative entropy of the maximum likelihood estimate for the model is high, entropyCross $\left(A_{\mathrm{o}} * T_{\mathrm{o}}, V_{\mathrm{o}}^{\mathrm{C}} * T_{\mathrm{o}}\right)>\ln \left|T_{\mathrm{o}}^{-1}\right|$, (a) the log likelihood of the iso-transform-independent conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the log likelihood of the iso-derived conditional stuffed historical probability distribution at the sample,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, \tilde{T}_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

(b) the sum sensitivity varies against the log-likelihood,

$$
\operatorname{sum}\left(\operatorname{sensitivity}(U)\left(\hat{Q}_{\mathrm{h}, \mathrm{y}, \tilde{T}_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\right)\right) \sim-\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

and (c) the sensitivity to model varies against the log likelihood,
$-\ln \mid \max \left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{y}, T, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right.\right.\right.$,

$$
\left.\left.A_{\mathrm{o}}^{\mathrm{X}} * T=\left(A_{\mathrm{o}} * T\right)^{\mathrm{x}}, A_{\mathrm{o}}=A_{\mathrm{o}} * T * T^{\dagger A_{\mathrm{o}}}\right\}\right) \mid \sim
$$

$$
-\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

So (a) by weakening the induction condition from law-like necessary derived to entity-like necessary abstract, (b) by strengthening the induction condition with necessary formal and (c) by strengthening the constraints on the sample to be ideal and have formal-abstract equivalence, the likelihood and sensitivity properties of aligned modelled induction approximate to those of classical modelled induction.

Insofar as the uniform possible iso-derived history probability function approximates to the necessary iso-transform-independent history probability function, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, T_{\mathrm{o}}} \approx P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{o}, \mathrm{H}}$, conjecture that the model, $D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}$, obtained by the maximisation of the tractable summed alignment valencydensity inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is also a tractable approximation to the maximum likelihood estimate for the model for uniform possible iso-derived induction,

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}} \approx A_{\mathrm{o}} * T * T^{\dagger}\right\}\right)
$$

That is, in the aligned, formal-abstract, ideal, high relative entropy case, a tractable maximum likelihood estimate for the model may be obtained for classical modelled induction by optimisation of the summed alignment valency-density inducer,

$$
\tilde{T}_{\mathrm{o}} \approx D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}
$$

The accuracy of the approximation can be defined as the ratio of the tractable model uniform possible iso-derived likelihood to the maximum model uniform possible iso-derived likelihood,

$$
0<\frac{\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}} U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{T}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \leq 1
$$

Just as the tractable model iso-transform-independent accuracy varies with the log-likelihood, so too does the tractable model uniform possible iso-derived accuracy,

$$
\frac{\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}, \mathrm{~S} \mathrm{~d}}^{\mathrm{T}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{T}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

Again, in the cases where the log-likelihood is high, and so the sensitivity to model is low, the tractable approximation in the aligned, formal-abstract, ideal, high relative entropy case may be reasonably close.

This positive correlation between the tractable model uniform possible isoderived accuracy and the log-likelihood,

$$
\frac{\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{T}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

has already been established indirectly in section 'Tractable transform induction', above, by comparing the entropy properties of the tractable summed alignment valency-density inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, and the specialising fud decomposition substrate history coder, $C_{\mathrm{G}, V, \mathrm{D}, \mathrm{F}, \mathrm{H}}$. These properties are described in section 'Inducers and Compression' which considers the relations between the summed alignment valency-density and the specialising space. In particular, it is shown that the summed alignment valency-density (a) varies against the derived entropy of the nullable transform,

$$
\operatorname{algnValDensSum}(U)\left(A, D^{\mathrm{D}}\right) \sim-\operatorname{entropy}\left(A * D^{\mathrm{T}}\right)
$$

(b) varies against the possible derived volume $w^{\prime}=\left|\left(D^{\mathrm{T}}\right)^{-1}\right|$,

$$
\operatorname{algnValDensSum}(U)\left(A, D^{\mathrm{D}}\right) \sim 1 / w^{\prime}
$$

(c) varies with the expected component entropy,

$$
\operatorname{algnValDensSum}(U)\left(A, D^{\mathrm{D}}\right) \sim \text { entropyComponent }\left(A, D^{\mathrm{T}}\right)
$$

and (d) varies with the component size cardinality relative entropy,

$$
\operatorname{algnValDensSum}(U)\left(A, D^{\mathrm{D}}\right) \sim \text { entropyRelative }\left(A * D^{\mathrm{T}}, V^{\mathrm{C}} * D^{\mathrm{T}}\right)
$$

Given these relations it is conjectured in section 'Tractable transform induction' that the maximum likelihood estimate for the model for specialising induction,

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{G}, T, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

or

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{mind}\left(\left\{\left(T, C_{\mathrm{G}, V_{0}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

can be tractably approximated by the maximisation of the tractable limitedmodels summed alignment valency-density substrate aligned non-overlapping infinite-layer fud decomposition inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$,

$$
\tilde{T}_{\mathrm{o}} \approx D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}
$$

and the accuracy of the tractable model varies with the specialising loglikelihood,

$$
\frac{\hat{Q}_{\mathrm{G}, D_{\mathrm{o}, \mathrm{~s} \mathrm{H}}^{\mathrm{H}}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{G}, \tilde{T}_{\mathrm{o}}^{\mathrm{H}}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \sim \ln \hat{Q}_{\mathrm{G}, T_{\mathrm{o}} \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

Then it is conjectured that, insofar as the uniform possible iso-derived history probability function approximates to the specialising history probability function, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, \mathrm{p}, T_{\mathrm{o}}} \approx P_{U, X, \mathrm{G}, T_{\mathrm{o}}, \mathrm{H}}$, the model, $D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}$, obtained by the maximisation of the tractable summed alignment valency-density inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is also a tractable approximation to the maximum likelihood estimate for the model for uniform possible iso-derived induction,

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}} \approx A_{\mathrm{o}} * T * T^{\dagger}\right\}\right)
$$

That is, in the near-natural, high relative entropy case, a tractable maximum likelihood estimate for the model may be obtained for classical modelled induction by optimisation of the summed alignment valency-density inducer,

$$
\tilde{T}_{\mathrm{o}} \approx D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}
$$

Just as the tractable model specialising accuracy varies with the log-likelihood, so too does the tractable model uniform possible iso-derived accuracy,

$$
\frac{\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}, \mathrm{~s} \mathrm{~d}}^{T}} U\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{T}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{o}, U}\left(A_{\mathrm{o}, \tilde{\mathrm{~h}}_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

This indirect derivation of the relation between the tractable model uniform possible iso-derived accuracy and the log-likelihood via the entropy properties of the tractable inducer and specialising coder in natural classical modelled induction provides corroboration for the more direct derivation in formalabstract ideal aligned modelled induction. The tractable summed alignment valency-density inducer, $I_{z, \mathrm{Sa}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is directly derived from the aligned induction assumptions by removing the intractabilities from the literal derived alignment integral-independent substrate ideal formal-abstract transform inducer, $I_{z, \mathrm{a}, \mathrm{l}}^{\prime}$, while maintaining the positive correlation with the fi nite transform-dependent-sample distributed iso-transform-independent conditional dependent multinomial space integral-independent substrate ideal formal abstract transform search set,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{~T}, \mathrm{y}, \mathrm{fa}, \mathrm{j}, k}, \operatorname{maxr} \circ I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime *}\right) \geq 0\right)
$$

Then, given the formal-abstract ideal constraints on the sample in aligned modelled induction it is conjectured that the log likelihood of the iso-transformindependent conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the log likelihood of the iso-derived conditional stuffed historical probability distribution at the sample,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, \tilde{T}_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, \tilde{z}_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

leading to the relation between the tractable model uniform possible isoderived accuracy and the log-likelihood,

$$
\frac{\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}, \mathrm{sd}}^{\mathrm{T}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{T}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

That is, the indirect derivation via the entropy properties is separate evidence for the conjecture that the formal-abstract ideal aligned induction loglikelihood varies with the natural classical induction log-likelihood.

In the discussion of classical modelled induction, above, consideration is given to the case where the model is extended from a transform first to a functional definition set and then to a fud decomposition. Now consider an outline for the same in aligned modelled induction.

In section 'Necessary derived functional definition set' the model is extended to a functional definition set from the transform of section 'Necessary derived'. Given some known substrate fud, $F_{\mathrm{o}} \in \mathcal{F}_{U, V_{0}}$, such that there exists a top transform, $\exists T \in F_{\mathrm{o}}\left(\operatorname{der}(T)=\operatorname{der}\left(F_{\mathrm{O}}\right)\right)$, the derived histogram set of the distribution probability histogram is $\left\{\hat{E}_{\mathrm{h}} * T_{F_{\mathrm{o}}}: T \in F_{\mathrm{o}}\right\}$, where $T_{F}:=\operatorname{depends}(F, \operatorname{der}(T))^{\mathrm{T}}$. In classical functional definition set induction, while the distribution probability histogram, $\hat{E}_{\mathrm{h}}$, remains unknown, the derived distribution probability histogram set, $\left\{\hat{E}_{\mathrm{h}} * T_{F_{\mathrm{o}}}: T \in F_{\mathrm{o}}\right\}$, is known and necessary. That is, the history probability function, $P$, is historically distributed but constrained such that all drawn histories have a derived probability histogram equal to the known derived distribution probability histogram for each of the transforms of the fud, $\forall T \in F_{\mathrm{o}}\left(\hat{A}_{H} * T_{F_{\mathrm{o}}}=\hat{E}_{\mathrm{h}} * T_{F_{\mathrm{o}}}\right)$. The iso-fud historically distributed history probability function $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, F_{\mathrm{o}}} \in\left(\mathcal{H}_{U, X}: \rightarrow\right.$ $\left.\mathrm{Q}_{[0,1]}\right) \cap \mathcal{P}$ is defined and the corresponding iso-fud conditional stuffed historical probability distribution is now conditional on the set of iso-fuds,

$$
\begin{aligned}
& \hat{Q}_{\mathrm{h}, \mathrm{~d}, F, U}(E, z) \\
&:=\left\{\left(A, \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum_{B \in D_{U, \mathrm{i}, F, z}^{-1}\left(\left\{A * T_{F}: T \in F\right\}\right)} Q_{\mathrm{h}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \leq E\right\}^{\wedge} \cup \\
&\left\{(A, 0): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \not \leq E\right\}
\end{aligned}
$$

where the finite set of iso-fuds of derived histogram set $\left\{A * T_{F}: T \in F\right\}$ is

$$
D_{U, i, F, z}^{-1}\left(\left\{A * T_{F}: T \in F\right\}\right)=\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, \forall T \in F\left(B * T_{F}=A * T_{F}\right)\right\}
$$

Similarly, in aligned functional definition set induction, while the distribution probability histogram, $\hat{E}_{\mathrm{h}}$, remains unknown, the formal-abstract-pair distribution probability histogram set, $\left\{\left(\hat{E}_{\mathrm{h}}^{\mathrm{X}} * T_{F_{\mathrm{o}}},\left(\hat{E}_{\mathrm{h}} * T_{F_{\mathrm{o}}}\right)^{\mathrm{X}}\right): T \in F_{\mathrm{o}}\right\}$, is known and necessary. That is, the history probability function, $P$, is historically distributed but constrained such that all drawn histories have a formal probability histogram equal to the known formal distribution probability histogram and an abstract probability histogram equal to the known abstract distribution probability histogram for each of the transforms of the fud, $\forall T \in F_{\mathrm{o}}\left(\hat{A}_{H}^{\mathrm{X}} * T_{F_{\mathrm{o}}}=\hat{E}_{\mathrm{h}}^{\mathrm{X}} * T_{F_{\mathrm{o}}} \wedge\left(\hat{A}_{H} * T_{F_{\mathrm{o}}}\right)^{\mathrm{X}}=\left(\hat{E}_{\mathrm{h}} * T_{F_{\mathrm{o}}}\right)^{\mathrm{X}}\right)$. The iso-fudindependent historically distributed history probability function $P_{U, X, H_{\mathrm{h}}, \mathrm{y}, F_{\mathrm{o}}} \in$ $\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}$ can be defined analogously to the iso-fud historically distributed history probability function, $P_{U, X, H_{h}, \mathrm{~d}, F_{\mathrm{o}}}$, and the corresponding iso-fud-independent conditional stuffed historical probability distribution is now conditional on the set of iso-fud-independents,

$$
\begin{aligned}
& \hat{Q}_{\mathrm{h}, \mathrm{y}, F, U}(E, z) \\
&:=\left\{\left(A, \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum_{B \in Y_{U, \mathrm{i}, F, z}^{-1}\left(Y_{U, F, z}(A)\right)} Q_{\mathrm{h}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \leq E\right\}^{\wedge} \cup \\
&\left\{(A, 0): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \not \leq E\right\}
\end{aligned}
$$

where the finite set of integral iso-fud-independents of formal-abstract-pair histogram set $\left\{\left(A^{\mathrm{X}} * T_{F},\left(A * T_{F}\right)^{\mathrm{X}}\right): T \in F\right\}$ is

$$
\begin{aligned}
& Y_{U, i, F, z}^{-1}\left(\left\{\left(A^{\mathrm{x}} * T_{F},\left(A * T_{F}\right)^{\mathrm{x}}\right): T \in F\right\}\right)= \\
& \quad\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, \forall T \in F\left(B^{\mathrm{x}} * T_{F}=A^{\mathrm{x}} * T_{F} \wedge\left(B * T_{F}\right)^{\mathrm{x}}=\left(A * T_{F}\right)^{\mathrm{x}}\right)\right\}
\end{aligned}
$$

which is the intersection of the iso-fud-formals and the iso-fud-abstracts

$$
\begin{aligned}
Y_{U, \mathrm{i}, F, z}^{-1}\left(\left\{\left(A^{\mathrm{X}} *\right.\right.\right. & \left.\left.\left.T_{F},\left(A * T_{F}\right)^{\mathrm{X}}\right): T \in F\right\}\right)= \\
& Y_{U, \mathrm{i}, F, \mathrm{~V}, z}^{-1}\left(\left\{A^{\mathrm{x}} * T_{F}: T \in F\right\}\right) \cap Y_{U, \mathrm{i}, F, \mathrm{~W}, z}^{-1}\left(\left\{\left(A * T_{F}\right)^{\mathrm{X}}: T \in F\right\}\right)
\end{aligned}
$$

In classical transform induction the special case is considered where the sample is constrained to be equal to the independent analogue, which is the naturalisation, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$. In this case, the maximum likelihood estimate is necessarily equal to the sample probability histogram,

$$
A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger} \Longrightarrow A_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)}=A_{\mathrm{o}} \Longrightarrow \tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

The naturalisation is the likely histogram of the iso-derived,

$$
\begin{aligned}
& \left\{A * T * T^{\dagger}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(E, \sum\left(Q_{\mathrm{m}, U}(E, z)(B): B \in D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right)\right): E \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The fud independent analogue corresponding to the naturalisation is the fudindependent, $A^{\mathrm{E}_{\mathrm{F}}(F)} \in \mathcal{A}_{U, V, z}$, defined,

$$
\begin{aligned}
& \left\{A^{\mathrm{E}_{\mathrm{F}}(F)}\right\}= \\
& \quad \quad \operatorname{maxd}\left(\left\{\left(E, \sum\left(Q_{\mathrm{m}, U}(E, z)(B): B \in D_{U, \mathrm{i}, F, z}^{-1}\left(D_{U, F, z}(A)\right)\right)\right): E \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The fud-independent approximates to the arithmetic average of the naturalisations,

$$
A^{\mathrm{E}_{\mathrm{F}}(F)} \approx Z_{1 /|F|} * \sum_{T \in F} A * T_{F} * T_{F}^{\dagger}
$$

In classical fud induction, it is only in the case where the histogram equals the fud-independent that the maximum likelihood estimate is necessarily equal to the sample probability histogram,

$$
A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{F}}\left(F_{\mathrm{o}}\right)} \Longrightarrow A_{\mathrm{o}}^{\mathrm{DFF}^{\left(F_{\mathrm{o}}\right)}}=A_{\mathrm{o}} \Longrightarrow \tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

In aligned transform induction, however, the sample is not constrained to be equal to the independent analogue, $A_{\mathrm{o}}^{\mathrm{X}\left(T_{\mathrm{o}}\right)}$, but instead (a) the sample formal equals the sample abstract, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, and (b) the sample is ideal, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$. In this case the log likelihood of the iso-transform-independent conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the log likelihood of the isoderived conditional stuffed historical probability distribution at the sample,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

The corresponding likely histogram in aligned fud induction is the solution to

$$
\begin{aligned}
&\left\{A^{\mathrm{X}_{\mathrm{F}, f \mathrm{fa}, \mathrm{j}}(F)}\right\} \in \\
& \quad \operatorname{maxd}\left(\left\{\left(E, \sum\left(Q_{\mathrm{m}, U}(E, z)(B): B \in Y_{U, \mathrm{i}, F, z}^{-1}\left(Y_{U, F, z}(A)\right),\right.\right.\right.\right. \\
&\left.\quad \forall T \in F\left(B^{\mathrm{X}} * T_{F}=\left(B * T_{F}\right)^{\mathrm{X}} \wedge B * T_{F} * T_{F}^{\dagger B}=A * T_{F} * T_{F}^{\dagger A}\right)\right): \\
&\left.\left.E \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

Then, in section 'Unknown necessary derived', the case is considered where the model, $T_{\mathrm{o}}$, is unknown and it is found that there is no singular solution to the optimisation,

$$
\begin{aligned}
& \operatorname{maxd}\left(\left\{\left((E, T), \frac{Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in D_{U, i, T, z_{\mathrm{o}}}^{-1}\left(A_{\mathrm{o}} * T\right)} Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)(B)}\right):\right.\right. \\
& \left.\left.\quad E \in \mathcal{A}_{U, V_{o}, 1}, T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right) \supseteq \mathcal{A}_{U, V_{\mathrm{o}}, 1} \times\left\{T_{\mathrm{s}}\right\}
\end{aligned}
$$

where $T_{\mathrm{s}}$ is a self transform. The discussion of classical induction goes on to consider a weakening of necessary derived to uniform possible derived in section 'Uniform possible derived induction' and the corresponding extension of the model to fud in section 'Uniform possible derived functional definition set induction'. This is not required in aligned modelled induction, however, because it is conjectured that in transform induction there are some cases in which there is a unique solution for the pair $\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right)$, where the optimisation is

$$
\begin{aligned}
& \left\{\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right)\right\} \\
& \qquad=\operatorname{maxd}\left(\left\{\left((E, T), \frac{Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in \mathcal{A}_{U, i, \mathrm{i}, T, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)} Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)(B)}\right)\right.\right. \\
& \left.\left.\quad E \in \mathcal{A}_{U, V_{o}, 1}, T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
\end{aligned}
$$

The corresponding optimisation in aligned fud induction is

$$
\begin{aligned}
& \left\{\left(\tilde{E}_{\mathrm{o}}, \tilde{F}_{\mathrm{o}}\right)\right\} \\
& =\operatorname{maxd}\left(\left\{\left((E, F), \frac{Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in Y_{U, i, F, z_{\mathrm{o}}}^{-1}\left(Y_{U, F, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)\right)} Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)(B)}\right):\right.\right. \\
& \left.\left.\quad E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}, F \in \mathcal{F}_{U, V_{\mathrm{o}}}\right\}\right)
\end{aligned}
$$

The discussion of classical induction goes on, in section 'Specialising induction', to consider induction assumptions that do not depend on the multinomial probability given a distribution histogram, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)$, but instead are based on specialising coder space, $C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)^{\mathrm{s}}$. The corresponding extension of the model to fud, based on specialising fud coder space, $C_{\mathrm{G}, \mathrm{F}, \mathrm{H}}\left(F_{\mathrm{o}}\right)^{\mathrm{s}}$, is discussed in section 'Specialising functional definition set induction'.

Then the discussion of classical induction goes on to consider tractable induction in section 'Tractable transform induction'. There it is conjectured that the model, $D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}$, obtained by the maximisation of the tractable summed alignment valency-density inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is a tractable approximation to the maximum likelihood estimate for the model for specialising induction,

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{G}, T, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

or

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{mind}\left(\left\{\left(T, C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

and so a tractable approximation to the maximum likelihood estimate for the model for uniform possible iso-derived induction,

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}} \approx A_{\mathrm{o}} * T * T^{\dagger}\right\}\right)
$$

The discussion of the corresponding extension of the model to fud, in section 'Tractable functional definition set induction', does not depend on tractable inducers but rather conjectures that the model, $F_{\mathrm{o}, \mathrm{gr}, \mathrm{lsq}}$, obtained by the maximisation of the least squares gradient descent fud search function, $Z_{\mathrm{F}, \mathrm{P}, P, \mathrm{gr}, \mathrm{lsq}}$, is a tractable approximation to the maximum likelihood estimate for the model for specialising induction,

$$
\tilde{F}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(F, \hat{Q}_{\mathrm{G}, F, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): F \in \mathcal{F}_{U, V_{\mathrm{o}}}\right\}\right)
$$

or

$$
\tilde{F}_{\mathrm{o}} \in \operatorname{mind}\left(\left\{\left(F, C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~F}, \mathrm{H}}\left(F^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right): F \in \mathcal{F}_{U, V_{\mathrm{o}}}\right\}\right)
$$

and so is a tractable approximation to the maximum likelihood estimate for the model for uniform possible iso-fud induction,

$$
\begin{aligned}
\tilde{F}_{\mathrm{o}} \in \operatorname{maxd}( & \left\{\left(F, \hat{Q}_{\mathrm{h}, \mathrm{~d}, F, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right. \\
& \left.\left.F \in \mathcal{F}_{U, V_{\mathrm{o}}}, \exists T \in F\left(W_{T}=W_{F}\right), A_{\mathrm{o}} \approx A_{\mathrm{o}}^{\mathrm{E} F(F)}\right\}\right)
\end{aligned}
$$

where the least squares gradient descent fud search function is defined

$$
\begin{aligned}
& Z_{\mathrm{F}, \mathrm{P}, P, \mathrm{gr}, \mathrm{lsq}}(H)= \\
& \quad\left\{(\operatorname{fud}(\sigma)(G),-\operatorname{lsq}(\sigma)(A, G, K)): Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, \mathrm{gr}, \mathrm{lsq}}\right)\right), \quad\{G\}=Q\right\}
\end{aligned}
$$

and the least squares gradient descent substrate net tree searcher, $Z_{P, A, \mathrm{gr}, \mathrm{lsq}}$, is, in turn, defined in terms of the neural net substrate fud set, $\mathcal{F}_{\infty, U, V, \sigma}=$ $\mathcal{F}_{\infty, U, V} \cap(\operatorname{fud}(\sigma) \circ$ nets $)$. The accuracy of the approximation is defined as the ratio of the tractable model uniform possible iso-fud likelihood to the maximum model uniform possible iso-fud likelihood,

$$
0<\frac{\hat{Q}_{\mathrm{h}, \mathrm{~d}, F_{\mathrm{o}, \mathrm{gr}, \mathrm{lsq}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{F}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \leq 1
$$

The corresponding aligned accuracy is defined as the ratio of the tractable model iso-fud-independent likelihood to the maximum model iso-fud-independent
likelihood. The accuracy, defined with respect to the finite fud-dependent-sample-distributed iso-fud-independent conditional dependent multinomial space integral-independent substrate ideal formal-abstract fud search set, $X_{z, \mathrm{xi}, \mathrm{F}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}, k}$, may be stated explicitly,

$$
\begin{aligned}
& \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}, k}^{\mathrm{Y}_{\mathrm{F}}\left(F_{\mathrm{o}, \mathrm{gr}, \mathrm{sq}}\right)}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum Q_{\mathrm{m}, U}\left(A_{\mathrm{o}, k}^{\mathrm{Y}_{\mathrm{F}}\left(F_{\mathrm{o}, \mathrm{gr}, \mathrm{lsq}}\right)}, z_{\mathrm{o}}\right)(B): B \in Y_{U, \mathrm{i}, F_{\mathrm{o}, \mathrm{gr}, 1 \mathrm{sq}}, z_{\mathrm{o}}}^{-1}\left(Y_{U, F_{\mathrm{o}, \mathrm{gr}, l \mathrm{sq}}, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)\right)} \\
& / \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}, k}^{\mathrm{Y}_{\mathrm{F}}\left(\tilde{F}_{\mathrm{o}}\right)}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum Q_{\mathrm{m}, U}\left(A_{\mathrm{o}, k}^{\mathrm{Y}_{\mathrm{F}}\left(\tilde{F}_{\mathrm{o}}\right)}, z_{\mathrm{o}}\right)(B): B \in Y_{U, i, \tilde{F}_{\mathrm{o}}, z_{\mathrm{o}}}^{-1}\left(Y_{U, \tilde{F}_{\mathrm{o}}, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)\right)}
\end{aligned}
$$

Now consider the outline of aligned modelled induction for the extension of the model to a functional definition set.

In section 'Necessary derived functional definition set decomposition' the model is extended to a functional definition set decomposition from the functional definition set of section 'Necessary derived functional definition set'. Given some non-empty known substrate fud decomposition, $D_{o} \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}$, such that there exists a top transform for all of the fuds, $\forall F \in \operatorname{fuds}\left(D_{\mathrm{o}}\right) \exists T \in$ $F(\operatorname{der}(T)=\operatorname{der}(F))$, the component derived set of the distribution probability histogram is $\left\{\left(C,\left\{\hat{E}_{\mathrm{h}} * C * T_{F}: T \in F\right\}\right):(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right)\right\}$, where $\operatorname{cont}(D)=\operatorname{elements}(\operatorname{contingents}(D))$ and $T_{F}:=\operatorname{depends}(F, \operatorname{der}(T))^{\mathrm{T}}$. In classical functional definition set decomposition induction, while the distribution probability histogram, $\hat{E}_{\mathrm{h}}$, remains unknown, the component derived distribution probability set, $\left\{\left(C,\left\{\hat{E}_{\mathrm{h}} * C * T_{F}: T \in F\right\}\right):(C, F) \in\right.$ $\left.\operatorname{cont}\left(D_{\mathrm{o}}\right)\right\}$, is known and necessary. That is, the history probability function, $P$, is historically distributed but constrained such that all drawn histories have a derived probability histogram equal to the known derived distribution probability histogram for each of the transforms of the fud for each slice, $\forall(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right) \forall T \in F\left(\hat{A}_{H} * C * T_{F}=\hat{E}_{\mathrm{h}} * C * T_{F}\right)$. The iso-fud-decomposition historically distributed history probability function $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, D_{\mathrm{o}}} \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}$ is defined and the corresponding iso-fud-decomposition conditional stuffed historical probability distribution is now conditional on the set of iso-fud-decompositions,

$$
\begin{aligned}
\hat{Q}_{\mathrm{h}, \mathrm{~d}, D, U} & (E, z) \\
:= & \left\{\left(A, \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum_{B \in D_{U U, \mathrm{i}, \mathrm{~F}, z}^{-1}\left(D_{U, D, \mathrm{~F}, z}(A)\right)} Q_{\mathrm{h}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \leq E\right\}^{\wedge} \cup \\
& \left\{(A, 0): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \notin E\right\}
\end{aligned}
$$

where the finite iso-fud-decompositions of component-derived-set $D_{U, D, F, z}(A)$ is

$$
\begin{aligned}
& D_{U, \mathrm{i}, D, \mathrm{~F}, z}^{-1}\left(D_{U, D, \mathrm{~F}, z}(A)\right)= \\
& \quad\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, \forall(C, F) \in \operatorname{cont}(D) \forall T \in F\left(B * C * T_{F}=A * C * T_{F}\right)\right\}
\end{aligned}
$$

Similarly, in aligned functional definition set decomposition induction, while the distribution probability histogram, $\hat{E}_{\mathrm{h}}$, remains unknown, the component formal-abstract-pair set distribution probability histogram set, $\left\{\left(C,\left\{\left(\left(\hat{E}_{\mathrm{h}} *\right.\right.\right.\right.\right.$ $\left.\left.\left.\left.C)^{\mathrm{X}} * T_{F},\left(\hat{E}_{\mathrm{h}} * C * T_{F}\right)^{\mathrm{X}}\right): T \in F\right\}\right):(C, F) \in \operatorname{cont}\left(D_{\mathrm{o}}\right)\right\}$, is known and necessary. That is, the history probability function, $P$, is historically distributed but constrained such that all drawn histories have a formal probability histogram equal to the known formal distribution probability histogram and an abstract probability histogram equal to the known abstract distribution probability histogram for each of the transforms of the fud for each slice, $\forall(C, F) \in$ $\operatorname{cont}\left(D_{\mathrm{o}}\right) \forall T \in F\left(\left(\hat{A}_{H} * C\right)^{\mathrm{x}} * T_{F}=\left(\hat{E}_{\mathrm{h}} * C\right)^{\mathrm{x}} * T_{F} \wedge\left(\hat{A}_{H} * C * T_{F}\right)^{\mathrm{x}}=\left(\hat{E}_{\mathrm{h}} *\right.\right.$ $\left.\left.C * T_{F}\right)^{\mathrm{X}}\right)$. The iso-fud-decomposition-independent historically distributed history probability function $P_{U, X, H_{\mathrm{h}}, \mathrm{y}, D_{\mathrm{o}}} \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{[0,1]}\right) \cap \mathcal{P}$ can be defined analogously to the iso-fud-decomposition historically distributed history probability function, $P_{U, X, H_{\mathrm{h}}, \mathrm{d}, D_{\mathrm{o}}}$, and the corresponding iso-fud-decompositionindependent conditional stuffed historical probability distribution is now conditional on the set of iso-fud-decomposition-independents,

$$
\begin{aligned}
\hat{Q}_{\mathrm{h}, \mathrm{y}, D, U} & (E, z) \\
:= & \left\{\left(A, \frac{Q_{\mathrm{h}, U}(E, z)(A)}{\sum_{B \in Y_{U \in, \mathrm{i}, \mathrm{~F}, z}^{-1}\left(Y_{U, D, \mathrm{~F}, z}(A)\right)} Q_{\mathrm{h}, U}(E, z)(B)}\right): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \leq E\right\}^{\wedge} \cup \\
& \left\{(A, 0): A \in \mathcal{A}_{U, \mathrm{i}, V, z}, A \not \leq E\right\}
\end{aligned}
$$

where the finite set of integral iso-fud-decomposition-independents of component formal-abstract-pair set $Y_{U, D, \mathrm{~F}, z}(A)$ is

$$
\begin{aligned}
& Y_{U, \mathrm{i}, D, \mathrm{~F}, z}^{-1}\left(Y_{U, D, \mathrm{~F}, z}(A)\right)= \\
& \quad\left\{B: B \in \mathcal{A}_{U \mathrm{i}, V, z}, \forall(C, F) \in \operatorname{cont}(D) \forall T \in F\right. \\
& \left.\quad\left((B * C)^{\mathrm{x}} * T_{F}=(A * C)^{\mathrm{x}} * T_{F} \wedge\left(B * C * T_{F}\right)^{\mathrm{x}}=\left(A * C * T_{F}\right)^{\mathrm{x}}\right)\right\}
\end{aligned}
$$

In classical transform induction the special case is considered where the sample is constrained to be equal to the independent analogue, which is the naturalisation, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger}$. In this case, the maximum likelihood estimate is necessarily equal to the sample probability histogram,

$$
A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger} \Longrightarrow A_{\mathrm{o}}^{\mathrm{D}\left(T_{\mathrm{o}}\right)}=A_{\mathrm{o}} \Longrightarrow \tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

The naturalisation is the likely histogram of the iso-derived,

$$
\begin{aligned}
& \left\{A * T * T^{\dagger}\right\}= \\
& \quad \operatorname{maxd}\left(\left\{\left(E, \sum\left(Q_{\mathrm{m}, U}(E, z)(B): B \in D_{U, \mathbf{i}, T, z}^{-1}(A * T)\right)\right): E \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The fud-decomposition-independent analogue corresponding to the naturalisation is the fud-decomposition-independent, $A^{\mathrm{ED}, \mathrm{F}(D)} \in \mathcal{A}_{U, V, z}$, defined,

$$
\begin{aligned}
& \left\{A^{\mathrm{E}_{\mathrm{D}, \mathrm{~F}}(D)}\right\}= \\
& \quad \quad \operatorname{maxd}\left(\left\{\left(E, \sum\left(Q_{\mathrm{m}, U}(E, z)(B): B \in D_{U, \mathrm{i}, D, \mathrm{~F}, z}^{-1}\left(D_{U, D, \mathrm{~F}, z}(A)\right)\right)\right): E \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

The fud-decomposition-independent approximates to the scaled sum of the slice arithmetic average of the naturalisations,

$$
A^{\mathrm{E}_{\mathrm{D}, \mathrm{~F}}(D)} \approx Z_{z} *\left(\sum_{(C, F) \in \operatorname{cont}(D)}\left(Z_{1 /|F|} * \sum_{T \in F} A * C * T_{F} * T_{F}^{\dagger}\right)\right)^{\wedge}
$$

In classical fud decomposition induction, it is only in the case where the histogram equals the fud-decomposition-independent that the maximum likelihood estimate is necessarily equal to the sample probability histogram,

$$
A_{\mathrm{o}}=A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{~F}}\left(D_{\mathrm{o}}\right)} \Longrightarrow A_{\mathrm{o}}^{\mathrm{D}_{\mathrm{D}, \mathrm{~F}}\left(D_{\mathrm{o}}\right)}=A_{\mathrm{o}} \Longrightarrow \tilde{E}_{\mathrm{o}}=\hat{A}_{\mathrm{o}}
$$

In aligned transform induction, however, the sample is not constrained to be equal to the independent analogue, $A_{\mathrm{o}}^{\mathrm{X}\left(T_{\mathrm{o}}\right)}$, but instead (a) the sample formal equals the sample abstract, $A_{\mathrm{o}}^{\mathrm{X}} * T_{\mathrm{o}}=\left(A_{\mathrm{o}} * T_{\mathrm{o}}\right)^{\mathrm{X}}$, and (b) the sample is ideal, $A_{\mathrm{o}}=A_{\mathrm{o}} * T_{\mathrm{o}} * T_{\mathrm{o}}^{\dagger A_{\mathrm{o}}}$. In this case the log likelihood of the iso-transform-independent conditional stuffed historical probability distribution at the maximum likelihood estimate varies with the log likelihood of the isoderived conditional stuffed historical probability distribution at the sample,

$$
\ln \hat{Q}_{\mathrm{h}, \mathrm{y}, T_{\mathrm{o}}, U}\left(\tilde{E}_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \sim \ln \hat{Q}_{\mathrm{h}, \mathrm{~d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)
$$

The corresponding likely histogram in aligned fud decomposition induction is the solution to

$$
\begin{aligned}
& \left\{A^{\mathrm{X}_{\mathrm{D}, \mathrm{~F}, \mathrm{fa}, \mathrm{j}}(D)}\right\} \in \\
& \quad \operatorname{maxd}\left(\left\{\left(E, \sum\left(Q_{\mathrm{m}, U}(E, z)(B): B \in Y_{U, \mathrm{i}, D, \mathrm{~F}, z}^{-1}\left(Y_{U, D, \mathrm{~F}, z}(A)\right),\right.\right.\right.\right. \\
& \quad \forall(C, F) \in \operatorname{cont}(D) \forall T \in F \\
& \quad\left((B * C)^{\mathrm{x}} * T_{F}=\left(B * C * T_{F}\right)^{\mathrm{X}} \wedge\right. \\
& \\
& \left.\left.\quad B * C * T_{F} * T_{F}^{\dagger B * C}=A * C * T_{F} * T_{F}^{\dagger A * C}\right)\right): \\
& \left.\left.E \in \mathcal{A}_{U, V, z}\right\}\right)
\end{aligned}
$$

Then, in section 'Unknown necessary derived', the case is considered where the model, $T_{\mathrm{o}}$, is unknown and it is found that there is no singular solution to the optimisation,

$$
\begin{aligned}
& \operatorname{maxd}\left(\left\{\left((E, T), \frac{Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in D_{U, i, T, z_{\mathrm{o}}}^{-1}\left(A_{\mathrm{o}} * T\right)} Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)(B)}\right):\right.\right. \\
& \left.\left.E \in \mathcal{A}_{U, V_{o}, 1}, T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right) \supseteq \mathcal{A}_{U, V_{\mathrm{o}}, 1} \times\left\{T_{\mathrm{s}}\right\}
\end{aligned}
$$

where $T_{\mathrm{s}}$ is a self transform. The discussion of classical induction goes on to consider a weakening of necessary derived to uniform possible derived in section 'Uniform possible derived induction' and the corresponding extension of the model to fud decomposition in section 'Uniform possible derived functional definition set decomposition induction'. This is not required in aligned modelled induction, however, because it is conjectured that in transform induction there are some cases in which there is a unique solution for the pair ( $\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}$ ), where the optimisation is

$$
\begin{aligned}
& \left\{\left(\tilde{E}_{\mathrm{o}}, \tilde{T}_{\mathrm{o}}\right)\right\} \\
& \qquad \begin{aligned}
&=\operatorname{maxd}\left(\left\{\left((E, T), \frac{Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in \mathcal{A}_{U, i, \mathrm{y}, T, z_{o}}\left(A_{\mathrm{o}}\right)} Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)(B)}\right)\right.\right. \\
& E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}, T
\end{aligned} \\
& \left.\left.\qquad \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
\end{aligned}
$$

The corresponding optimisation in aligned fud decomposition induction is

$$
\begin{aligned}
& \left\{\left(\tilde{E}_{\mathrm{o}}, \tilde{D}_{\mathrm{o}}\right)\right\} \\
& =\operatorname{maxd}\left(\left\{\left((E, D), \frac{Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum_{B \in Y_{U, i, D, \mathrm{~F}, z_{\mathrm{o}}}^{-1}\left(Y_{U, D, \mathrm{~F}, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)\right)} Q_{\mathrm{m}, U}\left(E, z_{\mathrm{o}}\right)(B)}\right):\right.\right. \\
& \left.\left.\quad E \in \mathcal{A}_{U, V_{\mathrm{o}}, 1}, D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}}\right\}\right)
\end{aligned}
$$

The discussion of classical induction goes on, in section 'Specialising induction', to consider induction assumptions that do not depend on the multinomial probability given a distribution histogram, $\hat{Q}_{\mathrm{h}, \mathrm{d}, T_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)$, but instead are based on specialising coder space, $C_{\mathrm{G}, \mathrm{T}, \mathrm{H}}\left(T_{\mathrm{o}}\right)^{\mathrm{s}}$. The corresponding extension of the model to fud decomposition, based on specialising fud decomposition coder space, $C_{\mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}\left(D_{\mathrm{o}}\right)^{\mathrm{s}}$, is discussed in section 'Specialising functional definition set decomposition induction'.

Then the discussion of classical induction goes on to consider tractable induction in section 'Tractable transform induction'. There it is conjectured that the model, $D_{\mathrm{o}, \mathrm{Sd}}^{\mathrm{T}}$, obtained by the maximisation of the tractable summed
alignment valency-density inducer, $I_{z, \mathrm{Sd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{n}, \mathrm{q}}^{\prime}$, is a tractable approximation to the maximum likelihood estimate for the model for specialising induction,

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{G}, T, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

or

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{mind}\left(\left\{\left(T, C_{\mathrm{G}, V_{\mathrm{o}}, \mathrm{~T}, \mathrm{H}}(T)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}\right\}\right)
$$

and so a tractable approximation to the maximum likelihood estimate for the model for uniform possible iso-derived induction,

$$
\tilde{T}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(T, \hat{Q}_{\mathrm{h}, \mathrm{~d}, T, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): T \in \mathcal{T}_{U, V_{\mathrm{o}}}, A_{\mathrm{o}} \approx A_{\mathrm{o}} * T * T^{\dagger}\right\}\right)
$$

The discussion of the corresponding extension of the model to fud decomposition, in section 'Tractable functional definition set decomposition induction', does not depend so much on the tractable inducer but rather conjectures that the model, $D_{\mathrm{o}, \mathrm{Scs}, P}$, obtained by the maximisation of the practicable highestlayer summed shuffle content alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}$, is a practicable approximation to the maximum likelihood estimate for the model for specialising induction,

$$
\tilde{D}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(D, \hat{Q}_{\mathrm{G}, D, \mathrm{H}, U}\left(z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right): D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}}\right\}\right)
$$

or

$$
\tilde{D}_{\mathrm{o}} \in \operatorname{mind}\left(\left\{\left(D, C_{\mathrm{G}, V_{o}, \mathrm{D}, \mathrm{~F}, \mathrm{H}}\left(D^{V_{\mathrm{o}}}\right)^{\mathrm{s}}\left(H_{\mathrm{o}}\right)\right): D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}}\right\}\right)
$$

and so is a practicable approximation to the maximum likelihood estimate for the model for uniform possible iso-fud-decomposition induction,

$$
\begin{aligned}
& \tilde{D}_{\mathrm{o}} \in \operatorname{maxd}\left(\left\{\left(D, \hat{Q}_{\mathrm{h}, \mathrm{~d}, D, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)\right):\right.\right. \\
& D \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}} \backslash\{\emptyset\}, \forall F \in \operatorname{fuds}(D) \exists T \in F\left(W_{T}=W_{F}\right), \\
& A_{\mathrm{o}}\left.\left.\approx A_{\mathrm{o}}^{\mathrm{E}_{\mathrm{D}, \mathrm{~F}}(D)}\right\}\right)
\end{aligned}
$$

where, given parameter tuple $P \in \mathcal{L}(\mathcal{X})$, the practicable fud decomposition inducer is defined as

$$
\begin{aligned}
& I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime *}(A)= \\
& \operatorname{if}\left(Q \neq \emptyset,\left\{\left(D, I_{\text {Scsd }}^{*}((A, D))\right)\right\},\left\{\left(D_{\emptyset}, 0\right)\right\}\right): \\
& \quad Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A, \mathrm{D}, \mathrm{~F}, \mathrm{~d}}\right)\right),\{D\}=Q
\end{aligned}
$$

and the summed shuffle content alignment valency-density computer $I_{\mathrm{Scsd}} \in$ computers is defined as

$$
\begin{aligned}
& I_{\text {Scsd }}^{*}((A, D))= \\
& \quad \sum\left(I_{\mathrm{a}}^{*}\left(A * C * F^{\mathrm{T}}\right)-I_{\mathrm{a}}^{*}\left((A * C)_{R(A * C)} * F^{\mathrm{T}}\right)\right) / I_{\mathrm{cvl}}^{*}(F):(C, F) \in \operatorname{cont}(D)
\end{aligned}
$$

and $Z_{P, A, \mathrm{D}, \mathrm{F}, \mathrm{d}}$ is the highest-layer limited-models infinite-layer substrate fud decompositions tree searcher.

The accuracy of the approximation is defined as the ratio of the tractable model uniform possible iso-fud-decomposition likelihood to the maximum model uniform possible iso-fud-decomposition likelihood,

$$
0<\frac{\hat{Q}_{\mathrm{h}, \mathrm{~d}, D_{\mathrm{o}, \mathrm{Scs}, P}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\hat{Q}_{\mathrm{h}, \mathrm{~d}, \tilde{D}_{\mathrm{o}}, U}\left(A_{\mathrm{o}, z_{\mathrm{h}}}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)} \leq 1
$$

The corresponding aligned accuracy is defined as the ratio of the tractable model iso-fud-decomposition-independent likelihood to the maximum model iso-fud-decomposition-independent likelihood. The accuracy, with respect to the finite fud-decomposition-dependent-sample-distributed iso-fud-decompositionindependent conditional dependent multinomial space integral-independent substrate ideal formal-abstract fud decomposition search set, $X_{z, \mathrm{xi}, \mathrm{D}, \mathrm{F}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}, k}$, may be stated explicitly,

$$
\begin{aligned}
& \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}, k}^{\mathrm{Y}_{\mathrm{D}, \mathrm{~F}}\left(D_{\mathrm{o}, \mathrm{Scsd}, P}\right)}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right)}{\sum Q_{\mathrm{m}, U}\left(A_{\mathrm{o}, k}^{\mathrm{Y}_{\mathrm{D}, \mathrm{~F}}\left(D_{\mathrm{o}, \mathrm{Scss}, P)}\right.}, z_{\mathrm{o}}\right)(B): B \in Y_{U, i, D_{\mathrm{o}, \mathrm{Scsd}, P}, \mathrm{~F}, z_{\mathrm{o}}}^{-1}\left(Y_{U, D_{\mathrm{o}}, \mathrm{Scsd}, P, \mathrm{~F}, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)\right)} \\
& \left./ \frac{Q_{\mathrm{m}, U}\left(A_{\mathrm{o}, k}^{\mathrm{Y}_{\mathrm{D}, \mathrm{~F}}} \tilde{D}_{\mathrm{o}}\right)}{}, z_{\mathrm{o}}\right)\left(A_{\mathrm{o}}\right) \\
& \sum Q_{\mathrm{m}, U}\left(A_{\mathrm{o}, k}^{\mathrm{Y}_{\mathrm{D}, \mathrm{~F}}\left(\tilde{D}_{\mathrm{o}}\right)}, z_{\mathrm{o}}\right)(B): B \in Y_{U, \mathrm{i}, \tilde{D}_{\mathrm{o}}, \mathrm{~F}, z_{\mathrm{o}}}^{-1}\left(Y_{U, \tilde{D}_{\mathrm{o}}, \mathrm{~F}, z_{\mathrm{o}}}\left(A_{\mathrm{o}}\right)\right)
\end{aligned}
$$

This definition of accuracy can be derived more directly by considering the definition of fud decomposition inducers. The fud-decomposition-dependent-sample-distributed iso-fud-decomposition-independent conditional dependent multinomial space integral-independent substrate ideal formal-abstract fud decomposition search set is defined,

$$
\begin{aligned}
& X_{z, \mathrm{xi}, \mathrm{D}, \mathrm{~F}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}}(A)= \\
& \left\{\left(D, \ln \frac{\hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{Y}_{\mathrm{D}, \mathrm{~F}}(D)}, z\right)(A)}{\sum \hat{Q}_{\mathrm{m}, U_{A}}\left(A^{\mathrm{Y}, \mathrm{~F}}(D)\right.}, z\right)(B): B \in Y_{U_{A}, \mathrm{i}, D, \mathrm{~F}, z}^{-1}\left(Y_{U_{A}, D, \mathrm{~F}, z}(A)\right) \quad\right): \\
& \left.D \in \mathcal{D}_{\mathrm{F}, U_{A}, V_{A}}, \quad A=A^{\mathrm{X}_{\mathrm{D}, \mathrm{~F}, \mathrm{fa}, \mathrm{j}}(D)}\right\}
\end{aligned}
$$

The fud decomposition induction correlation of inducer $I_{z}$ must be positive,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{D}, \mathrm{~F}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ I_{z}^{*}\right) \geq 0\right)
$$

Conjecture that, for some parameter tuples, $P$, the fud decomposition induction correlation of the practicable highest-layer summed shuffle content alignment valency-density fud decomposition inducer, $I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime}$, is positive,

$$
\forall z \in \mathbf{N}_{>0}\left(\operatorname{cov}(z)\left(\operatorname{maxr} \circ X_{z, \mathrm{xi}, \mathrm{D}, \mathrm{~F}, \mathrm{yy}, \mathrm{fa}, \mathrm{j}}, \operatorname{maxr} \circ I_{z, \mathrm{Scsd}, \mathrm{D}, \mathrm{~F}, \infty, \mathrm{q}, P, \mathrm{~d}}^{\prime *}\right) \geq 0\right)
$$

Evidence for this conjecture may be seen by considering (a) the extension of the aligned induction assumptions for fud decompositions and (b) the approximation made by the practicable inducer.

In aligned transform induction, where (i) the history probability function is iso-transform-independent historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{y}, T_{\mathrm{o}}}$, given some unknown substrate transform in the sample variables $T_{\mathrm{o}} \in \mathcal{T}_{U, V_{\mathrm{o}}}$, if it is the case that (ii) the iso-transform-independent dependent-independent antioptimisation assumption is true, (iii) the iso-transform-independent underlyinglifted optimisation assumption is true, and (iv) the iso-transform-independent conditional-relative optimisation assumption is true, then the maximum likelihood estimate of the model, $\tilde{T}_{\mathrm{o}}$, at the maximum likelihood estimate of the distribution, $\tilde{E}_{\mathrm{o}}$, is

$$
\left\{\tilde{T}_{\mathrm{o}}\right\}=\operatorname{maxd}\left(\left\{\left(T, \operatorname{algn}\left(A_{\mathrm{o}} * T\right)\right): T \in \mathcal{T}_{U, V_{o}}\right\}\right)
$$

So, in aligned functional definition set decomposition induction, where (i) the history probability function is iso-fud-decomposition-independent historically distributed, $P=P_{U, X, H_{\mathrm{h}}, \mathrm{y}, D_{\mathrm{o}}}$, given some unknown substrate fud decomposition in the sample variables $D_{\mathrm{o}} \in \mathcal{D}_{\mathrm{F}, U, V_{\mathrm{o}}}$, if it is the case that (ii) the iso-fud-decomposition-independent dependent-independent anti-optimisation assumption is true, (iii) the iso-fud-decomposition-independent underlyinglifted optimisation assumption is true, and (iv) the iso-fud-decompositionindependent conditional-relative optimisation assumption is true, then the maximum likelihood estimate of the model, $\tilde{D}_{\mathrm{o}}$, at the maximum likelihood estimate of the distribution, $\tilde{E}_{\mathrm{o}}$, depends on a maximisation of the set of derived alignments for each transform for each fud of the decomposition,

$$
\left\{\left(C,\left\{\left(T, \operatorname{algn}\left(A_{\mathrm{o}} * C * T_{F}\right)\right): T \in F\right\}\right):(C, F) \in \operatorname{cont}\left(D_{\circ}\right)\right\}
$$

As shown in section 'Inducers and Compression', above, in the case of the practicable search function, $Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{q}, \mathrm{d}, P, \mathrm{Scsd}}$, defined,

```
\(Z_{\mathrm{D}, \mathrm{F}, \mathrm{P}, \mathrm{q}, \mathrm{d}, P, \mathrm{Scsd}}(H)=\)
    \(\left\{\left(D, I_{\text {Scsd }}^{*}\left(\left(A_{H}, D\right)\right)\right): Q=\operatorname{leaves}\left(\operatorname{tree}\left(Z_{P, A_{H}, \mathrm{D}, \mathrm{F}, \mathrm{d}}\right)\right), Q \neq \emptyset,\{D\}=Q\right\} \cup\)
    \(\left\{\left(D_{\mathrm{u}}, 0\right)\right\}\)
```

the fuds of the decomposition are built layer by layer,

$$
\forall(i, F) \in L(\operatorname{layer}(F, \operatorname{der}(F))=i)
$$

where $\{L\}=\operatorname{paths}\left(\operatorname{tree}\left(Z_{P, B, B_{R}, \mathrm{~L}, \mathrm{~d}}\right)\right)$, slice $B=A * C$ and the highest-layer limited-layer limited-underlying limited-breadth fud tree searcher is

$$
Z_{P, B, B_{R}, \mathrm{~L}, \mathrm{~d}}=\operatorname{searchTreer}\left(\mathcal{F}_{\infty, U_{B}, V_{B}} \cap \mathcal{F}_{\mathrm{u}} \cap \mathcal{F}_{\mathrm{b}} \cap \mathcal{F}_{\mathrm{h}}, P_{P, B, B_{R}, \mathrm{~L}, \mathrm{~d}},\{\emptyset\}\right)
$$

So the properties of the fuds of the decomposition also depend on layer. In particular the highest-layer fud tree searcher, $Z_{P, B, B_{R}, \mathrm{~L}, \mathrm{~d}}$, is constrained such that the shuffle content alignment valency-density of the derived variables set increases in each layer. The shuffle content alignment valency-density increases in each layer, so, in general, the derived alignment increases up the layers,

$$
\forall i \in\{2 \ldots l\}\left(\operatorname{algn}\left(B * F_{\{1 \ldots i\}}^{\mathrm{T}}\right)>\operatorname{algn}\left(B * F_{\{1 \ldots i-1\}}^{\mathrm{T}}\right)\right)
$$

and so

$$
\forall i \in\{2 \ldots l\}\left(\operatorname{algn}\left(A * C * F_{\{1 \ldots i\}}^{\mathrm{T}}\right)>\operatorname{algn}\left(A * C * F_{\{1 \ldots i-1\}}^{\mathrm{T}}\right)\right)
$$

The limited-layer limited-underlying limited-breadth fud tree searcher neighbourhood function is

$$
\begin{aligned}
& P_{P, B, B_{R}, \mathrm{~L}}(F)= \\
& \quad\left\{G: F \cup\left\{\begin{array}{l} 
\\
G=F \cup\left\{T \in \operatorname{topd}(\lfloor\operatorname{bmax} / \operatorname{mmax}\rfloor)\left(\operatorname{elements}\left(Z_{P, B, B_{R}, F, \mathrm{~B}}\right)\right),\right. \\
\\
H \in \operatorname{topd}(\operatorname{pmax})\left(\operatorname{elements}\left(Z_{P, B, B_{R}, F, \mathrm{n},-, K}\right)\right), \\
\\
\left.w \in \operatorname{der}(H), I=\operatorname{depends}(\operatorname{explode}(H),\{w\}), T=I^{\mathrm{TPT}}\right\}, \\
\operatorname{layer}(G, \operatorname{der}(G)) \leq \operatorname{lmax}\}
\end{array}\right.\right.
\end{aligned}
$$

where $Z_{P, B, B_{R}, F, \mathrm{n},-, K}$ is the contracted decrementing linear non-overlapping fuds list maximiser. The decrementing maximiser optimiser function is

$$
\begin{aligned}
X_{P, B, B_{R}, F, \mathrm{n},-, K}=\{ & \left(H, I_{\mathrm{csd}}^{*}\left(\left(B, B_{R}, G^{\prime}\right)\right)\right): \\
& \left.H \in \mathcal{F}_{U_{B}, \mathrm{n},-, K, \overline{\mathrm{~b}, \mathrm{mmax}, \overline{2}}}, G^{\prime}=\operatorname{depends}(F \cup H, \operatorname{der}(H))\right\}
\end{aligned}
$$

The shuffle content alignment valency-density increases in each layer because the decrementing maximiser, $Z_{P, B, B_{R}, F, \mathbf{n},-, K}$, maximises the shuffle content alignment valency-density, $I_{\mathrm{csd}}^{*}\left(\left(B, B_{R}, G^{\prime}\right)\right)$, by value rolling the underlying tuple, $K$. Conjecture, therefore that the derived alignment for the transform for the fud, $\operatorname{algn}\left(A * C * G^{\prime \mathrm{T}}\right)$, also tends to be maximised. In fact, the fud tree searcher, $Z_{P, B, B_{R}, \mathrm{~L}, \mathrm{~d}}$, explodes the resultant fud, explode $(H)$, so the
cardinality of the set of iso-fud-independents, $Y_{U, i, G, z_{B}}^{-1}\left(Y_{U, G, z_{B}}(B)\right)$, is larger than it otherwise would be. This, however, is merely a detail of the implementation, and a practicable inducer can easily be defined with the stricter iso-set, $Y_{U, \mathrm{i}, F \cup\left\{H^{\mathrm{T}}\right\}, z_{B}}^{-1}\left(Y_{U, F \cup\left\{H^{\mathrm{T}}\right\}, z_{B}}(B)\right)$.

To conclude, conjecture that for all model types there is a definition of aligned modelled induction corresponding to every definition of classical modelled induction. That is, both classical induction and aligned induction may be regarded as special cases of induction in general.

## A Miscellaneous

## A. 1 Algebra of history

The multiply $(*)$ and reduce $(V)$ functions are more obviously dual, in the sense that they increase or decrease the cardinality of the set of variables, when defined for history. These functions do not require equality to be determined for the event identifier. For multiplication we can simply put the event identifiers in a pair to preserve uniqueness, $(*) \in \mathcal{H} \times \mathcal{H} \rightarrow \mathcal{H}$,
$H * G:=\{((X, Y), S \cup T):(X, S) \in H,(Y, T) \in G,|\operatorname{vars}(S \cup T)|=|S \cup T|\}$
In the case of reduction the event identifiers are left entirely alone, reduce $\epsilon$ $\mathrm{P}(\mathcal{V}) \rightarrow(\mathcal{H} \rightarrow \mathcal{H})$

$$
\text { reduce }(V)(H):=\{(X, \text { filter }(V, S)):(X, S) \in H\}
$$

By contrast, addition and particularly subtraction are more awkward for histories because we must concern ourselves with the equality of the event identifiers. The natural definition for addition would be $H+G:=H \cup G$,
but only where $\operatorname{dom}(H) \cap \operatorname{dom}(G)=\emptyset$. If this condition does not hold, then we must prefix the event identifiers with positional identifiers, for example,

$$
H+G:=\{((l, X), S):(X, S) \in H\} \cup\{((r, Y), T):(Y, T) \in G\}
$$

where $\operatorname{vars}(H)=\operatorname{vars}(G)$. Similarly, the natural definition for subtraction would be $H-G:=H \backslash G$, but only where $G \subseteq H$. This would be the case if $G$ is drawn from $H$, thus appearing in the support of the historical distribution. If not, however, we must map the event identifiers with an outer dot product and then do the set minus, for example,

$$
H-G:=H \backslash\left\{\left(D_{X}, S\right):(X, S) \in G\right\}
$$

where $D \in H \cdot=G$ and $\forall((X, S),(Y, T)) \in D(S=T)$.
The reciprocal ( $1 /$ ) is not easy to implement for history at all. Division of histories may be best left as quotient pair $\mathcal{H} \times \mathcal{H}$, similar to the definition of the rational numbers $\mathbf{Q}$.

## A. 2 Histogram expressions

The set of operators $\mathcal{O}_{U}$ on histograms in system $U$ is defined

$$
\mathcal{O}_{U}=\{(+),(-),(*),(1 /)\} \cup\{\operatorname{reduce}(V): V \in \mathrm{P}(\operatorname{vars}(U))\}
$$

A histogram expression in system $U$ is an ordered tree where the nodes are (i) histograms, $\mathcal{A}_{U}$, or (ii) free variable identifiers which are pairs of (a) a natural number and (b) a set of variables, $\mathbf{N} \times \mathrm{P}(\mathcal{V})$, or (iii) pairs of (a) an operator and (b) a non-empty recursive list of histogram expressions, $\mathcal{O}_{U} \times \mathcal{L}\left(\mathcal{E}_{U}\right)$. The arity of the operator-expression list pair $(\mathrm{op}, L) \in \mathcal{O}_{U} \times \mathcal{L}\left(\mathcal{E}_{U}\right)$ is the length of the list, $|L|$. The reduction operators are unary. There are $2^{|U|}$ reduction operators. The reciprocal operator is unary. The subtraction operator is binary. The addition and multiplication operators are n -ary, with notation $\sum$ and $\Pi$ respectively, where they are not specifically binary.

The set of all histogram expressions $\mathcal{E}_{U}$ in system $U$ is recursively defined as

$$
\mathcal{E}_{U}=\mathcal{A}_{U} \cup(\mathbf{N} \times \mathrm{P}(\mathcal{V})) \cup\left(\mathcal{O}_{U} \times \mathcal{L}\left(\mathcal{E}_{U}\right)\right)
$$

where $\mathcal{L}$ is the generic list. The set of histogram expressions is a special case of a lambda calculus.

The function vars $\in \mathcal{E}_{U} \rightarrow \mathrm{P}(\mathcal{V})$ returns the variables of the root of a histogram expression. Histogram expressions are constrained such that the free variable identifier pairs, $\mathbf{N} \times \mathrm{P}(\mathcal{V})$, in the expression tree form a list. The function free $\in \mathcal{E}_{U} \rightarrow \mathcal{L}(\mathrm{P}(\mathcal{V}))$ returns the list of free variable identifiers. The function paths $\in \mathcal{E}_{U} \rightarrow \mathrm{P}\left(\mathcal{L}\left(\mathcal{E}_{U}\right)\right)$ returns all paths in the tree between a free variable identifier and the root.

The function substitute $\in \mathcal{L}(\mathcal{A}) \times \mathcal{E}_{U} \rightarrow \mathcal{E}_{U}$ substitutes the free variables in the expression tree. The substitution substitute $(L, N)$ is defined if $|L|=$ $\mid$ free $(N) \mid$ and $\forall i \in\{1 \ldots|L|\}\left(\operatorname{vars}\left(L_{i}\right)=\right.$ free $\left.(N)(i)\right)$. The substituted $e x$ pression has no free variables, free(substitute $(L, N))=\emptyset$.

The function evaluate $\in \mathcal{E}_{U} \rightarrow \mathcal{A}_{U}$ evaluates an expression. It is defined only for expressions without free variables free $(N)=\emptyset$.

Define a notation of a histogram expression $N \in \mathcal{E}_{U}$ followed by an argument list of histograms in round brackets, $N(A), N(A, B)$, etc, for the substitution of the argument list and evaluation of the substituted histogram expression. That is, the histogram expression application is

$$
N(A)=\operatorname{evaluate}(\text { substitute }(\{(1, A)\}, N))
$$

and

$$
N(A, B)=\operatorname{evaluate}(\text { substitute }(\{(1, A),(2, B)\}, N))
$$

and so on.

The implementation of the substitution and evaluation steps are not described here, except to note that there are a number of ways in which an expression can be simplified before substitution. Operators are left associative, but multiplications are commutative and additions are commutative. For example, a sequence of multiplications on histograms in an expression can be reduced to a single histogram, for example, $A * B * C * D=A * E$ where $A$ is the free variable. A sequence of reductions is equivalent to the reduction of the intersection of the variables $A \% W \% V=A \%(W \cap V)$. An addition followed by a reduction can be split into the addition of reductions $(A+B) \% W=(A \% W)+(B \% W)$ where $A$ and $B$ are free variables.

The set of models $\mathcal{M}_{U}$ in system $U$ are a subset of histogram expressions, $\mathcal{M}_{U} \subset \mathcal{E}_{U}$. A model $M \in \mathcal{M}_{U}$ in variables $V$, (i) is a histogram expression which has a single free variable histogram, free $(M)=\{(1, V)\}$, (ii) evaluates to a histogram in the same variables, $\operatorname{vars}(M)=\operatorname{vars}(M(A))=V$ where
$V=\operatorname{vars}(A)$, and (iii) is constrained such that all paths at some point are reduced to exclude the argument variables

$$
\forall P \in \operatorname{paths}(M) \exists E \in \operatorname{set}(P)(\operatorname{vars}(E) \cap V=\emptyset)
$$

Models are frames between $M(A)$ and $A$ such that at some point there is an internal representation in variables exclusive of the variables of start and end nodes of the graph of the histogram expression.

The application notation can be extended to lists of histogram expressions. A histogram expression list $R \in \mathcal{L}\left(\mathcal{E}_{U}\right)$ may be applied to an argument histogram $A \in \mathcal{A}_{U}$ in sequence to produce a list of histograms. Define histogram expression list application $R(A) \in \mathcal{L}\left(\mathcal{A}_{U}\right)$ such that $R(A)_{1}=A$, $|R(A)|=|R|+1$ and $\forall i \in\{1 \ldots|R|\}\left(R(A)_{i+1}=R_{i}\left(R(A)_{i}\right)\right)$. Each of the expressions in the expression list has exactly one free variable, $\forall N \in$ $\operatorname{set}(R)(|\operatorname{free}(N)|=1)$, which has the same variables as the previous expression, $\forall i \in\{1 \ldots|R|-1\}\left(\operatorname{free}\left(R_{i+1}\right)=\left\{\left(1, \operatorname{vars}\left(R_{i}\right)\right)\right\}\right)$. The histogram expression list, $R$, and its application, $R(A)$, together resemble a Markov chain if the histogram expression list is independent of the application. The application, $R(A)$, is size conserving if the histograms have the same size as the argument, $\forall B \in \operatorname{set}(R(A))(\operatorname{size}(B)=\operatorname{size}(A))$. The application, $R(A)$, is variables conserving if the histograms have the same variables as the argument, $\forall B \in \operatorname{set}(R(A))(\operatorname{vars}(B)=\operatorname{vars}(A))$. The application, $R(A)$, is congruent if the histograms are congruent to the argument, $\forall B \in$ $\operatorname{set}(R(A))(\operatorname{congruent}(B, A))$.

Similarly, the application notation can be extended to trees of histogram expressions. A histogram expression tree $R \in \operatorname{trees}\left(\mathcal{E}_{U}\right)$ may be applied to an argument histogram $A \in \mathcal{A}_{U}$ recursively to produce a tree of histograms. Define histogram expression tree application $R(A) \in \operatorname{trees}\left(\mathcal{A}_{U}\right)$ such that $\operatorname{dom}(\operatorname{roots}(R(A)))=\{A\}$ and $R(A)=\left\{\left(A, R^{\prime}(N(A))\right):\left(N, R^{\prime}\right) \in R\right\}$ where $\emptyset(A)=\emptyset$. Each of the expressions in the expression tree has exactly one free variable, $\forall N \in \operatorname{elements}(R)(|\operatorname{free}(N)|=1)$.

Let $N_{(D, I)} \in \mathcal{E}_{U}$ be a histogram expression of delta $(D, I) \in \mathcal{A} \times \mathcal{A}$ having variables $\operatorname{vars}(D)=\operatorname{vars}(I)=V$. The expression application to histogram $A$ in variables $V$ is such that $N_{(D, I)}(A)=A-D+I \in \mathcal{A}$. Define

$$
N_{(D, I)}=((+),\{(1,((-),\{(1,(1, V)),(2, D)\})),(2, I)\})
$$

Let $N_{R} \in \mathcal{E}_{U}$ be a histogram expression of roll $R \in$ rolls having variables $V$. The expression application to histogram $A$ in variables $V$ is such that
$N_{R}(A)=A * R \in \mathcal{A}$. The roll histogram expression can be defined in terms of a delta histogram expression, $N_{R}=N_{\left(N_{D}, N_{I}\right)}$. The delta is defined as

$$
\left(\sum_{S \in A^{\mathrm{S}} \cap \operatorname{dom}(R)}\left\{\left(S, A_{S}\right)\right\}, \sum_{S \in A^{\mathrm{S}} \cap \operatorname{dom}(R)}\left\{\left(R_{S}, A_{S}\right)\right\}\right)
$$

which equals

$$
\left(\sum_{S \in A^{\mathrm{S}} \cap \operatorname{dom}(R)} A *\{S\}^{\mathrm{U}}, \sum_{S \in A^{\mathrm{S}} \cap \operatorname{dom}(R)} A *\{S\}^{\mathrm{U}} \% \emptyset *\left\{R_{S}\right\}^{\mathrm{U}}\right)
$$

so define

$$
\begin{aligned}
N_{D} & =\left((\Sigma),\left\{\left(Q_{S}, N_{S}\right): S \in \operatorname{dom}(Q)\right\}\right) \\
N_{I} & =\left((\Sigma),\left\{\left(Q_{S}, N_{S, R}\right): S \in \operatorname{dom}(Q)\right\}\right)
\end{aligned}
$$

where

$$
N_{S}=\left((*),\left\{(1,(1, V)),\left(2,\{S\}^{\mathrm{U}}\right)\right\}\right)
$$

and

$$
N_{S, R}=\left((*),\left\{\left(1,\left(\operatorname{reduce}(\emptyset),\left\{\left(1, N_{S}\right)\right\}\right)\right),\left(2,\left\{R_{S}\right\}^{\mathrm{U}}\right)\right\}\right)
$$

and $Q \in \operatorname{enums}\left(A^{\mathrm{S}} \cap \operatorname{dom}(R)\right)$.
Let $N_{T} \in \mathcal{E}_{U}$ be a histogram expression of transform $T \in \mathcal{T}$ having underlying variables und $(T)=V$. The expression application to histogram $A$ in variables $V$ is such that $N_{T}(A)=A * T=A * X \% W$ where $(X, W)=T$. Define

$$
N_{T}=(\operatorname{reduce}(W),\{(1,((*),\{(1,(1, V)),(2, X)\}))\})
$$

## A. 3 Cardinality of the power functional definition set

We can calculate an upper bound on the cardinality of the power functional definition set on variables $V$ in system $U$. Let the dimension of the zeroth layer $n=|V|$ and the maximum valency $d=\operatorname{maxr}\left(\left\{\left|U_{v}\right|: v \in V\right\}\right)$. The number of layers $l=\operatorname{bell}\left(d^{n}\right)$. Let $N, D, C \in \mathcal{L}(\mathrm{~N})$ and $|N|=|D|=|C|=$ $l+1$. Let $N_{1}=n$ and $D_{1}=d$. Let $C_{i}=\sum_{j \in\{1 \ldots i\}} N_{j}$.

Let $D$ be such that

$$
\forall i \in\{1 \ldots l\}\left(D_{i+1}=D_{i}^{C_{i}}\right)
$$

Let $N$ be such that

$$
\forall i \in\{1 \ldots l\}\left(N_{i+1}=2^{C_{i}} \operatorname{bell}\left(D_{i+1}\right)\right)
$$

Then

$$
|\operatorname{power}(U)(V)|<C_{l+1}-n
$$

## A. 4 Constructing states order from variables and values orders

Let $D_{\mathrm{V}}$ be an order on the variables in system $U, D_{\mathrm{V}} \in \operatorname{enums}(\operatorname{vars}(U))$. Let $D_{\mathrm{W}} \in \mathcal{V} \rightarrow(\mathcal{W} \leftrightarrow \mathbf{N})$ be a set of orders on the values on each of the variables, such that

$$
\forall(v, Y) \in D_{\mathrm{W}}\left(Y \in \operatorname{enums}\left(U_{v}\right)\right)
$$

then we can construct an order $D_{\mathrm{S}}$ on the states, $D_{\mathrm{S}} \in \operatorname{enums}\left(\mathcal{S}_{U}\right)$
$D_{\mathrm{S}}=\operatorname{order}\left(\left\{\left(S, \sum\left(t^{j} i:(v, w) \in S, j=D_{\mathrm{V}}(v), i=D_{\mathrm{W}}(v)(w)\right)\right): S \in \mathcal{S}_{U}\right\}, \mathcal{S}_{U}\right)$
where $t=\operatorname{maxr}(\{(v,|W|):(v, W) \in U\})+1$.

## A. 5 Coders

A code is an algorithm or type which defines a code domain, an encode method and a decode method such that there is a bijection between the code domain and the natural numbers. Define the set of codes as codes. Define $\mathcal{X}$ as the universal set. Define domain $\in$ codes $\rightarrow \mathrm{P}(\mathcal{X})$. Define encode $\in$ codes $\rightarrow(\mathcal{X} \rightarrow \mathbf{N})$ such that encode $(C) \in$ domain $(C): \rightarrow \mathbf{N}$. Define decode $\in$ codes $\rightarrow(\mathbf{N} \rightarrow \mathcal{X})$ such that decode $(C) \in \mathbf{N} \rightarrow$ : domain $(C)$. Finally constrain codes such that

$$
\forall C \in \operatorname{codes} \forall x \in \operatorname{domain}(C)(\operatorname{decode}(C)(\operatorname{encode}(C)(x))=x)
$$

A subset of the codes are list codes, codeLists $\subset$ codes, for which the code domains are lists of objects in a non-empty listable domain. Define listable $\in$ codeLists $\rightarrow \mathrm{P}(\mathcal{X})$.

$$
\left.\forall C \in \operatorname{codeLists} \diamond Y=\text { listable }(C) \forall i \in \mathbf{N} \forall Q \in Y^{i} \quad \text { list }(Q) \in \operatorname{domain}(C)\right)
$$

An example of a list code is $C \in$ codeLists which is parameterised by some bijection $K_{C} \subset \mathcal{L}(\mathcal{X}) \leftrightarrow \mathbf{N}$. This bijection maps lists of objects to natural numbers. Here the code domain domain $(C)=\operatorname{dom}\left(K_{C}\right)$ and the
listable domain $Y=\operatorname{listable}(C)$ is such that $\operatorname{dom}\left(K_{C}\right)=\{\operatorname{list}(Q): i \in$ $\left.\mathbf{N}, Q \in Y^{i}\right\}$. Define encode for $C$ as encode $(C)(L):=K_{C}(L)$ and decode as decode $(C)(n):=\operatorname{flip}\left(K_{C}\right)(n)$. Thus $C$ encodes any list of objects $L \in \mathcal{L}(Y)$ into a natural number $K_{C}(L) \in \mathbf{N}$ and decodes the natural number $n$ back to the original list $(L, n) \in K_{C}$. Here the encode and decode functions of this list code are easily defined in terms of the relation $K_{C}$.

Now consider a subset of list codes, called coders, coders $\subset$ codeLists, which are not parameterised by straightforward relations, but instead are defined by the code and space of each object of the list domain. In this context list domains are called coder domains. Coders also define the encode and decode methods in terms of code and space rather than by indexing a relation with a list of objects. Coders redefine the decode method to add an extra argument which specifies the length of the list to be decoded. Consider a coder $C \in$ coders which is parameterised by a tuple $Q_{C} \in(\mathcal{X} \leftrightarrow \mathbf{N}) \times\left(\mathcal{X} \rightarrow \mathbf{N}_{>0}\right) \times(\mathbf{N} \rightarrow \mathcal{X})$. Coder definition $Q_{C}$ is a tuple of (i) a code represented by a bijection between objects and natural numbers, (ii) a space function of the objects and (iii) a function which decodes the head object of an encoded list. Define the parameterisation of coders

$$
\text { definition } \in \text { coders } \rightarrow(\mathcal{X} \leftrightarrow \mathbf{N}) \times\left(\mathcal{X} \rightarrow \mathbf{N}_{>0}\right) \times(\mathbf{N} \rightarrow \mathcal{X})
$$

such that
$\forall C \in \operatorname{coders} \forall(E, S, D)=\operatorname{def}(C)(\operatorname{dom}(E)=\operatorname{dom}(S)=\operatorname{ran}(D)=$ listable $(C))$
and

$$
\forall C \in \operatorname{coders} \diamond(E, S, D)=\operatorname{def}(C) \forall x \in \operatorname{listable}(C)\left(E_{x}<S_{x}\right)
$$

and

$$
\forall C \in \operatorname{coders} \diamond(E, S, D)=\operatorname{def}(C)(\operatorname{flip}(E) \subset D)
$$

Define encode $\in$ coders $\rightarrow(\mathcal{L}(\mathcal{X}) \rightarrow \mathbf{N})$ and encode $(C) \in \mathcal{L}(Y): \rightarrow \mathbf{N}$ as

$$
\text { encode }(C)(L):=\operatorname{encode}(C) \text { (sequence }(L))
$$

where $Y=\operatorname{listable}(C)$.
Define encode $(C) \in \mathcal{K}(Y): \rightarrow \mathbf{N}$

$$
\begin{aligned}
\operatorname{encode}(C)((x, K)) & :=\operatorname{encode}(C)(K) \times S_{x}+E_{x} \\
\operatorname{encode}(C)(\emptyset) & :=0
\end{aligned}
$$

where $(E, S, D)=$ definition $(C)$.
Define decode $\in$ coders $\rightarrow(\mathbf{N} \times \mathbf{N} \rightarrow \mathcal{L}(\mathcal{X}))$ and decode $(C) \in \mathbf{N} \times \mathbf{N} \rightarrow$ : $\mathcal{L}(Y)$ as

$$
\operatorname{decode}(C)(l, n):=\operatorname{list}(\operatorname{decode}(C)(l, n))
$$

Define decode $(C) \in \mathbf{N} \times \mathbf{N} \rightarrow: \mathcal{K}(Y)$

$$
\begin{aligned}
\operatorname{decode}(C)(l, n) & :=\left(D_{n}, \operatorname{decode}(C)\left(l-1, n / S\left(D_{n}\right)\right)\right) \\
\operatorname{decode}(C)(0, n) & :=\emptyset
\end{aligned}
$$

The divide operator is the natural number operator.
Now we constrain coders to be list codes

$$
\begin{aligned}
& \forall C \in \text { coders } \diamond Y=\operatorname{listable}(C) \\
& \quad \forall i \in \mathbf{N} \forall Q \in Y^{i} \diamond L=\operatorname{list}(Q)(\operatorname{decode}(C)(|L|, \operatorname{encode}(C)(L))=L)
\end{aligned}
$$

If the coder domain is finite then $E$ and $S$ are finite. However $D$ is always infinite because its domain is the encoding of any list of the coder domain.

This definition of coder allows us to define space for each of the elements of the coder domain, space $(C) \in Y: \rightarrow \ln \mathbf{N}_{>0}$, where $Y=$ listable $(C)$,

$$
\operatorname{space}(C)(x):=\ln S_{x}
$$

where $(E, S, D)=$ definition $(C)$.
The space required to encode a list $L \in \mathcal{L}(Y)$ is the sum of the spaces of the list elements,

$$
\sum_{i \in\{1 \ldots|L|\}} \operatorname{space}(C)\left(L_{i}\right) \geq \ln (\operatorname{encode}(C)(L)+1)
$$

In the case where the space is constant, $|\operatorname{ran}(S)|=1$, the decode method can be implemented generically. This is called the fixed-width case. All other cases are variable-width coders. In the fixed-width case, where $\{s\}=\operatorname{ran}(S)$, we can define a decode function in terms of the code parameter $E$ and the space parameter $Y \times\{s\}$ of the coder definition

$$
\begin{aligned}
\operatorname{decode}(C)(l, n) & :=(\operatorname{flip}(E)(n \% s), \operatorname{decode}(C)(l-1, n / s)) \\
\operatorname{decode}(C)(0, n) & :=\emptyset
\end{aligned}
$$

Modulus and divide are the natural number operators.
The decode parameter $D$, where $(E, S, D)=$ definition $(C)$, for variable-width coders must have an algorithm that is explicitly defined for the coder.

Define the subset of coders having some particular listable domain $Y$ with a convenient construct, coders $(Y) \subset$ coders

$$
\operatorname{coders}(Y)=\{C: C \in \text { coders, listable }(C)=Y\}
$$

The total space of a coder of a non-empty finite coder domain, $Y$, is the space of any of the lists of $Y,\{\operatorname{flip}(N): N \in \operatorname{enums}(Y)\}$. By Gibbs' inequality,

$$
\sum_{x \in Y} \operatorname{space}(C)(x) \geq|Y| \ln |Y|
$$

where $C \in \operatorname{coders}(Y)$. A minimal coder is a member of the subset of the coders which are such that the total space is equal to $|Y| \ln |Y|$. Contrast this to an enumeration of $Y$ which cannot itself be the space in a valid coder $\forall S \in \operatorname{enums}(Y)((E, S, D) \neq$ definition $(C))$, because

$$
\sum_{x \in Y} \ln S_{x}=\sum_{i \in\{1 \ldots|Y|\}} \ln i=\ln |Y|!<|Y| \ln |Y|
$$

where $S \in \operatorname{enums}(Y)$. We can see that such a coder which had an enumeration of $Y$ as the definition of the space would have total space equal to that required for a permutation of $Y$, but not a list, and hence $Y$ would not be listable by the coder.

Consider a non-empty list $L \in \mathcal{L}(Y)$ of a coder domain $Y$. The list, $L$, implies a probability function $P \in\left(Y: \rightarrow \mathbf{Q}_{>0}\right) \cap \mathcal{P}$ which is such that $\operatorname{dom}(P)=Y$ and $\operatorname{sum}(P)=1$. Let $Q=\operatorname{count}(f l i p(L))$ in

$$
P=\{(x, f / \operatorname{sum}(Q)):(x, f) \in Q\} \cup((Y \backslash \operatorname{dom}(Q)) \times\{0\})
$$

Let coder $C$ have domain $Y$ so that decode $(|L|$, encode $(C)(L))=L$. The expected space of coder $C$ of an element in $Y$ in probability function $P$ is

$$
\operatorname{expected}(P)(\operatorname{space}(C))=\sum_{x \in Y} P_{x} \times \operatorname{space}(C)(x)
$$

The scaled expected space in the uniform probability function $P=Y \times\{1 /|Y|\}$ where $\operatorname{flip}(L) \in$ enums $(Y)$ equals the total space

$$
|Y| \times \operatorname{expected}(Y \times\{1 /|Y|\})(\operatorname{space}(C))=\operatorname{sum}(\operatorname{space}(C))
$$

See the discussion 'Coders and entropy', below, for the case where the expected space equals the entropy of the probability function.

One can go on to consider coders of coders. That is, coders that encode and decode by means of nested coders. An example is of the variable coder of histories which has an entropy coder of states for each history. See appendix 'Entropy encoding of states', below. Another example is where the coder domain consists of lists or trees. See appendix 'List and tree coders', below.

## A.5.1 List and tree coders

Consider the subset coders $(\mathcal{L}(\mathcal{Z}))$ of coders where the coder domains are lists of some underlying type, $\mathcal{Z}$, which itself has a coder in $\operatorname{coders}(\mathcal{Z})$. The underlying coder is specified in the parameters of the coders of lists. Here we shall define two kinds of coder where the coder domain consists of lists. The first kind, called the limited coder of lists has a maximum list length also specified in the parameters, so that the limited coder domain is finite if the underlying coder domain is also finite. The second kind, called the unlimited coder of lists, needs no such parameter, using a termination flag instead. The coder domain of the unlimited coder of lists is by definition infinite, regardless of whether the underlying coder domain is infinite.

Define the limited coder of lists

$$
\text { coderListLimited } \in \operatorname{coders}(\mathcal{Z}) \times \mathbf{N} \rightarrow \operatorname{coders}(\mathcal{L}(\mathcal{Z}))
$$

Let $C_{\mathrm{Z}} \in \operatorname{coders}(\mathcal{Z})$ in

$$
C_{\mathrm{L}}=\operatorname{coderListLimited}\left(C_{\mathrm{Z}}, y\right) \in \operatorname{coders}\left(\mathcal{L}_{y}(\mathcal{Z})\right)
$$

where $\mathcal{L}_{y}(\mathcal{Z})$ is the set of all lists of the underlying coder domain of length less than or equal to $y, \mathcal{L}_{y}(\mathcal{Z})=\{L: L \in \mathcal{L}(\mathcal{Z}),|L| \leq y\} . \mathcal{L}_{y}(\mathcal{Z})$ is a finite set if $\mathcal{Z}$ is finite.

The code $E_{\mathrm{L}}$ of the coder definition of $C_{\mathrm{L}},\left(E_{\mathrm{L}}, S_{\mathrm{L}}, D_{\mathrm{L}}\right)=\operatorname{definition}\left(C_{\mathrm{L}}\right)$, is defined such that a list $L \in \mathcal{L}_{y}(\mathcal{Z})$ is encoded as a pair of its length and the list itself $(|L|, L)$

$$
\begin{aligned}
E_{\mathrm{L}}(L) & :=\operatorname{encode}\left(C_{\mathrm{Z}}\right)(L) \times(y+1)+|L| \\
E_{\mathrm{L}}(\emptyset) & :=0
\end{aligned}
$$

The space is defined

$$
\begin{aligned}
S_{\mathrm{L}}(L) & :=(y+1) \prod_{(i, x) \in L} S_{\mathrm{Z}}(x) \\
S_{\mathrm{L}}(\emptyset) & :=(y+1)
\end{aligned}
$$

where $\left(E_{\mathrm{Z}}, S_{\mathrm{Z}}, D_{\mathrm{Z}}\right)=$ definition $\left(C_{\mathrm{Z}}\right)$. Define the decode parameter

$$
\begin{aligned}
D_{\mathrm{L}}(n) & :=\operatorname{decode}\left(C_{\mathrm{Z}}\right)(n \%(y+1), n /(y+1)) \\
D_{\mathrm{L}}(0) & :=\emptyset
\end{aligned}
$$

If we take the core space of a list $L$ as $\sum_{(i, x) \in L}$ space $\left(C_{\mathrm{Z}}\right)(x)$, then the additional overhead space to encode the list in coder $C_{\mathrm{L}}$ is $\ln (y+1)$.

In the case of a fixed-width underlying coder, $S_{\mathrm{Z}}=\mathcal{Z} \times\{s\}$, then we can simplify. Define $\operatorname{dec\operatorname {Lim}}\left(E_{\mathrm{Z}}, s\right) \in \mathbf{N} \times \mathbf{N} \rightarrow \mathcal{K}(\mathcal{Z})$.

$$
\begin{aligned}
D_{\mathrm{L}}(n) & :=\operatorname{list}\left(\operatorname{dec} \operatorname{Lim}\left(E_{\mathrm{Z}}, s\right)(n \%(y+1), n /(y+1))\right) \\
D_{\mathrm{L}}(0) & :=\emptyset
\end{aligned}
$$

and

$$
\begin{aligned}
\operatorname{dec} \operatorname{Lim}\left(E_{\mathrm{Z}}, s\right)(i, n) & :=\left(\operatorname{flip}\left(E_{\mathrm{Z}}\right)(n \% s), \operatorname{dec} \operatorname{Lim}\left(E_{\mathrm{Z}}, s\right)(i-1, n / s)\right) \\
\operatorname{dec} \operatorname{Lim}\left(E_{\mathrm{Z}}, s\right)(0, n) & :=\emptyset
\end{aligned}
$$

The space parameter of a list is $S_{\mathrm{L}}(L):=(y+1) s^{|L|}$ and so space $\left(C_{\mathrm{L}}\right)(L)=$ $\ln (y+1)+|L| \ln s$.

A closely related limited list coder $C_{\mathrm{L}, \mathrm{N}}$ allows only non-empty lists in the coder domain

$$
C_{\mathrm{L}, \mathrm{~N}}=\operatorname{coderListNonEmptyLimited}\left(C_{\mathrm{Z}}, y\right) \in \operatorname{coders}\left(\mathcal{L}_{y}(\mathcal{Z}) \backslash\{\emptyset\}\right)
$$

The code $E_{\mathrm{L}, \mathrm{N}}$ is defined $E_{\mathrm{L}, \mathrm{N}}(L):=\operatorname{encode}\left(C_{\mathrm{Z}}\right)(L) \times y+|L|-1$, the space $S_{\mathrm{L}, \mathrm{N}}$ is defined $S_{\mathrm{L}, \mathrm{N}}(L):=y \prod_{(i, x) \in L} S_{\mathrm{Z}}(x)$ and the decode $D_{\mathrm{L}, \mathrm{N}}$ parameter is defined $D_{\mathrm{L}, \mathrm{N}}(n):=\operatorname{list}\left(\operatorname{dec} \operatorname{Lim}\left(S_{\mathrm{Z}}, D_{\mathrm{Z}}\right)(n \% y+1, n / y)\right)$. The difference between $C_{\mathrm{L}}$ and $C_{\mathrm{L}, \mathrm{N}}$ is that the space of a non-empty list is smaller in $C_{\mathrm{L}, \mathrm{N}}$. The overhead space to encode the list in coder $C_{\mathrm{L}, \mathrm{N}}$ is $\ln y$.

Also related to limited list coders are set coders where the coder domain is not a list of some underlying coder domain, $\mathcal{L}(\mathcal{Z})$ but instead a set, $\mathrm{P}(\mathcal{Z})$.

Set coder domains are finite and their underlying coder domains are also finite.

$$
C_{\mathrm{S}}=\operatorname{coderSet}\left(C_{\mathrm{Z}}\right) \in \operatorname{coders}(\mathrm{P}(\mathcal{Z}))
$$

$C_{\mathrm{S}}$ encodes a subset $Q \subset \mathcal{Z}$ by first encoding the subset cardinality $|Q|$, then the combination. The combination maps to a list of the underlying objects ordered by the encode parameter of the underlying coder definition, $\operatorname{order}\left(E_{\mathrm{Z}}, Q\right)$. The space is space $\left(C_{\mathrm{S}}\right)(Q)=\ln (y+1)+\ln (y!/(z!(y-z)!)$ where $y=|\mathcal{Z}|$ and $z=|Q|$. Note that there is no need to encode the underlying directly. An alternative method is to encode a list of bits which signify set membership. In this method the space comes to $y \ln 2$.

The second kind of coder, which is the unlimited coder of lists, uses a termination flag to stop the decode iteration. The coder domain is infinite, whether the underlying coder domain is finite or not. Define the unlimited coder of lists

$$
\text { coderListTerminating } \in \operatorname{coders}(\mathcal{Z}) \rightarrow \operatorname{coders}(\mathcal{L}(\mathcal{Z}))
$$

Let $C_{\mathrm{Z}} \in \operatorname{coders}(\mathcal{Z})$ in

$$
C_{\mathrm{U}}=\operatorname{coderListTerminating}\left(C_{\mathrm{Z}}\right) \in \operatorname{coders}(\mathcal{L}(\mathcal{Z}))
$$

The code $E_{\mathrm{U}}$ of the coder definition of $C_{\mathrm{U}},\left(E_{\mathrm{U}}, S_{\mathrm{U}}, D_{\mathrm{U}}\right)=$ definition $\left(C_{\mathrm{U}}\right)$, is defined such that a list $L \in \mathcal{L}(\mathcal{Z})$ is encoded as a list of pairs of a continuation code $0 \in$ bits and the element of the list itself, or the termination code $1 \in$ bits, $\mathcal{L}((\{0\} \times \mathcal{Z}) \cup\{1\})$

$$
E_{\mathrm{U}}(L):=\operatorname{encTerm}\left(E_{\mathrm{Z}}, S_{\mathrm{Z}}\right)(\text { sequence }(L))
$$

where $\left(E_{\mathrm{Z}}, S_{\mathrm{Z}}, D_{\mathrm{Z}}\right)=\operatorname{definition}\left(C_{\mathrm{Z}}\right)$. Define $\operatorname{encTerm}\left(E_{\mathrm{Z}}, S_{\mathrm{Z}}\right) \in \mathcal{K}(\mathcal{Z}) \rightarrow \mathbf{N}$ as

```
\(\operatorname{encTerm}\left(E_{\mathrm{Z}}, S_{\mathrm{Z}}\right)((x, K)):=\left(\operatorname{encTerm}\left(E_{\mathrm{Z}}, S_{\mathrm{Z}}\right)(K) \times S_{\mathrm{Z}}(x)+E_{\mathrm{Z}}(x)\right) \times 2\)
    \(\operatorname{encTerm}\left(E_{\mathrm{Z}}, S_{\mathrm{Z}}\right)(\emptyset):=1\)
```

The space is defined

$$
\begin{aligned}
& S_{\mathrm{U}}(L):=2 \prod_{(i, x) \in L} 2 S_{\mathrm{Z}}(x)=2^{(|L|+1)} \prod_{(i, x) \in L} S_{\mathrm{Z}}(x) \\
& S_{\mathrm{U}}(\emptyset):=2
\end{aligned}
$$

Define the decode parameter

$$
\begin{aligned}
D_{\mathrm{U}}(n) & :=\operatorname{list}\left(\operatorname{decTerm}\left(S_{\mathrm{Z}}, D_{\mathrm{Z}}\right)(n)\right) \\
D_{\mathrm{U}}(1) & :=\emptyset \\
D_{\mathrm{U}}(0) & :=\emptyset
\end{aligned}
$$

Define $\operatorname{dec} \operatorname{Term}\left(S_{\mathrm{Z}}, D_{\mathrm{Z}}\right) \in \mathbf{N} \rightarrow \mathcal{K}(\mathcal{Z})$ as

$$
\operatorname{dec} \operatorname{Term}\left(S_{\mathrm{Z}}, D_{\mathrm{Z}}\right)(n):=\left(D_{\mathrm{Z}}(n / 2), \operatorname{dec} \operatorname{Term}\left(S_{\mathrm{Z}}, D_{\mathrm{Z}}\right)\left(n /\left(2 S_{\mathrm{Z}}\left(D_{\mathrm{Z}}(n / 2)\right)\right)\right)\right)
$$

where $n \% 2=0$, otherwise $\operatorname{dec} \operatorname{Term}\left(S_{\mathrm{Z}}, D_{\mathrm{Z}}\right)(n):=\emptyset$.
The overhead space to encode the list in coder $C_{\mathrm{U}}$ is $(|L|+1) \ln 2$.
In the case of a fixed-width underlying coder, $S_{\mathrm{Z}}=\mathcal{Z} \times\{s\}$, that by definition must have a finite coder domain $\mathcal{Z}$, we can replace the termination flag with a terminating code number $s, \mathcal{L}(\mathcal{Z} \cup\{s\})$

$$
C_{\mathrm{U}, \mathrm{~F}}=\operatorname{coderListTerminatingFixed}\left(C_{\mathrm{Z}}\right) \in \operatorname{coders}(\mathcal{L}(\mathcal{Z}))
$$

Then

$$
\left.E_{\mathrm{U}, \mathrm{~F}}(L):=\operatorname{encTerm}\left(E_{\mathrm{Z}}, s\right) \text { (sequence }(L)\right)
$$

Define encTerm $\left(E_{\mathrm{Z}}, s\right) \in \mathcal{K}(\mathcal{Z}) \rightarrow \mathbf{N}$ as

$$
\begin{aligned}
\operatorname{encTerm}\left(E_{\mathrm{Z}}, s\right)((x, K)) & :=\operatorname{encTerm}\left(E_{\mathrm{Z}}, s\right)(K) \times(s+1)+E_{\mathrm{Z}}(x) \\
\operatorname{encTerm}\left(E_{\mathrm{Z}}, s\right)(\emptyset) & :=s
\end{aligned}
$$

The space is defined

$$
S_{\mathrm{U}, \mathrm{~F}}(L):=(s+1)^{|L|+1}
$$

Define the decode parameter

$$
\begin{aligned}
D_{\mathrm{U}, \mathrm{~F}}(n) & :=\operatorname{list}\left(\operatorname{dec} \operatorname{Term}\left(E_{\mathrm{Z}}, s\right)(n)\right) \\
D_{\mathrm{U}, \mathrm{~F}}(s) & :=\emptyset
\end{aligned}
$$

Define $\operatorname{dec} \operatorname{Term}\left(E_{\mathbf{Z}}, s\right) \in \mathbf{N} \rightarrow \mathcal{K}(\mathcal{Z})$ as

$$
\operatorname{dec} \operatorname{Term}\left(E_{\mathrm{Z}}, s\right)(n):=\left(\operatorname{flip}\left(E_{\mathrm{Z}}\right)(n \%(s+1)), \operatorname{dec} \operatorname{Term}\left(E_{\mathrm{Z}}, s\right)(n /(s+1))\right)
$$

where $n \%(s+1) \neq s$, otherwise $\operatorname{dec} \operatorname{Term}\left(E_{\mathrm{Z}}, s\right)(n):=\emptyset$.
The overhead space to encode the list in coder $C_{\mathrm{U}, \mathrm{F}}$ is $(|L|+1) \ln (s+1)-$ $|L| \ln s$.

Another unlimited list coder, $C_{\mathrm{U}, \mathrm{N}}$, allows only non-empty lists in the coder domain

$$
C_{\mathrm{U}, \mathrm{~N}}=\operatorname{coderListNonEmptyTerminating}\left(C_{\mathrm{Z}}\right) \in \operatorname{coders}(\mathcal{L}(\mathcal{Z}) \backslash\{\emptyset\})
$$

The code $E_{\mathrm{U}, \mathrm{N}}$ of the coder definition of $C_{\mathrm{U}, \mathrm{N}}$ is defined such that a nonempty list $L \in \mathcal{L}(\mathcal{Z} \backslash\{\emptyset\})$ is encoded as a list of pairs of a termination flag and the element of the list itself, $\mathcal{L}($ bits $\times \mathcal{Z})$. The overhead space to encode the list in coder $C_{\mathrm{U}, \mathrm{N}}$ is $|L| \ln 2$.

In some cases the underlying coder depends on the list so far. In order to implement this requirement we define a function of the list which returns the underlying coder. These list coders are called lookback list coders. For example the lookback unlimited list coder

$$
\text { coderListTerminatingLookback } \in(\mathcal{L}(\mathcal{Z}) \rightarrow \operatorname{coders}(\mathcal{Z})) \rightarrow \operatorname{coders}(\mathcal{L}(\mathcal{Z}))
$$

Let $B_{\mathrm{Z}} \in \mathcal{L}(\mathcal{Z}) \rightarrow \operatorname{coders}(\mathcal{Z})$ in

$$
C_{\mathrm{U}, \mathrm{~B}}=\operatorname{coderListTerminatingLookback}\left(B_{\mathrm{Z}}\right) \in \operatorname{coders}(\mathcal{L}(\mathcal{Z}))
$$

The coder $C_{\mathrm{U}, \mathrm{B}}$ is defined exactly as $C_{\mathrm{U}}$ above except that we replace $\left(E_{\mathrm{Z}}, S_{\mathrm{Z}}, D_{\mathrm{Z}}\right)=$ definition $\left(C_{\mathrm{Z}}\right)$ with $\left(E_{\mathrm{Z}}, S_{\mathrm{Z}}, D_{\mathrm{Z}}\right)=$ definition $\left(B_{\mathrm{Z}}(M)\right)$ where $M \in \mathcal{L}(\mathcal{Z})$ is the list already encoded or decoded. For example

$$
E_{\mathrm{U}, \mathrm{~B}}(L):=\operatorname{encTerm}\left(B_{\mathrm{Z}}\right)(\emptyset, \text { sequence }(L))
$$

Define $\operatorname{encTerm}\left(B_{\mathrm{Z}}\right) \in \mathcal{K}(\mathcal{Z}) \times \mathcal{K}(\mathcal{Z}) \rightarrow \mathbf{N}$ as

$$
\begin{aligned}
\operatorname{encTerm}\left(B_{\mathrm{Z}}\right)(M,(x, K)) & :=\left(\operatorname{encTerm}\left(B_{\mathrm{Z}}\right)((x, M), K) \times S_{\mathrm{Z}}(x)+E_{\mathrm{Z}}(x)\right) \times 2 \\
\operatorname{encTerm}\left(B_{\mathrm{Z}}\right)(M, \emptyset) & :=1
\end{aligned}
$$

where $\left(E_{\mathrm{Z}}, S_{\mathrm{Z}}, D_{\mathrm{Z}}\right)=\operatorname{definition}\left(B_{\mathrm{Z}}(\operatorname{reverse}(\operatorname{list}(M)))\right)$.
The underlying coder function $B_{\mathrm{Z}}$ is infinite, but the space of $C_{\mathrm{U}, \mathrm{B}}$ is well defined given a finite argument list.

Consider the coder of trees, $\operatorname{trees}(\mathcal{Z})$, of some underlying type $\mathcal{Z}$. Trees are functions and hence are sets, so it is possible to define a limited coder, as above, say by defining the maximum depth and cardinality of tree. There are a number of different ways in which limits could be imposed. However, here we shall consider unlimited trees with the constraint that circularities are
excluded. Sets can only be encoded as sets if they are finite, so to encode an unlimited tree $T \in \operatorname{trees}(\mathcal{Z})$ we must first convert it to a list tree listTrees $(\mathcal{Z})$ with an order $D \in \mathcal{Z} \leftrightarrow \mathbf{N}$, listTree $(D, T) \in \operatorname{listTrees}(\mathcal{Z})$, and then use an unlimited list tree coder

$$
\operatorname{coderListTree} \in \operatorname{coders}(\mathcal{Z}) \rightarrow \operatorname{coders}(\operatorname{listTrees}(\mathcal{Z}))
$$

Let $C_{\mathrm{Z}} \in \operatorname{coders}(\mathcal{Z})$ in

$$
C_{\mathrm{U}, \mathrm{~T}}=\operatorname{coderListTree}\left(C_{\mathrm{Z}}\right) \in \operatorname{coders}(\operatorname{list} \operatorname{Trees}(\mathcal{Z}))
$$

The code $E_{\mathrm{U}, \mathrm{T}}$ of the coder definition of $C_{\mathrm{U}, \mathrm{T}}$, where $\left(E_{\mathrm{U}, \mathrm{T}}, S_{\mathrm{U}, \mathrm{T}}, D_{\mathrm{U}, \mathrm{T}}\right)=$ definition $\left(C_{\mathrm{U}, \mathrm{T}}\right)$, is defined similarly to the encode of an unlimited list coder $C_{\mathrm{U}}$, except that recursion excludes the current list tree to prevent circularities

$$
E_{\mathrm{U}, \mathrm{~T}}(L):=\operatorname{encListTree}\left(C_{\mathrm{U}, \mathrm{~T}}^{\prime}, E_{\mathrm{Z}}, S_{\mathrm{Z}}\right)(\text { sequence }(L))
$$

where $C_{\mathrm{U}, \mathrm{T}}^{\prime} \in \operatorname{coders}(\operatorname{listTrees}(\mathcal{Z}) \backslash\{L\})$ and $\left(E_{\mathrm{Z}}, S_{\mathrm{Z}}, D_{\mathrm{Z}}\right)=\operatorname{definition}\left(C_{\mathrm{Z}}\right)$. $C_{\mathrm{U}, \mathrm{T}}^{\prime}$ is equal to $C_{\mathrm{U}, \mathrm{T}}$ except that it is undefined for list tree $L, L \notin \operatorname{dom}\left(E_{\mathrm{U}, \mathrm{T}}^{\prime}\right)$. Define encListTree $\left(C_{\mathrm{U}, \mathrm{T}}, E_{\mathrm{Z}}, S_{\mathrm{Z}}\right) \in \mathcal{K}(\mathcal{Z}) \rightarrow \mathbf{N}$ as
encListTree $\left(C_{\mathrm{U}, \mathrm{T}}, E_{\mathrm{Z}}, S_{\mathrm{Z}}\right)(((x, M), K)):=$

$$
\left(\left(\operatorname{encListTree}\left(C_{\mathrm{U}, \mathrm{~T}}^{\prime}, E_{\mathrm{Z}}, S_{\mathrm{Z}}\right)(K) \times S_{\mathrm{Z}}(x)+E_{\mathrm{Z}}(x)\right) \times S_{\mathrm{U}, \mathrm{~T}}(M)+E_{\mathrm{U}, \mathrm{~T}}(M)\right) \times 2
$$

where encListTree $\left(C_{\mathrm{U}, \mathrm{T}}, E_{\mathrm{Z}}, S_{\mathrm{Z}}\right)(\emptyset):=1$ and $\left(E_{\mathrm{U}, \mathrm{T}}, S_{\mathrm{U}, \mathrm{T}}, D_{\mathrm{U}, \mathrm{T}}\right)=\operatorname{definition}\left(C_{\mathrm{U}, \mathrm{T}}\right)$ and listable $\left(C_{\mathrm{U}, \mathrm{T}}^{\prime}\right)=\operatorname{listable}\left(C_{\mathrm{U}, \mathrm{T}}\right) \backslash\{\operatorname{list}(((x, M), K))\}$.

The space is defined

$$
\begin{aligned}
S_{\mathrm{U}, \mathrm{~T}}(L) & :=2 \prod_{(i,(x, M)) \in L} 2 \times S_{\mathrm{Z}}(x) \times S_{\mathrm{U}, \mathrm{~T}}^{\prime}(M) \\
S_{\mathrm{U}, \mathrm{~T}}(\emptyset) & :=2
\end{aligned}
$$

Define the decode parameter

$$
\begin{aligned}
D_{\mathrm{U}, \mathrm{~T}}(n) & :=\operatorname{list}\left(\operatorname{decListTree}\left(C_{\mathrm{U}, \mathrm{~T}}^{\prime}, S_{\mathrm{Z}}, D_{\mathrm{Z}}\right)(n)\right) \\
D_{\mathrm{U}, \mathrm{~T}}(1) & :=\emptyset \\
D_{\mathrm{U}, \mathrm{~T}}(0) & :=\emptyset
\end{aligned}
$$

$C_{\mathrm{U}, \mathrm{T}}^{\prime}$ is equal to $C_{\mathrm{U}, \mathrm{T}}^{\prime}$ except that $n \notin \operatorname{dom}\left(D_{\mathrm{U}, \mathrm{T}}^{\prime}\right)$. Define $\operatorname{dec} \operatorname{ListTree}\left(C_{\mathrm{U}, \mathrm{T}}, S_{\mathrm{Z}}, D_{\mathrm{Z}}\right) \in$ $\mathrm{N} \rightarrow \mathcal{K}(\mathcal{Z})$ as
$\operatorname{decListTree}\left(C_{\mathrm{U}, \mathrm{T}}, S_{\mathrm{Z}}, D_{\mathrm{Z}}\right)(n):=\left((x, M), \operatorname{decListTree}\left(C_{\mathrm{U}, \mathrm{T}}^{\prime}, S_{\mathrm{Z}}, D_{\mathrm{Z}}\right)\left(m / S_{\mathrm{Z}}(x)\right)\right)$
where $M=D_{\mathrm{U}, \mathrm{T}}(n / 2), m=n /\left(2 S_{\mathrm{U}, \mathrm{T}}(M)\right), x=D_{\mathrm{Z}}(m)$ if $n \% 2=0$ otherwise decListTree $\left(C_{\mathrm{U}, \mathrm{T}}, S_{\mathrm{Z}}, D_{\mathrm{Z}}\right)(n):=\emptyset$.

If we take the core space of a list tree $L$ as $\sum_{(i, x) \in Q} \operatorname{space}\left(C_{\mathrm{Z}}\right)(x)$, where $Q=\operatorname{concat}(L)$ is the depth-first traversal concatenation, then the additional overhead space to encode the list tree in coder $C_{\mathrm{U}, \mathrm{T}}$ is $(2|Q|+1) \ln 2$.

We can define a lookback unlimited list tree coder in a similar manner to the lookback unlimited list coder above. Again we supply a function returning underlying coders but here it has two arguments. The first argument is the previous sibling list tree and the second is the sub list tree for this node

$$
\begin{aligned}
& \text { coderListTreeLookback } \in \\
& \quad(\text { listTrees }(\mathcal{Z}) \times \text { listTrees }(\mathcal{Z}) \rightarrow \operatorname{coders}(\mathcal{Z})) \rightarrow \operatorname{coders}(\operatorname{listTrees}(\mathcal{Z}))
\end{aligned}
$$

Let $B_{\mathrm{Z}} \in \operatorname{listTrees}(\mathcal{Z}) \times \operatorname{list} \operatorname{Trees}(\mathcal{Z}) \rightarrow \operatorname{coders}(\mathcal{Z})$ in

$$
C_{\mathrm{U}, \mathrm{~T}, \mathrm{~B}}=\operatorname{coderListTreeLookback}\left(B_{\mathrm{Z}}\right) \in \operatorname{coders}(\operatorname{list} \operatorname{Trees}(\mathcal{Z}))
$$

Then the encode and decode methods are as above except that $\left(E_{\mathrm{Z}}, S_{\mathrm{Z}}, D_{\mathrm{Z}}\right)=$ definition $\left(B_{\mathrm{Z}}(L, M)\right)$ in the definition of encListTree $\left(C_{\mathrm{U}, \mathrm{T}, \mathrm{B}}, E_{\mathrm{Z}}, S_{\mathrm{Z}}\right)(L,((x, M), K))$ where $L$ is the previous sibling list tree and $M$ is the child list tree.

If a list $L$ contains the same object in more than place, $|\operatorname{ran}(L)|<|L|$, we can possibly reduce the space of a list coder by using references to the objects. A reference is a position in the list, $\operatorname{dom}(L) \subset \mathbf{N}_{>0}$. A referencing list coder, having coder domain of lists, seeks to use references rather than encoding objects in order to reduce space. Encoding a referencing coder requires a check on each object in the list to see if it already exists elsewhere in the list and if so creating a reference pointing to the existing object. Decoding a reference is dereferencing. Although the overhead space of a referencing list coder is larger than for a non-referencing list coder, requiring space for a flag to indicate whether the head object is a reference or a literal object and also space for the position in a reference, the space of highly redundant lists having large space of objects may be lower.

Referencing list tree coders can be constructed too, for example by defining a reference as a position in the concatenated tree. The position is in $\operatorname{dom}(\operatorname{concat}(\operatorname{listTree}(D, T))) \subset \mathbf{N}_{>0}$ for some tree $T$ and order $D$. Another method would be to define the reference as a tuple in $\bigcup\left\{\mathbf{N}_{>0}^{i}: i \in \mathbf{N}_{>0}\right\}$ of the node position in the list tree. Note that these references refer to the objects of the nodes. That is, the first of the pair.

A graph is a tree that contains the same node at more than one position in the tree, $|\operatorname{nodes}(T)|<|\operatorname{concat}(\operatorname{listTree}(D, T))|$ for some tree $T$ and any order $D$. If a duplicate node has children and the recursive set of descendants contains the node, then there is a circularity. We can encode graphs by using node references. A node reference is similar to a reference except that it refers to the entire node. That is, the pair of the object and children. If the children of a node is empty then a node reference is equivalent to a reference

## A.5.2 Coders and entropy

If a finite coder domain $Y$ has some probability function $P \in\left(Y: \rightarrow \mathbf{Q}_{>0}\right) \cap \mathcal{P}$, which is such that $\operatorname{dom}(P)=Y$ and $\operatorname{sum}(P)=1$, associated with it, then we may be able to construct an entropy coder $C \in \operatorname{coders}(Y)$ such that

$$
\forall x \in Y\left(\operatorname{space}(C)(x)=\ln \frac{1}{P_{x}}\right)
$$

That is, the space of an element of the coder domain is the logarithm of the surprisal. In most cases of probability functions an entropy coder cannot be constructed. The coder requires that

$$
\forall x \in Y\left(\frac{1}{P_{x}} \in \mathbf{N}\right)
$$

at least. Also there are constraints on the parameters of the coder definition $(E, S, D)=$ definition $(C)$.

If the entropy coder exists, the expected space of an element in the coder domain is

$$
\begin{aligned}
& \operatorname{expected}(P)(\operatorname{space}(C))= \\
& \qquad \sum_{x \in Y} P_{x} \times \operatorname{space}(C)(x)=\sum_{x \in Y} P_{x} \ln \frac{1}{P_{x}}=-\sum_{x \in Y} P_{x} \ln P_{x}=\operatorname{entropy}(P)
\end{aligned}
$$

The scaled expected space $|Y| \times \operatorname{entropy}(P)$ is greater than or equal to the minimal space of the coder domain $|Y| \ln |Y|$, with equality only for the uniform probability function $P=Y \times\{1 /|Y|\}$.

An entropy coder $C_{\mathrm{e}}$ has the smallest expected space of all coders given the probability function, $P$, because the relative entropy of any other coder is positive by Gibbs' Inequality,

$$
\forall C \in \operatorname{coders}(\operatorname{dom}(P))\left(\operatorname{expected}(P)\left(C^{\mathrm{s}}\right) \geq \operatorname{expected}(P)\left(C_{\mathrm{e}}^{\mathrm{s}}\right)\right)
$$

where $\operatorname{expected}(P)\left(C_{\mathrm{e}}^{\mathrm{s}}\right)=\operatorname{entropy}(P)$.

## A.5.3 Binary coders

An example of a fixed-width coder is

$$
\text { coderBitstringShortest } \in \text { coders(bits) }
$$

Let $C_{\mathbf{B}}=$ coderBitstringShortest and $(E, S, D)=$ definition $\left(C_{\mathbf{B}}\right)$. Let $E=$ $\{(0,0),(1,1)\}, S=$ bits $\times\{2\}$ and $D(n):=n \% 2$. A bits coder implies a bijection $\mathbf{N} \leftrightarrow \mathcal{L}$ (bits). In this case it provides a means to map any number to the shortest bitstring that can contain it. Obviously this is useful in a physical implementation in computer memory.

We can apply bits coder $C_{\mathbf{B}}$ to the encode method of coder $C \in \operatorname{coders}(Y)$ to produce a bitstring, decode $\left(C_{\mathbf{B}}\right)(\operatorname{encode}(C)(L)) \in \mathcal{L}($ bits $)$ where $L \in$ $\mathcal{L}(Y)$. If it is also the case that the space parameter $S$, where $(E, S, D)=$ definition $(C)$, is always a multiple of two, $\forall x \in Y\left(S_{x} \in\left\{2^{n}: n \in \mathrm{~N}\right\}\right)$ then $C$ is a binary coder and the maximum length of any bitstring is constrained

$$
\forall L \in \mathcal{L}(Y)\left(\left|\operatorname{decode}\left(C_{\mathbf{B}}\right)(|L|, \operatorname{encode}(C)(L))\right| \leq \sum_{(i, x) \in L} \log _{2}\left(S_{x}\right)\right)
$$

This means that, for binary coders, the space required for implementation in a bitstring is no greater than the space required for the coder itself. (Note that the function space $(C) \in Y \rightarrow \ln \mathbf{N}_{>0}$ is defined as the natural logarithm rather than the base 2 logarithm.)

A prefix-free coder $C$ is a binary coder constrained such that

$$
\sum\left(\frac{1}{S_{x}}:(x, i) \in E\right) \leq 1
$$

where $(E, S, D)=$ definition $(C)$. If it is the case that the sum is 1 and there is a probability mass function on the coder domain, $P \in Y \rightarrow \mathbf{Q}_{>0}$, such that $P=\left\{\left(x, 1 / S_{x}\right): x \in Y\right\}$, then $C$ is also an entropy coder for $P$. However, no prefix-free coder can be a minimal coder because the sum of a fixed-width prefix-free coder, required for a uniform probability mass function, must be less than 1.

## A. 6 Entropy encoding of states

The index coder $C_{\mathrm{H}}$ which encodes a history's events space into a list of states, $\mathcal{L}(\mathcal{S})$, and thence to a list of natural numbers, $\mathcal{L}(\mathbf{N})$, above, is a fixedwidth coder of the states because the space required is proportional to the
size, spaceEvents $(U)(H):=z \ln v$. However, a variable-width coder of the states may require less space. Define a theoretical variable-width coder $C_{\mathrm{E}}$ of histories

$$
C_{\mathrm{E}}=\operatorname{coderHistoryVariable}\left(U, X, D_{\mathrm{V}}, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)
$$

This coder contains a nested entropy coder of states which is constructed separately for the histogram $A$ of each given history of the listable domain $H \in \mathcal{H}_{U, X}$, where $A=\operatorname{histogram}(A)$. The entropy coder of states enables us to encode a variable-width list of states which is ordered in the same way as the event identifiers of the given history $H$. Let $C \in \operatorname{coders}(\operatorname{states}(A))$, having definition $(E, S, D)=$ definition $(C)$, be defined such that $S=(A \% \emptyset) / A$, where $S \in \operatorname{states}(A) \rightarrow \mathbf{N}_{>0}$. Here we assume that the histogram $A$ happens to define an entropy coder

$$
\forall R \in \operatorname{states}(A)\left(\operatorname{space}(C)(R)=\ln \frac{1}{P_{R}}=\ln \frac{z}{A_{R}}\right)
$$

where $P=A /(A \% \emptyset)$ and $z=\operatorname{size}(A)$. Of course, this is rarely the case, but we shall assume that it is true in order to determine the minimum space of variable coder $C_{\mathrm{E}}$. The space parameter, $S \in \operatorname{states}(A) \rightarrow \mathbf{N}_{>0}$, of the entropy coder of states, $C$, is defined by $A$, so the space to encode $S$ itself is the same as the coder of histograms, $C_{\mathrm{A}}$ previously defined as the sum of the variables space, size space and counts space

$$
\operatorname{space}\left(C_{\mathrm{A}}\right)(A)=\mathrm{sp} \operatorname{Var}(U)(|\operatorname{vars}(A)|)+\operatorname{space}(|X|+1)+\operatorname{spCt}(U)(A)
$$

where $\mathrm{spVar}=$ spaceVariables, and $\mathrm{spCt}=$ spaceCounts. We shall not define the encode parameter $E \in \operatorname{states}(A) \rightarrow \mathbf{N}$, but merely determine the space required for a definition. Define spaceCodeEntropy $\in \mathcal{A}_{\mathrm{i}} \rightarrow \ln \mathbf{N}_{>0}$ so that

$$
\operatorname{spaceCodeEntropy}(A)=\sum_{R \in A^{\mathrm{S}}} \ln S_{R}
$$

as

$$
\operatorname{spaceCodeEntropy}(A):=\sum_{R \in A^{\mathrm{S}}} \ln \frac{z}{A_{R}}
$$

where $z=\operatorname{size}(A), z>0$ and $A=\operatorname{trim}(A)$. The space of $E$ is spaceEntropy $(A)$.
Not only shall we not define the infinite relation $D \in \mathcal{L}(\operatorname{states}(A)) \rightarrow \mathbf{N}$, we shall completely ignore the space required to define it. In practice we can define coders of states using algorithms, such as the Huffman binary coder, which can be entropy coders. For these the decode algorithm can be considered part of the definition of the coder.

Having defined the minimum space of the entropy coder of states, $C$, for the history $H$ we can define the variable events space spaceEventsVariable $\in$ $\mathcal{A}_{\mathrm{i}} \rightarrow \ln \mathrm{N}_{>0}$ so that

$$
\operatorname{spaceEventsVariable}(A)=\sum_{R \in A^{\mathrm{S}}} A_{R} \ln S_{R}
$$

as

$$
\operatorname{spaceEventsVariable}(A):=\sum_{R \in A^{\mathrm{s}}} A_{R} \ln \frac{z}{A_{R}}
$$

where $z=\operatorname{size}(A), z>0$ and $A=\operatorname{trim}(A)$. The variable events space is the sized entropy, spaceEventsVariable $(A)=z \times \operatorname{entropy}(A)$.

The total minimum space of a theoretical variable coder of a history $H$ is the sum of the variables space, ids space, histogram counts space, entropy code space and variable events space

$$
\begin{aligned}
& \operatorname{space}\left(C_{\mathrm{E}}\right)(H)= \\
& \quad \operatorname{sp} \operatorname{Var}(U)(|\operatorname{vars}(H)|)+\operatorname{spId}(|X|,|H|)+\operatorname{spCt}(U)(A)+\operatorname{spEnt}(A)+\operatorname{spEvVar}(A)
\end{aligned}
$$

where $A=\operatorname{histogram}(H)$, spVar $=$ spaceVariables, $\operatorname{spId}=$ spaceIds, $\operatorname{spCt}=$ spaceCounts, $s p E n t=$ spaceCodeEntropy and $\mathrm{spEvVar}=$ spaceEventsVariable.

If we compare the space of the variable coder to that of the classification coder of histories we find that the former is always greater than or equal to the latter

$$
\begin{aligned}
\operatorname{space} & \left(C_{\mathrm{E}}\right)(H)-\operatorname{space}\left(C_{\mathrm{G}}\right)(H)= \\
& \operatorname{spEnt}(A)+\operatorname{spEvVar}(A)-\operatorname{spCl}(A) \\
= & \sum_{R \in A^{\mathrm{S}}}\left(A_{R}+1\right) \ln \frac{z}{A_{R}}-\left(\ln z!-\sum_{R \in A^{\mathrm{S}}} \ln A_{R}!\right) \\
= & (z+|A|) \ln z-\ln z!-\sum_{R \in A^{\mathrm{S}}}\left(\left(A_{R}+1\right) \ln A_{R}-\ln A_{R}!\right) \\
\geq & 0
\end{aligned}
$$

where $\mathrm{spCl}=$ spaceClassification. Even if we ignore spaceCodeEntropy $(A)$, for example in the case of a variable-width history coder of the subset of histories having a constant parameter histogram, $C_{\mathrm{E}} \in \operatorname{coders}(\{H: H \in$ $\mathcal{H}_{U, X}$, $\left.\operatorname{histogram}(H)=A\right\}$ ), the space of the variable coder is still greater than or equal to that of the classification coder because the log unit-translated gamma function, $\ln \Gamma_{!} x$, is convex with respect to the log-linear function, $x \ln x$.

## A. 7 Independent histogram space

The integral congruent support of the multinomial distribution in variables $V$ and size $z$ in system $U$ is defined above as

$$
\mathcal{A}_{U, \mathrm{i}, V, z}=\left\{A: A \in \mathcal{A}_{U, \mathrm{i}}, A^{\mathrm{U}}=V^{\mathrm{C}}, \operatorname{size}(A)=z\right\}
$$

The cardinality of which is that of the weak compositions $\left|\mathrm{C}^{\prime}\left(V^{\mathrm{C}}, z\right)\right|$

$$
\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right|=\frac{(z+v-1)!}{z!(v-1)!}
$$

where $v=\operatorname{volume}(U)(V)$.
Define the subset of the integral congruent support that consists of independent histograms as

$$
\mathcal{A}_{U, \mathrm{i}, V, z, \mathrm{x}}=\left\{A: A \in \mathcal{A}_{U, \mathrm{i}, V, z}, \quad A=A^{\mathrm{x}}\right\}
$$

So

$$
\left|\mathcal{A}_{U, \mathrm{i}, \mathrm{~V}, z, \mathrm{x}}\right| \leq \frac{(z+v-1)!}{z!(v-1)!}
$$

As defined above, the subset of the independent function, $Y_{U, \mathrm{i}, V, z}=\left\{\left(A, A^{\mathrm{X}}\right)\right.$ : $\left.A \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\} \subset$ independent, partitions the integral congruent support, $\operatorname{ran}\left(\operatorname{inverse}\left(Y_{U, \mathrm{i}, V, z}\right)\right) \in \mathrm{B}\left(\mathcal{A}_{U, \mathrm{i}, V, z}\right)$. The cardinality of its range is

$$
\left|\operatorname{ran}\left(Y_{U, i, V, z}\right)\right|=\prod_{u \in V} \frac{\left(z+\left|U_{u}\right|-1\right)!}{z!\left(\left|U_{u}\right|-1\right)!}
$$

Now $\mathcal{A}_{U, \mathrm{i}, V, z, \mathrm{x}} \subseteq \operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)$ and so

$$
\left|\mathcal{A}_{U, \mathrm{i}, V, z, \mathrm{x}}\right| \leq \prod_{u \in V} \frac{\left(z+\left|U_{u}\right|-1\right)!}{z!\left(\left|U_{u}\right|-1\right)!}
$$

Consider an independent coder of histograms $C_{\mathrm{A}, \mathrm{x}}$

$$
C_{\mathrm{A}, \mathrm{x}}=\operatorname{coderHistogramIndependent}\left(U, y, D_{\mathrm{V}}, D_{\mathrm{S}}\right) \in \operatorname{coders}\left(\mathcal{A}_{U, \mathrm{i}, \leq y}\right)
$$

where $y=|X|$ and $X \subset \mathcal{X}$ is a finite subset of event identifiers. The coder domain is the set of trimmed histograms of size less than or equal to $y$ in system $U, \mathcal{A}_{U, \mathrm{i}, \leq y}$. So the independent coder can encode all histograms whether independent or not. However, it is defined to require less space for independent histograms, $A=A^{\mathrm{X}}$. The coder $C_{\mathrm{A}, \mathrm{x}}$ adds a flag $b \in$ bits $=\{0,1\}$
to indicate whether the histogram is independent or not. The coder $C_{\mathrm{A}, \mathrm{x}}$ has intermediate tuple $\left(\left(n, N_{V}\right), z, b, R_{A}\right) \in \mathbf{N}^{2} \times \mathbf{N} \times$ bits $\times \mathbf{N}$. If independent, then the space of the encoding of the histogram in $R_{A}$ is possibly smaller depending on the variables' valencies

$$
R_{A} \in\left\{1 \ldots\left|\mathcal{A}_{U, \mathrm{i}, V, z, \mathrm{x}}\right|\right\}
$$

instead of

$$
R_{A} \in\left\{1 \ldots \frac{(z+v-1)!}{z!(v-1)!}\right\}
$$

If not independent, then the space of the encoding of the histogram in $R_{A}$ is possibly smaller too

$$
R_{A} \in\left\{1 \ldots\left|\mathcal{A}_{U, \mathrm{i}, V, z} \backslash \mathcal{A}_{U, \mathrm{i}, V, z, \mathrm{x}}\right|\right\}
$$

The addition of the flag reduces the counts space of independent histograms, but the total space of this modification, $C_{\mathrm{A}, \mathrm{x}}$, of the histogram coder, $C_{\mathrm{A}}$, increases because of the cost of the additional bit for each histogram in the coder domain, $\left|\mathcal{A}_{U, i, \leq y}\right| \ln 2$. The additional total space is

$$
\begin{aligned}
& \left|\mathcal{A}_{U, \mathrm{i}, \leq y}\right| \ln 2+ \\
& \sum\left(\ln \left|\mathcal{A}_{U, \mathrm{i}, V_{A}, z_{A}, \mathrm{x}}\right|: A \in \mathcal{A}_{U, \mathrm{i}, \leq y}, \quad A=A^{\mathrm{x}}\right)+ \\
& \sum\left(\ln \left|\mathcal{A}_{U, \mathrm{i}, V_{A}, z_{A}} \backslash \mathcal{A}_{U, \mathrm{i}, V_{A}, z_{A}, \mathrm{x}}\right|: A \in \mathcal{A}_{U, \mathrm{i}, \leq y}, A \neq A^{\mathrm{x}}\right)- \\
& \sum\left(\ln \left|\mathcal{A}_{U, \mathrm{i}, V_{A}, z_{A}}\right|: A \in \mathcal{A}_{U, \mathrm{i}, \leq y}\right)
\end{aligned}
$$

where $z=$ size and $V=$ vars.
The remaining terms of the intermediate tuple, $\left(n, N_{V}\right)$ and $z$, are encoded in exactly the same way as for the histogram coder, $C_{\mathrm{A}}$.

The total space of the independent coder, $C_{\mathrm{A}, \mathrm{x}}$, is conjectured to be greater than or equal to the total space of the histogram coder, $C_{\mathrm{A}}$, $\operatorname{sum}\left(\operatorname{space}\left(C_{\mathrm{A}, \mathrm{x}}\right)\right) \geq$ $\operatorname{sum}\left(\operatorname{space}\left(C_{\mathrm{A}}\right)\right)$, and so $C_{\mathrm{A}, \mathrm{x}}$ is not a minimal coder. The difference in total space between the two coders depends on the system, $U$, which defines the coder domain, $\mathcal{A}_{U, \mathrm{i}, \leq y}$. For example, if $|\operatorname{vars}(U)|=1$ then all of the histograms of the support must be independent because they are mono-variate. In this case the flag is pure overhead.

The generic independent classification coder of histories $C_{\mathrm{G}, \mathrm{A}, \mathrm{x}}$ takes the independent coder, $C_{\mathrm{A}, \mathrm{x}}$, as the underlying coder of histograms

$$
C_{\mathrm{G}, \mathrm{~A}, \mathrm{x}}=\operatorname{coderClassificationGeneric}\left(C_{\mathrm{A}, \mathrm{x}}, X, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)
$$

The coder domain is $\mathcal{H}_{U, X}$, so the generic independent classification coder can encode all histories in a system $U$ and identifier set $X$ whether independent or not.

Now consider instead a coder $C_{\mathrm{A}, \mathrm{p}}$, similar to the independent coder $C_{\mathrm{A}, \mathrm{x}}$, that encodes the perimeter histogram expression that is equivalent to the independent histogram. If histogram $A$ is independent $A=A^{\mathrm{X}}$ then by definition

$$
A^{\mathrm{x}}=Z_{A} * \prod\left\{\frac{A}{Z_{A}} \%\{u\}: u \in V\right\}
$$

where $Z_{A}=A \% \emptyset$ and $V=\operatorname{vars}(A)$. This is equivalent to

$$
\operatorname{scalar}\left(z^{-(n-1)}\right) * \prod\{A \%\{u\}: u \in V\}
$$

where $z=\operatorname{size}(A)$ and $n=|V|$. This histogram expression is a scaled product of the reduced histograms for each variable in $V$.

Construct the perimeter coder of histograms $C_{\mathrm{A}, \mathrm{p}}$

$$
C_{\mathrm{A}, \mathrm{p}}=\operatorname{coderHistogramPerimeter}\left(U, y, D_{\mathrm{V}}, D_{\mathrm{S}}\right) \in \operatorname{coders}\left(\mathcal{A}_{U, \mathrm{i}, \leq y}\right)
$$

The intermediate tuple $\left(\left(n, N_{V}\right), z, b, L\right) \in \mathbf{N}^{2} \times \mathbf{N} \times$ bits $\times \mathcal{L}(\mathbf{N})$ adds a flag $b$ to indicate whether the histogram is independent or not. If it is not independent, $A \neq A^{\mathrm{X}}$, then the flag $b$ is reset (or false), 0 , and the next argument $L$ will be a list containing only the encoding of the histogram $L=\left\{\left(1, R_{A}\right)\right\}$ where $R_{A}$ is defined as in the histogram coder, $C_{\mathrm{A}}$

$$
R_{A} \in\left\{1 \ldots \frac{(z+v-1)!}{z!(v-1)!}\right\}
$$

where $v=\left|V^{\mathrm{C}}\right|$. If the histogram is independent, $A=A^{\mathrm{X}}$, then the flag $b$ is set (or true), 1 , and the list consists of encodings of the perimeter of reduced histograms for each variable. The perimeter histograms are integral because the histogram is integral, $A=A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$. Given order $D_{\mathrm{A}}$ choose enumerations R

$$
\forall u \in V\left(R_{u} \in \operatorname{enums}\left(\left\{\operatorname{trim}(B): B \in \mathcal{A}_{U, \mathbf{i},\{u\}, z}\right\}\right)\right)
$$

which are such that

$$
\forall u \in V\left(R_{u}\left(A^{\mathrm{x}} \%\{u\}\right) \in\left\{1 \ldots \frac{\left(z+\left|U_{u}\right|-1\right)!}{z!\left(\left|U_{u}\right|-1\right)!}\right\}\right)
$$

Given order $D_{\mathrm{V}}$ let $W=\operatorname{order}\left(D_{\mathrm{V}}, V\right)$ and so

$$
L=\left\{\left(W_{u}, R_{u}\left(A^{\mathrm{X}} \%\{u\}\right)\right): u \in V\right\}
$$

The decoding can rely on the fact that all the histograms in the list have the same size $z$. The list itself is a limited list and so its space is the sum of the counts space for each reduction of the histogram

$$
\sum_{u \in V} \operatorname{spaceCounts}(U)\left(A^{\mathrm{X}} \%\{u\}\right)=\sum_{u \in V} \ln \frac{\left(z+\left|U_{u}\right|-1\right)!}{z!\left(\left|U_{u}\right|-1\right)!}
$$

Define the space of the encoding of the perimeter as spacePerimeter $(U) \in$ $\mathcal{A}_{U, \mathrm{i}} \rightarrow \ln \mathbf{N}_{>0}$

$$
\operatorname{spacePerimeter}(U)(A):=\sum_{u \in V} \ln \frac{\left(z+\left|U_{u}\right|-1\right)!}{z!\left(\left|U_{u}\right|-1\right)!}
$$

When compared to the histogram coder, $C_{\mathrm{A}}$, the counts space of the histograms in the histogram expression of an independent history decreases by

$$
\ln \left|\mathcal{A}_{U, \mathrm{i}, V, z}\right|-\sum_{u \in V} \ln \left|\mathcal{A}_{U, \mathrm{i},\{u\}, z}\right|
$$

or

$$
\ln \frac{(z+v-1)!}{z!(v-1)!}-\sum_{u \in V} \ln \frac{\left(z+\left|U_{u}\right|-1\right)!}{z!\left(\left|U_{u}\right|-1\right)!}
$$

That is, spaceCounts $(U)(A)$ - spacePerimeter $(U)(A)$. As shown in the section 'Iso-independents' above, it is the case that

$$
\frac{(z+v-1)!}{z!(v-1)!} \geq \prod_{u \in V} \frac{\left(z+\left|U_{u}\right|-1\right)!}{z!\left(\left|U_{u}\right|-1\right)!}
$$

and so the difference is always positive

$$
\operatorname{spaceCounts}(U)(A)-\operatorname{spacePerimeter}(U)(A) \geq 0
$$

The space of an independent histogram, $A=A^{\mathrm{X}}$, in the perimeter coder, $C_{\mathrm{A}, \mathrm{p}}$, is greater than or equal to the space of the same histogram in the independent coder, $C_{\mathrm{A}, \mathrm{x}}$, that calculates the congruent independent histograms, $\mathcal{A}_{U, \mathrm{i}, V, z, \mathrm{x}}=$ $\left\{B: B \in \mathcal{A}_{U, \mathrm{i}, V, z}, B=B^{\mathrm{X}}\right\}$, explicitly because

$$
\left|\mathcal{A}_{U, \mathrm{i}, V, z, \mathrm{x}}\right| \leq \prod_{u \in V}\left|\mathcal{A}_{U, \mathrm{i},\{u\}, z}\right|=\prod_{u \in V} \frac{\left(z+\left|U_{u}\right|-1\right)!}{z!\left(\left|U_{u}\right|-1\right)!}
$$

Also, unlike $C_{\mathrm{A}, \mathrm{x}}$, there is not a symmetrical reduction in the space of nonindependent histograms that corresponds to the histogram expression encapsulation of the space of independent histograms. Hence the total space of $C_{\mathrm{A}, \mathrm{p}}$
is greater than that of $C_{\mathrm{A}, \mathrm{x}}, \operatorname{sum}\left(\operatorname{space}\left(C_{\mathrm{A}, \mathrm{p}}\right)\right) \geq \operatorname{sum}\left(\operatorname{space}\left(C_{\mathrm{A}, \mathrm{x}}\right)\right)$, which is greater than the total space of a minimal coder. However, depending on implementation, $C_{\mathrm{A}, \mathrm{p}}$ may be more practicable than $C_{\mathrm{A}, \mathrm{x}}$. In exchange for the larger space of both independent and non-independent histograms, an implementation of $C_{\mathrm{A}, \mathrm{p}}$ may only require a little more computation time than $C_{\mathrm{A}}$, less than that required by $C_{\mathrm{A}, \mathrm{x}}$, depending on the calculation of $\mathcal{A}_{U, \mathrm{i}, V, z, \mathrm{x}}$.

If the independent histogram $A=A^{\mathrm{X}}$ is also regular such that $\exists d \in \mathbf{N} \forall u \in$ $V\left(\left|U_{u}\right|=d\right)$ then the decrease in counts space between $C_{\mathrm{A}}$ and $C_{\mathrm{A}, \mathrm{p}}$ is

$$
\ln \frac{\left(z+d^{n}-1\right)!}{z!\left(d^{n}-1\right)!}-n \ln \frac{(z+d-1)!}{z!(d-1)!}
$$

where $z=\operatorname{size}(A)$ and $n=|V|$. If $z>d$, then the counts space in $C_{\mathrm{A}, \mathrm{p}}$ is at most $n d \ln z$. If $z \geq v^{2}$, where $v=d^{n}$, the counts space in $C_{\mathrm{A}}$ is at least $\left(d^{n}-1\right) \ln d^{n}$ and so the space decrease is at least $(v-1) \ln v-n d \ln z$. If the decrease is greater than the cost of the independent flag, space $(\mid$ bits $\mid)=\ln 2$, then there is an overall decrease in space. One can think of the perimeter coder as encoding the perimeter rather than the volume of histograms when they are independent.

The generic perimeter classification coder of histories $C_{\mathrm{G}, \mathrm{A}, \mathrm{p}}$ takes the perimeter coder, $C_{\mathrm{A}, \mathrm{p}}$, as the underlying histogram coder

$$
C_{\mathrm{G}, \mathrm{~A}, \mathrm{p}}=\operatorname{coderClassificationGeneric}\left(C_{\mathrm{A}, \mathrm{p}}, X, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)
$$

The coder domain is $\mathcal{H}_{U, X}$, so the generic perimeter classification coder can encode all histories in a system $U$ and identifier set $X$ whether independent or not.

Now consider the history $H$, in variables $V=\operatorname{vars}(H)$ and size $z=|H|$ in system $U$, which is such that its histogram $A=\operatorname{histogram}(H)$ is not necessarily independent. The dimensional classification coder reduces the history to a set of histories, one for each variable, regardless of whether the histogram is independent or not,

$$
\{(u,\{(x, S \%\{u\}):(x, S) \in H\}): u \in V\} \in V \rightarrow \mathcal{H}_{U, X}
$$

Define the constructor of the dimensional classification coder of histories

$$
C_{\mathrm{G}, \mathrm{n}}=\operatorname{coderClassificationDimensional}\left(U, X, D_{\mathrm{V}}, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)
$$

The intermediate tuple is $\left(\left(n, N_{V}\right),\left(z, Z_{I}\right), L, M\right) \in \mathbf{N}^{2} \times \mathbf{N}^{2} \times \mathcal{L}(\mathbf{N}) \times \mathcal{L}(\mathbf{N})$. The first pair encodes the set of variables in the same way as the classification coder, $C_{\mathrm{G}}$, above. The space is spaceVariables $(U)(n)$. The second pair encodes the set of event identifiers also in the same way as the classification coder. The space is $\operatorname{spaceIds}(y, z)$ where $y=|X|$.

The third element of the intermediate tuple, $L$, encodes the list of reduced perimeter histograms, $\{(u, A \%\{u\}): u \in V\} \in V \rightarrow \mathcal{A}_{U, \mathrm{i}}$. The method used is the same as that for the perimeter coder, $C_{\mathrm{A}, \mathrm{p}}$, above, in the special case of independent histogram. Here, however, the histogram, $A$, is reduced in all cases. Given order $D_{\text {A }}$ choose enumerations

$$
\forall u \in V\left(R_{u} \in \operatorname{enums}\left(\left\{\operatorname{trim}(B): B \in \mathcal{A}_{U, \mathbf{i},\{u\}, z}\right\}\right)\right)
$$

which is such that

$$
\forall u \in V\left(R_{u}(A \%\{u\}) \in\left\{1 \ldots \frac{\left(z+\left|U_{u}\right|-1\right)!}{z!\left(\left|U_{u}\right|-1\right)!}\right\}\right)
$$

Given order $D_{\mathrm{V}}$ let $W=\operatorname{order}\left(D_{\mathrm{V}}, V\right)$ and so

$$
L=\left\{\left(W_{u}, R_{u}(A \%\{u\})\right): u \in V\right\}
$$

The list itself is a limited list and so its space is the sum of the counts space for each reduction of the histogram, spacePerimeter $(U)(A)$.

The last element of the intermediate tuple, $M$, encodes the list of reduced classifications, $\{(u$, classification $(\{(x, S \%\{u\}):(x, S) \in H\})): u \in V\} \in$ $V \rightarrow \mathcal{G}_{U, X}$. The method is the same as for the classification coder, $C_{\mathrm{G}}$, above, applied to each reduced classification in sequence. That is

$$
\forall u \in V\left(F_{u}\left(Q_{u}\right) \in\left\{1 \cdots \frac{z!}{\prod_{S \in \operatorname{dom}\left(G_{u}\right)}\left|G_{u}(S)\right|!}\right\}\right)
$$

where $G_{u}=$ classification $(\{(x, S \%\{u\}):(x, S) \in H\})$ and $Q_{u}=\operatorname{ran}\left(G_{u}\right)$. So

$$
M=\left\{\left(W_{u}, F_{u}\left(Q_{u}\right)\right): u \in V\right\}
$$

Again, the list itself is a limited list and so its space is the sum of the classification space for each reduction of the histogram

$$
\sum_{u \in V} \text { spaceClassification }(A \%\{u\})=n \ln z!-\sum_{u \in V} \sum_{S \in(A \%\{u\})^{\mathrm{S}}} \ln (A \%\{u\})(S)!
$$

where $n=|V|$. The total classification space can be approximated by Stirling's approximation

$$
n z \ln z-\sum_{u \in V} \sum_{S \in(A \%\{u\})^{\mathrm{S}}} A \%\{u\}(S) \ln A \%\{u\}(S)
$$

The dimensional classification coder decodes by joining the reduced histories, $\left\{\left(x, \bigcup\left\{N_{i}(x): i \in\{1 \ldots n\}\right\}\right): x \in \operatorname{dom}(H)\right\}=H$ where $N \in \mathcal{L}\left(\mathcal{H}_{U, X}\right)$.

In the case of a regular history of dimension $n=|V|$ and valency $\{d\}=$ $\left\{\left|U_{u}\right|: u \in V\right\}$ the counts space may be less than that of the classification coder, $C_{\mathrm{G}}$, depending on the size $z$ and the volume $d^{n}$ as can be seen above for the perimeter classification coder when encoding an independent histogram. The total classification space of the dimensional classification coder, $C_{\mathrm{G}, \mathrm{n}}$, in the case of uniform history, $A=\operatorname{resize}\left(z, V^{\mathrm{C}}\right)$, approximates to

$$
n z \ln z-n d \frac{z}{d} \ln \frac{z}{d}=n z \ln d
$$

which may be compared to that of the classification $\operatorname{coder}, C_{\mathrm{G}}$

$$
z \ln z-d^{n} \frac{z}{d^{n}} \ln \frac{z}{d^{n}}=z \ln d^{n}=n z \ln d
$$

Conjecture that in some high entropy cases the space of a history in the dimensional classification coder, $C_{\mathrm{G}, \mathrm{n}}$, is less than that of the classification coder, $C_{\mathrm{G}}$. Conversely, conjecture that in some low entropy cases the space in the dimensional classification coder, $C_{\mathrm{G}, \mathrm{n}}$, is greater than that of the classification coder, $C_{\mathrm{G}}$.

Unlike the generic independent classification coder, $C_{\mathrm{G}, \mathrm{A}, \mathrm{x}}$, and the generic perimeter classification coder, $C_{\mathrm{G}, \mathrm{A}, \mathrm{p}}$, the dimensional classification coder, $C_{\mathrm{G}, \mathrm{n}}$, does modify the calculation of the events classification space. Therefore there is no underlying coder of histograms which encapsulates all the differences in encoding logic between the dimensional classification coder, $C_{\mathrm{G}, \mathrm{n}}$, and the classification coder, $C_{\mathrm{G}}$.

Now consider a coder of histograms based on the iso-independent set. Each complete histogram, $A^{\mathrm{U}}=V^{\mathrm{C}}$, has an associated finite set of integral isoindependents. This set is the equivalence class component of the partition of the trimmed integral histograms, $\mathcal{A}_{U, \mathrm{i}, \leq y}$, implied by the subset of the independent function, $Y_{U, \mathrm{i}, \leq y}=\left\{\left(A, A^{\mathrm{X}}\right): A \in \mathcal{A}_{U, \mathrm{i}, \leq y}\right\} \subset$ independent. That is, the partition $\operatorname{ran}\left(Y_{U, \mathrm{i}, \leq y}^{-1}\right) \in \mathrm{B}\left(\mathcal{A}_{U, \mathrm{i}, \leq y}\right)$. The set of iso-independents of
histogram $A$ is $Y_{U, i, \leq y}^{-1}\left(A^{\mathrm{X}}\right) \subseteq \mathcal{A}_{U, \mathrm{i}, \leq y}$.
Define the constructor of the iso-independent coder of histograms

$$
C_{\mathrm{A}, \mathrm{y}}=\operatorname{coderHistogramIsoIndependent}\left(U, y, D_{\mathrm{V}}, D_{\mathrm{S}}\right) \in \operatorname{coders}\left(\mathcal{A}_{U, \mathrm{i}, \leq y}\right)
$$

The intermediate tuple is $\left(\left(n, N_{V}\right), z, L, J_{A}\right) \in \mathbf{N}^{2} \times \mathbf{N} \times \mathcal{L}(\mathbf{N}) \times \mathbf{N}$. The first pair encodes the set of variables in the same way as the histogram coder, $C_{\mathrm{A}}$, above. The space is spaceVariables $(U)(n)$. The second element encodes the size, also in the same way as the histogram coder. The space is spaceSize $(y)$ where $y=|X|$. The third element of the intermediate tuple, $L$, encodes the list of reduced perimeter histograms, $\{(u, A \%\{u\}): u \in V\} \in V \rightarrow \mathcal{A}_{U, \mathrm{i}}$. The method used is the same as that for the dimensional classification coder, $C_{\mathrm{G}, \mathrm{n}}$, above. The histogram is encoded as a perimeter regardless of whether it is independent or not. The space of the list $L$ is the sum of the counts space for each reduction of the histogram, spacePerimeter $(U)(A)$.

The fourth element, $J_{A}$, is the position of the histogram, $A$, in an ordering of the trimmed iso-independents. When the perimeter has been decoded from $L$ the trimmed independent histogram, $A^{\mathrm{X}}$, is known, where $A^{\mathrm{X}}=\operatorname{scalar}\left(z^{-(n-1)}\right) * \prod_{u \in V} L\left(W_{u}\right)$ and $W=\operatorname{order}\left(D_{\mathrm{V}}, V\right)$. Given order $D_{\mathrm{A}}$ choose $J \in \operatorname{enums}\left(Y_{U, \mathrm{i}, \leq y}^{-u}\left(A^{\mathrm{X}}\right)\right)$. Thus

$$
J_{A} \in\left\{1 \ldots\left|Y_{U, i, \leq y}^{-1}\left(A^{\mathrm{x}}\right)\right|\right\}
$$

So the space of the iso-independent position, $J_{A}$, is $\ln \left|Y_{U, i, \leq y}^{-1}\left(A^{\mathrm{X}}\right)\right|$. Define the space of the encoding of the iso-independent position

$$
\text { spaceIsoIndependentPosition }(U) \in \mathcal{A}_{U} \rightarrow \ln \mathbf{N}_{>0}
$$

as

$$
\text { spaceIsoIndependentPosition }(U)(A):=\ln \left|Y_{U, i, \leq y}^{-1}\left(A^{\mathrm{X}}\right)\right|
$$

which is defined if $A^{\mathrm{X}} \in \operatorname{ran}\left(Y_{U, \mathrm{i}, \leq y}\right)$.
The space of the iso-independent coder $C_{\mathrm{A}, \mathrm{y}}$ of a trimmed histogram $A \in$ $\mathcal{A}_{U, \mathrm{i}, \leq y}$ is the sum of the variables space, size space, perimeter space and iso-independent position space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{A}, \mathrm{y}}\right)(A)= & \operatorname{spaceVariables}(U)(|\operatorname{vars}(A)|)+ \\
& \text { spaceSize }(y)+ \\
& \text { spacePerimeter }(U)(A)+ \\
& \text { spaceIsoIndependentPosition }(U)(A)
\end{aligned}
$$

As conjectured above, the cardinality of the iso-independents corresponding to $A$ varies with the entropy of $A^{\mathrm{X}}$

$$
\ln \left|Y_{U, \mathrm{i}, V, z}^{-1}\left(A^{\mathrm{X}}\right)\right| \sim z \times \operatorname{entropy}\left(A^{\mathrm{X}}\right)
$$

Therefore, those histograms that have low entropy independent histogram will require less space to encode the iso-independent position, $J_{A}$, in the iso-independent coder, $C_{\mathrm{A}, \mathrm{y}}$. The average iso-independent position space of the subset of the coder domain having variables $V$ and size $z,\{A: A \in$ $\left.\mathcal{A}_{U, \mathrm{i}, \leq y}, \operatorname{vars}(A)=V, \operatorname{size}(A)=z\right\}$, is

$$
\ln \frac{\left|\mathcal{A}_{U, \mathrm{i}, V, z}\right|}{\left|\operatorname{ran}\left(Y_{U, \mathrm{i}, V, z}\right)\right|}=\ln \frac{(z+v-1)!}{z!(v-1)!} \prod_{u \in V} \frac{z!\left(\left|U_{u}\right|-1\right)!}{\left(z+\left|U_{u}\right|-1\right)!}
$$

The generic iso-independent classification coder of histories $C_{\mathrm{G}, \mathrm{A}, \mathrm{y}}$ takes the iso-independent coder, $C_{\mathrm{A}, \mathrm{y}}$, as the underlying histogram coder

$$
C_{\mathrm{G}, \mathrm{~A}, \mathrm{y}}=\operatorname{coderClassificationGeneric}\left(C_{\mathrm{A}, \mathrm{y}}, X, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)
$$

The space of the generic iso-independent classification coder $C_{\mathrm{G}, \mathrm{A}, \mathrm{y}}$ of a history $H \in \mathcal{H}_{U, X}$ is the sum of the variables space, ids space, perimeter space, iso-independent position space and classification space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{G}, \mathrm{~A}, \mathrm{y}}\right)(H)= & \operatorname{spaceVariables}(U)(|\operatorname{vars}(H)|)+ \\
& \operatorname{spaceIds}(|X|,|H|)+ \\
& \text { spacePerimeter}(U)(A)+ \\
& \text { spaceIsoIndependentPosition }(U)(A)+ \\
& \text { spaceClassification }(A)
\end{aligned}
$$

where $A=\operatorname{histogram}(H)$.
There are non-generic classification coders of histories that are based on the iso-independent set. Define the constructor of the superposed isoindependent classification coder of histories
$C_{\mathrm{G}, \mathrm{y}, \mathrm{u}}=\operatorname{coderClassificationIsoSuperposed}\left(U, X, D_{\mathrm{V}}, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$
The intermediate tuple is $\left(\left(n, N_{V}\right),\left(z, Z_{I}\right), L, J_{A}, F_{Q}\right) \in \mathbf{N}^{2} \times \mathbf{N}^{2} \times \mathcal{L}(\mathbf{N}) \times$ $\mathbf{N} \times \mathbf{N}$. The tuple is calculated exactly as for the generic iso-independent classification coder, $C_{\mathrm{G}, \mathrm{A}, \mathrm{y}}$. In particular, the last element, $F_{Q}$, of the intermediate tuple encodes the classification of the events of history $H \in \mathcal{H}_{U, X}$.

Given $D_{\mathrm{X}}$, choose enumeration $F$ of the enumerations of the partitions of the event identifiers corresponding to the classification
$F \in \operatorname{enums}(\{P: P \in \mathrm{~B}(\operatorname{ids}(G)), \exists X \in P: \leftrightarrow: Q \forall(Y, Z) \in X(|Y|=|Z|)\})$
where $G=$ classification $(H)$ and $Q=\operatorname{ran}(G) \in \mathrm{B}(\mathrm{ids}(G))$ is the partition of the event identifiers. The classification is such that

$$
F_{Q} \in\left\{1 \cdots \frac{z!}{\prod_{S \in \operatorname{dom}(G)}\left|G_{S}\right|!}\right\}
$$

In the generic iso-independent classification coder, $C_{\mathrm{G}, \mathrm{A}, \mathrm{y}}$, the events classification space of histogram $A=\operatorname{histogram}(H)$ is spaceClassification $(A)$. Here, however, the space is fixed to the largest classification space of the iso-independents. That is,

$$
\begin{aligned}
& \ln \operatorname{maxr}\left(\left\{\left(B, \frac{z!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}\right): B \in Y_{U, \mathrm{i}, \leq y}^{-1}\left(A^{\mathrm{x}}\right)\right\}\right) \\
= & \operatorname{maxr}\left(\left\{(B, \text { spaceClassification }(B)): B \in Y_{U, \mathrm{i}, \leq y}^{-1}\left(A^{\mathrm{x}}\right)\right\}\right)
\end{aligned}
$$

Define the space of the encoding of the iso-independent superposed classification as spaceClassificationIsoSuperposed $(U) \in \mathcal{A}_{U} \rightarrow \ln \mathbf{N}_{>0}$

$$
\begin{aligned}
& \text { spaceClassificationIsoSuperposed }(U)(A):= \\
& \quad \operatorname{maxr}\left(\left\{(B, \text { spaceClassification }(B)): B \in Y_{U, \mathrm{i}, \leq y}^{-1}\left(A^{\mathrm{x}}\right)\right\}\right)
\end{aligned}
$$

which is defined if $A^{\mathrm{X}} \in \operatorname{ran}\left(Y_{U, \mathrm{i}, \leq y}\right)$. This space is always large enough to encode $F_{Q}$

$$
\text { spaceClassificationIsoSuperposed }(U)(A) \geq \operatorname{spaceClassification}(A)
$$

The space of the superposed iso-independent classification coder $C_{\mathrm{G}, \mathrm{y}, \mathrm{u}}$ of a history $H \in \mathcal{H}_{U, X}$ is the sum of the variables space, ids space, perimeter space, iso-independent position space and iso-independent superposed classification space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{G}, \mathrm{y}, \mathrm{u}}\right)(H)= & \text { spaceVariables }(U)(|\operatorname{vars}(H)|)+ \\
& \operatorname{spaceIds}(|X|,|H|)+ \\
& \text { spacePerimeter }(U)(A)+ \\
& \text { spaceIsoIndependentPosition }(U)(A)+ \\
& \text { spaceClassificationIsoSuperposed }(U)(A)
\end{aligned}
$$

where $A=\operatorname{histogram}(H)$.
The space of a history $H$ in the superposed iso-independent classification coder, $C_{\mathrm{G}, \mathrm{y}, \mathrm{u}}$, is always greater than or equal to the space of the history in the generic iso-independent classification coder, $C_{\mathrm{G}, \mathrm{A}, \mathrm{y}}$

$$
\forall H \in \mathcal{H}_{U, X}\left(\operatorname{space}\left(C_{\mathrm{G}, \mathrm{y}, \mathrm{u}}\right)(H) \geq \operatorname{space}\left(C_{\mathrm{G}, \mathrm{~A}, \mathrm{y}}\right)(H)\right)
$$

So the total space is larger, $\operatorname{sum}\left(\operatorname{space}\left(C_{\mathrm{G}, \mathrm{y}, \mathrm{u}}\right)\right) \geq \operatorname{sum}\left(\operatorname{space}\left(C_{\mathrm{G}, \mathrm{A}, \mathrm{y}}\right)\right)$. However, the coder $C_{\mathrm{G}, \mathrm{y}, \mathrm{u}}$ has the property that all of the histories in any given iso-independent set parameterised by $V$ and $z$ have equal space

$$
\begin{aligned}
& \forall A^{\mathrm{X}} \in \operatorname{ran}\left(Y_{U \mathrm{i}, \leq y}\right) \\
& \quad\left(\left|\left\{\operatorname{space}\left(C_{\mathrm{G}, \mathrm{y}, \mathrm{u}}\right)(H): H \in \mathcal{H}_{U, X}, B=\operatorname{histogram}(H), B^{\mathrm{X}}=A^{\mathrm{X}}\right\}\right|=1\right)
\end{aligned}
$$

In addition, if the independent histogram is integral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, and hence an iso-independent, $A^{\mathrm{X}} \in Y_{U, i, \leq y}^{-1}\left(A^{\mathrm{X}}\right)$, then it is conjectured that its classification space is greater than or equal to the classification space of the iso-independents

$$
\forall B \in Y_{U, i, \leq y}^{-1}\left(A^{\mathrm{X}}\right)\left(\text { spaceClassification }(B) \leq \operatorname{spaceClassification}\left(A^{\mathrm{X}}\right)\right)
$$

See the discussion of alignment where the independent histogram is integral in the section 'Minimum alignment', below. In this case the iso-independent superposed classification space equals the classification space of the independent histogram
spaceClassificationIsoSuperposed $(U)(A)=\operatorname{spaceClassification}\left(A^{\mathrm{X}}\right)$
Note that the classification space of the independent histogram does not depend on system $U$.

Next consider another non-generic classification coder of histories. Define the constructor of the parallel iso-independent classification coder of histories

$$
C_{\mathrm{G}, \mathrm{y}, \mathrm{p}}=\operatorname{coderClassificationIsoParallel}\left(U, X, D_{\mathrm{V}}, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)
$$

The intermediate tuple is $\left(\left(n, N_{V}\right),\left(z, Z_{I}\right), L, K_{Q}\right) \in \mathbf{N}^{2} \times \mathbf{N}^{2} \times \mathcal{L}(\mathbf{N}) \times \mathbf{N}$. The first three elements of the tuple are calculated as for the generic isoindependent classification coder, $C_{\mathrm{G}, \mathrm{A}, \mathrm{y}}$. The last element, $K_{Q}$, encodes the position of the partition of the event identifiers, $Q=\operatorname{ran}(G)$ where $G=$
classification $(H)$, in an enumeration of the partitions corresponding to the iso-independent histograms of $A^{\mathrm{X}}$. Given $D_{\mathrm{X}}$, choose enumeration $K$

$$
\begin{aligned}
& K \in \operatorname{enums}\left(\left\{P: P \in \mathrm{~B}(\operatorname{ids}(G)), B \in Y_{U, i, \leq y}^{-1}\left(A^{\mathrm{x}}\right),\right.\right. \\
& \left.\left.\quad \exists X \in P: \leftrightarrow: B^{\mathrm{S}} \forall(Y, S) \in X\left(|Y|=B_{S}\right)\right\}\right)
\end{aligned}
$$

The enumeration is such that

$$
K_{Q} \in\left\{1 \ldots \sum_{B \in Y_{U, i, \leq y}^{-1}\left(A^{\mathrm{X}}\right)} \frac{z!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}\right\}
$$

Define the space of the encoding of the parallel iso-independent classification as spaceClassificationIsoParallel $(U) \in \mathcal{A}_{U} \rightarrow \ln \mathbf{N}_{>0}$

$$
\text { spaceClassificationIsoParallel }(U)(A):=\ln \sum_{B \in Y_{U, i, \leq y}^{-1}\left(A^{\mathrm{X}}\right)} \frac{z!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}
$$

which is defined if $A^{\mathrm{X}} \in \operatorname{ran}\left(Y_{U, \mathrm{i}, \leq y}\right)$. The space of the parallel iso-independent classification coder $C_{\mathrm{G}, \mathrm{y}, \mathrm{p}}$ of a history $H \in \mathcal{H}_{U, X}$ is the sum of the variables space, ids space, perimeter space, and parallel iso-independent classification space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{G}, \mathrm{y}, \mathrm{u}}\right)(H)= & \operatorname{spaceVariables}(U)(|\operatorname{vars}(H)|)+ \\
& \operatorname{spaceIds}(|X|,|H|)+ \\
& \text { spacePerimeter }(U)(A)+ \\
& \text { spaceClassificationIsoParallel }(U)(A)
\end{aligned}
$$

where $A=\operatorname{histogram}(H)$.
Although the parallel iso-independent classification coder, $C_{\mathrm{G}, \mathrm{y}, \mathrm{p}}$, does not encode the iso-independent position space, spaceIsoIndependentPosition $(U)(A)$, the space of a history in the parallel iso-independent classification coder, $C_{\mathrm{G}, \mathrm{y}, \mathrm{p}}$, is always greater than or equal to the space of the history in the superposed iso-independent classification coder, $C_{\mathrm{G}, \mathrm{y}, \mathrm{u}}$

$$
\forall H \in \mathcal{H}_{U, X}\left(\operatorname{space}\left(C_{\mathrm{G}, \mathrm{y}, \mathrm{p}}\right)(H) \geq \operatorname{space}\left(C_{\mathrm{G}, \mathrm{y}, \mathrm{u}}\right)(H)\right)
$$

The coder $C_{\mathrm{G}, \mathrm{y}, \mathrm{p}}$ also has the property that all of the histories in any given iso-independent set parameterised by $V$ and $z$ have equal space

$$
\begin{aligned}
& \forall A^{\mathrm{x}} \in \operatorname{ran}\left(Y_{U \mathrm{i}, \leq y}\right) \\
& \quad\left(\left|\left\{\operatorname{space}\left(C_{\mathrm{G}, \mathrm{y}, \mathrm{p}}\right)(H): H \in \mathcal{H}_{U, X}, B=\operatorname{histogram}(H), B^{\mathrm{x}}=A^{\mathrm{x}}\right\}\right|=1\right)
\end{aligned}
$$

Following the parallel iso-independent classification coder, define the constructor of the sequential iso-independent classification coder of histories
$C_{\mathrm{G}, \mathrm{y}, \mathrm{S}}=\operatorname{coderClassificationIsoSequential}\left(U, X, D_{\mathrm{V}}, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$
The intermediate tuple is $\left(\left(n, N_{V}\right),\left(z, Z_{I}\right), L, M\right) \in \mathbf{N}^{2} \times \mathbf{N}^{2} \times \mathcal{L}(\mathbf{N}) \times \mathcal{L}(\mathbf{N})$. The first three elements of the tuple are calculated as for the generic isoindependent classification coder, $C_{\mathrm{G}, \mathrm{A}, \mathrm{y}}$. The last element, $M$, encodes a list whose elements correspond to the iso-independent histograms of $A^{\mathrm{X}}$, $|M|=\left|Y_{U, i, \leq y}^{-1}\left(A^{\mathrm{X}}\right)\right|$. Each element of $M$ encodes the partitions of the event identifiers corresponding to the iso-independent histogram. Given order $D_{\mathrm{A}}$ choose $J \in \operatorname{enums}\left(Y_{U, i, \leq y}^{-1}\left(A^{\mathrm{X}}\right)\right)$. Thus

$$
J_{A} \in\left\{1 \ldots\left|Y_{U, i, \leq y}^{-1}\left(A^{\mathrm{X}}\right)\right|\right\}
$$

Then

$$
M_{J_{A}}(Q) \in\left\{1 \cdots \frac{z!}{\prod_{S \in \operatorname{dom}(G)}\left|G_{S}\right|!}\right\}
$$

where $A=\operatorname{histogram}(H), G=\operatorname{classification}(H)$ and $Q=\operatorname{ran}(G)$. Define the space of the encoding of the sequential iso-independent classification in the enumeration, $M$, as spaceClassificationIsoSequential $(U) \in \mathcal{A}_{U} \rightarrow \ln \mathbf{N}_{>0}$

$$
\text { spaceClassificationIsoSequential }(U)(A):=\sum_{B \in Y_{U, i, \leq y}^{-1}\left(A^{\mathrm{X}}\right)} \ln \frac{z!}{\prod_{S \in B^{\mathrm{S}}} B_{S}!}
$$

which is defined if $A^{\mathrm{X}} \in \operatorname{ran}\left(Y_{U, \mathrm{i}, \leq y}\right)$. Thus
spaceClassificationIsoSequential $(U)(A)=\sum_{B \in Y_{U, i, 1}^{-1}\left(A^{\mathrm{X}}\right)}$ spaceClassification $(B)$
The space of the sequential iso-independent classification coder $C_{\mathrm{G}, \mathrm{y}, \mathrm{s}}$ of a history $H \in \mathcal{H}_{U, X}$ is the sum of the variables space, ids space, perimeter space, and sequential iso-independent classification space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{G}, \mathrm{y}, \mathrm{~s}}\right)(H)= & \operatorname{spaceVariables}(U)(|\operatorname{vars}(H)|)+ \\
& \text { spaceIds }(|X|,|H|)+ \\
& \text { spacePerimeter }(U)(A)+ \\
& \text { spaceClassificationIsoSequential }(U)(A)
\end{aligned}
$$

where $A=\operatorname{histogram}(H)$.

The space of a history $H$ in the sequential iso-independent classification coder, $C_{\mathrm{G}, \mathrm{y}, \mathrm{s}}$, is always greater than or equal to the space of the history in the parallel iso-independent classification coder, $C_{\mathrm{G}, \mathrm{A}, \mathrm{p}}$

$$
\forall H \in \mathcal{H}_{U, X}\left(\operatorname{space}\left(C_{\mathrm{G}, \mathrm{y}, \mathrm{~s}}\right)(H) \geq \operatorname{space}\left(C_{\mathrm{G}, \mathrm{~A}, \mathrm{p}}\right)(H)\right)
$$

Thus

$$
\operatorname{sum}\left(C_{\mathrm{G}, \mathrm{y}, \mathrm{~s}}^{\mathrm{s}}\right) \geq \operatorname{sum}\left(C_{\mathrm{G}, \mathrm{y}, \mathrm{p}}^{\mathrm{s}}\right) \geq \operatorname{sum}\left(C_{\mathrm{G}, \mathrm{y}, \mathrm{u}}^{\mathrm{s}}\right) \geq \operatorname{sum}\left(C_{\mathrm{G}, \mathrm{~A}, \mathrm{y}}^{\mathrm{s}}\right)
$$

where $C^{\mathrm{s}}:=\operatorname{space}(C)$. The coder $C_{\mathrm{G}, \mathrm{y}, \mathrm{s}}$ also has the property that all of the histories in any given iso-independent set parameterised by $V$ and $z$ have equal space

$$
\begin{aligned}
& \forall A^{\mathrm{X}} \in \operatorname{ran}\left(Y_{U, \mathrm{i}, \leq y}\right) \\
& \quad\left(\left|\left\{\operatorname{space}\left(C_{\mathrm{G}, \mathrm{y}, \mathrm{~s}}\right)(H): H \in \mathcal{H}_{U, X}, B=\operatorname{histogram}(H), B^{\mathrm{x}}=A^{\mathrm{X}}\right\}\right|=1\right)
\end{aligned}
$$

There are other examples of history coders, $C \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$, that use the independent histogram, $A^{\mathrm{X}}$, or related concepts to modify the space function, space $(C) \in \mathcal{H}_{U, X} \rightarrow \ln \mathbf{N}_{>0}$, in order to minimise the space of expected histories, expected $(P)($ space $(C)) \in \mathbf{Q}_{\geq 0} \ln \mathbf{N}_{>0}$, which depend on the probability function, $P \in\left(\mathcal{H}_{U, X} \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$.

For example, if there exists an integral independent histogram $B^{\mathrm{X}}$ which is such that $B^{\mathrm{X}} \leq A$ and the difference in size between the integral independent histogram and the history's histogram, $\operatorname{size}\left(A-B^{\mathrm{X}}\right)$, is small, then the space of the size of the perimeter plus space of a perimeter encoding of $B^{\mathrm{X}}$ plus the counts space of the encoding of the difference, $A-B^{\mathrm{X}}$, may be less than the counts space of the histogram, $A$

$$
\begin{aligned}
& \operatorname{space}(z)+\operatorname{spacePerimeter}(U)\left(B^{\mathrm{X}}\right)+\operatorname{spaceCounts}(U)\left(A-B^{\mathrm{X}}\right) \\
\leq & \text { spaceCounts}(U)(A)
\end{aligned}
$$

Another example is the ideal transform coder, described in the section 'Inducers and Compression' below, which searches for an ideal transform $T$, which is such that $A * T * T^{\dagger A}=A$. The resultant transform partitions the volume, $T^{\mathrm{P}} \in \mathrm{B}\left(V^{\mathrm{CS}}\right)$, into independent components, $\forall C \in T^{\mathrm{P}}\left(A * C^{\mathrm{U}}=\left(A * C^{\mathrm{U}}\right)^{\mathrm{X}}\right)$, which can be individually encoded as perimeters given the derived histogram, $A * T$, that encodes their sizes.

## A. 8 Distribution space

The various history coders, above, have coder domain $\mathcal{H}_{U, X}$. The expected space of coder $C, \operatorname{expected}(P)($ space $(C))$, depends on the probability function
$P$ of the coder domain, $P \in\left(\mathcal{H}_{U, X} \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$. As can be seen above, the classification coder, $C_{\mathrm{G}}$, requires least space for low entropy histories. In contrast, the index history coder, $C_{\mathrm{H}}$, uses less space than the classification coder, $C_{\mathrm{G}}$, where the entropy is high. Thus the coder can be chosen such that the probability in $P$ of low space encodings is high and the probability of high space encodings is low. That is, such that the space varies inversely with the probability, space $(C) \sim\left\{\left(H, 1 / P_{H}\right): H \in \mathcal{H}_{U, X}\right\}$. For example, an entropy coder is defined such that space $(C)(H)=-\ln P_{H}$. See appendix 'Coders and entropy'. Minimal coders, where the probability function is uniform, $P=\mathcal{H}_{U, X} \times\left\{1 /\left|\mathcal{H}_{U, X}\right|\right\}$, imply an absolute standard of the expected space of $\ln \left|\mathcal{H}_{U, X}\right|$, by which coders may be compared. However, the calculation of the cardinality of $\mathcal{H}_{U, X}$ depends on the variables of the histories.

Consider a special case of history coders where the variables $V$ of the histories are fixed. Parameterise the coders with some non-empty distribution history $H_{E} \in \mathcal{H}_{U} \backslash\{\emptyset\}$, of size $z_{E}=\left|H_{E}\right|$ in variables $V$, from which a subset $H \subseteq H_{E}$ is drawn without replacement. The coder domain is the powerset of the distribution history, $\mathrm{P}\left(H_{E}\right)$. The cardinality of the distribution coder domain is $\left|\mathrm{P}\left(H_{E}\right)\right|=2^{z_{E}}$ which implies a minimal space per history of $z_{E} \ln 2$.

An example of a minimal distribution coder $C \in \operatorname{coders}\left(\mathrm{P}\left(H_{E}\right)\right)$ is such that the code is in enums $\left(\mathrm{P}\left(H_{E}\right)\right)$. The space of $H \subseteq H_{E}$ is space $(C)(H)=z_{E} \ln 2$.

Consider the fixed width analogue for the index coder of histories, $C_{\mathrm{H}}$, where the distribution history, $H_{E}$, is known. The index distribution coder, $C_{\mathrm{Q}, 1}$, is constructed

$$
C_{\mathrm{Q}, \mathrm{l}}=\operatorname{coderDistributionIndex}\left(H_{E}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathrm{P}\left(H_{E}\right)\right)
$$

The index distribution coder is parameterised by (i) the distribution history, $H_{E}$, and (ii) the order on the event identifiers, $D_{\mathrm{X}} \in \operatorname{enums}(X)$, where $X$ is some set of event identifiers such that $\operatorname{ids}\left(H_{E}\right) \subseteq X$.

The intermediate tuple is $(z, L) \in \mathbf{N} \times \mathcal{L}(\mathbf{N})$. The first element of the tuple encodes the size of the drawn history, $z=|H|$. The space is $\ln \left(z_{E}+1\right)$.

The second element of the tuple encodes a list of the subset of the events of $H_{E}$ indexed by the enumeration $\operatorname{order}\left(D_{\mathrm{X}}, \operatorname{ids}\left(H_{E}\right)\right) \in \operatorname{enums}\left(\operatorname{ids}\left(H_{E}\right)\right)$. That is, $\operatorname{set}(L) \subseteq\left\{1 \ldots z_{E}\right\}$ and $|\operatorname{set}(L)|=|L|=z$, where $z_{E}=\left|H_{E}\right|$. The space of the element $L$ is $z \ln z_{E}$.

The space of the index distribution coder is

$$
\operatorname{space}\left(C_{\mathrm{Q}, 1}\right)(H):=\operatorname{spaceSize}\left(z_{E}\right)+z \times \operatorname{space}\left(z_{E}\right)
$$

A similar coder of histories where the distribution history, $H_{E}$, is known, is the subset distribution coder, $C_{\mathrm{Q}, \mathrm{p}}$. It is constructed from the same parameters as $C_{\mathrm{Q}, 1}$. The intermediate tuple is $\left(z, N_{H}\right) \in \mathbf{N} \times \mathbf{N}$. The first element of the tuple encodes the size of the drawn history, $z=|H|$. The space is $\ln \left(z_{E}+1\right)$. The second element of the tuple encodes the subset of the events of $H_{E}$. Given order $D_{\mathrm{X}}$ choose an enumeration $N \in \operatorname{enums}(\{R$ : $\left.\left.R \in \mathrm{P}\left(H_{E}\right),|R|=z\right\}\right)$. The space of the element $N_{H}$ is

$$
\operatorname{spaceSubset}\left(z_{E}, z\right)=\ln \frac{z_{E}!}{z!\left(z_{E}-z\right)!}=\underline{z} \ln z_{E}-\underline{z} \ln z
$$

where $x^{\underline{y}}$ is falling factorial. The notation is abused such that $\underline{y} \ln x=\ln x^{\underline{y}}$.
The space of the subset distribution coder is

$$
\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{p}}\right)(H):=\operatorname{spaceSize}\left(z_{E}\right)+\operatorname{spaceSubset}\left(z_{E}, z\right)
$$

The space of the subset distribution coder is less than the space of the index distribution coder because $H$ is drawn without replacement from $H_{E}$. That is, $H$ is a subset, $H \subseteq H_{E}$,

$$
\operatorname{space}\left(C_{\mathrm{Q}, 1}\right)(H)-\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{p}}\right)(H)=z \ln z_{E}-\left(\underline{z} \ln z_{E}-\underline{z} \ln z\right)>0
$$

Neither the index distribution coder, $C_{\mathrm{Q}, 1}$, nor the subset distribution coder, $C_{\mathrm{Q}, \mathrm{p}}$, are defined in terms of distributions of histograms, $\mathcal{Q} \subset \mathcal{A}_{\mathrm{i}} \rightarrow \mathrm{Q}_{\geq 0}$. The historical distribution of histograms, $Q_{\mathrm{h}} \in \mathcal{A}_{\mathrm{i}} \times \mathbf{N} \rightarrow \mathcal{Q}$, forms the basis for the historical distribution coder of histories $C_{\mathrm{Q}, \mathrm{h}}$ constructed

$$
C_{\mathrm{Q}, \mathrm{~h}}=\operatorname{coderDistributionHistorical}\left(U, H_{E}, D_{\mathrm{V}}, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathrm{P}\left(H_{E}\right)\right)
$$

The historical distribution coder is parameterised by (i) the system, $U$, (ii) the non-empty distribution history, $H_{E}$, (iii) the order on the variables, $D_{\mathrm{V}}$, (iv) the order on the states, $D_{\mathrm{S}}$, and (v) the order on the event identifiers, $D_{\mathrm{x}}$.

The intermediate tuple is $\left(z, R_{A}, J_{H}\right) \in \mathbf{N} \times \mathbf{N} \times \mathbf{N}$. The first element of the tuple encodes the size of the drawn history, $z=|H|$. The space is $\ln \left(z_{E}+1\right)$.

The second element of the tuple encodes the set of counts of the histogram of the drawn history, $A=\operatorname{histogram}(H)$. The space of the element $R_{A}$ is spaceCounts $(U)(A)$.

The third element of the intermediate tuple, $J_{H}$, encodes the position in a list of the histories which are subsets of $H_{E}$ having histogram $A$. Given order $D_{\mathrm{A}}$, constructed from $D_{\mathrm{V}}$ and $D_{\mathrm{S}}$, and order $D_{\mathrm{X}}$ choose the enumeration

$$
J \in \operatorname{enums}\left(\left\{G: G \subseteq H_{E}, \operatorname{histogram}(G)=A\right\}\right)
$$

which is such that $J_{H} \in\left\{1 \ldots Q_{\mathrm{h}}(E, z)(A)\right\}$ where $E=\operatorname{histogram}\left(H_{E}\right)$ and the set of historical distributions $Q_{\mathrm{h}} \in \mathcal{A}_{\mathrm{i}} \times \mathbf{N} \rightarrow \mathcal{Q}$ is defined

$$
Q_{\mathrm{h}}(E, z)(A)=\prod_{S \in A^{\mathrm{S}}} \frac{E_{S}!}{A_{S}!\left(E_{S}-A_{S}\right)!} \in \mathbf{N}_{>0}
$$

Define historical distribution space spaceDistributionHistorical $\in \mathcal{A}_{\mathbf{i}} \times \mathbf{N} \rightarrow$ $\left(\mathcal{A}_{\mathbf{i}} \rightarrow \ln \mathbf{N}_{>0}\right)$ as

$$
\text { spaceDistributionHistorical }(E, z)(A):=\ln Q_{\mathrm{h}}(E, z)(A)
$$

The space of the historical distribution coder is

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{~h}}\right)(H)= & \operatorname{spaceSize}\left(z_{E}\right)+ \\
& \operatorname{spaceCounts}(U)(A)+ \\
& \operatorname{spaceDistributionHistorical}(E, z)(A)
\end{aligned}
$$

where $z_{E}=\left|H_{E}\right|, E=\operatorname{histogram}\left(H_{E}\right), A=\operatorname{histogram}(H)$ and $z=|H|$. Here the variables $V$ are known from the parameters of the constructor and so there is no need to encode them. The space required to encode the event identifiers is incorporated into the historical distribution space, $\ln Q_{\mathrm{h}}(E, z)(A)$. The counts space only depends on the volume and size of the history,

$$
\operatorname{spaceCounts}(U)(A)=\operatorname{spaceCompositionWeak}(v, z)
$$

where $v=$ volume $(U)\left(H_{E}\right)$. The space of the empty history is defined $\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{h}}\right)(\emptyset):=\operatorname{spaceSize}\left(z_{E}\right)$.

The space of the historical distribution coder may be compared to a minimal coder. In the case of a high entropy uniform cartesian histogram,
$A=\operatorname{scalar}(z / v) * V^{\mathrm{C}} \in \mathcal{A}_{\mathrm{i}}$ where $v=\left|V^{\mathrm{C}}\right|$, and a uniform cartesian distribution histogram, $E=\operatorname{scalar}\left(z_{E} / v\right) * V^{\mathrm{C}} \in \mathcal{A}_{\mathrm{i}}$, the space is

$$
\begin{aligned}
& \text { space }\left(C_{\mathrm{Q}, \mathrm{~h}}\right)(H) \\
& \quad=\ln \left(z_{E}+1\right)+\ln \frac{(z+v-1)!}{z!(v-1)!}+\ln \prod_{S \in A^{\mathrm{S}}} \frac{E_{S}!}{A_{S}!\left(E_{S}-A_{S}\right)!} \\
& =\ln \left(z_{E}+1\right)+\bar{v} \ln z-\underline{v} \ln v-\ln (z / v)-\sum_{S \in A^{\mathrm{S}}} \underline{A_{S}} \ln A_{S}+\sum_{S \in A^{\mathrm{S}}} \underline{A_{S}} \ln E_{S} \\
& =\ln \left(z_{E}+1\right)+\bar{v} \ln z-\underline{v} \ln v-\ln (z / v)-v \underline{(z / v)} \ln (z / v)+v \underline{(z / v)} \ln \left(z_{E} / v\right) \\
& \quad<\underline{(z / v)} \ln \left(z_{E} / v\right)+\bar{v} \ln z+\ln \left(z_{E}+1\right)
\end{aligned}
$$

where $x^{\bar{y}}$ is rising factorial and $x^{\underline{y}}$ is falling factorial. The notation is abused such that $\bar{y} \ln x=\ln x^{\bar{y}}$ and $\underline{y} \ln x=\ln x^{\underline{y}}$. It can be seen that in some cases, if $v \leq z \ll z_{E}$, the space is less than that for a minimal coder, $\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{h}}\right)(H)<z_{E} \ln 2$.

The space of a history in the historical distribution coder in the low entropy case of a singleton histogram $A=\{(S, z)\}$ and distribution histogram such that $E_{S}=z$ is

$$
\begin{aligned}
& \text { space }\left(C_{\mathrm{Q}, \mathrm{~h}}\right)(H) \\
& \quad=\ln \left(z_{E}+1\right)+\bar{v} \ln z-\underline{v} \ln v-\ln (z / v)-\underline{z} \ln z+-\underline{z} \ln z \\
& \quad<\bar{v} \ln z+\ln \left(z_{E}+1\right)
\end{aligned}
$$

For $v<z<z_{E}$ the space is less than that for an index distribution coder, $\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{h}}\right)(H)<\operatorname{space}\left(C_{\mathrm{Q}, 1}\right)(H)=z \ln z_{E}+\ln \left(z_{E}+1\right)$.

As shown above, the historical distribution can be rewritten in terms of the multinomial coefficient

$$
Q_{\mathrm{h}}(E, z)(A)=\prod_{S \in A^{\mathrm{S}}} \frac{E_{S}!}{A_{S}!\left(E_{S}-A_{S}\right)!}=\frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \frac{1}{z!} \prod_{S \in A^{\mathrm{S}}} E^{A_{S}}
$$

Compare this to a multinomial distribution in $Q_{\mathrm{m}} \in \mathcal{A}_{\mathrm{i}} \times \mathbf{N} \rightarrow \mathcal{Q}$ defined

$$
Q_{\mathrm{m}}(E, z)(A)=\frac{z!}{\prod_{S \in A^{\mathrm{s}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}} E_{S}^{A_{S}} \in \mathbf{N}_{>0}
$$

The coder domain of the powerset of the distribution histogram, $\mathrm{P}\left(H_{E}\right)$, can be encoded by means of the multinomial distribution, albeit requiring
more space than the historical distribution coder, $C_{\mathrm{Q}, \mathrm{h}}$. The multinomial distribution coder of histories $C_{\mathrm{Q}, \mathrm{m}}$ is defined
$C_{\mathrm{Q}, \mathrm{m}}=\operatorname{coderDistributionMultinomial}\left(U, H_{E}, D_{\mathrm{V}}, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathrm{P}\left(H_{E}\right)\right)$
The multinomial distribution coder, $C_{\mathrm{Q}, \mathrm{m}}$, is constructed with the same parameters as the historical distribution coder, $C_{\mathrm{Q}, \mathrm{h}}$.

The intermediate tuple is $\left(z, R_{A}, K_{H}\right) \in \mathbf{N} \times \mathbf{N} \times \mathbf{N}$. The first and second elements of the tuple encodes the size $z=|H|$ and the histogram $A=\operatorname{histogram}(H)$ in the same way as the historical distribution coder, $C_{\mathrm{Q}, \mathrm{h}}$.

The third element of the intermediate tuple, $K_{H}$, encodes the position in a list of the histories which have histogram A. The histories are constructed from subsets of $H_{E}^{z}=\left\{L: L \in \mathcal{L}\left(H_{E}\right),|L|=z\right\}$ by modifying the event identifiers. Given order $D_{\mathrm{A}}$, constructed from $D_{\mathrm{V}}$ and $D_{\mathrm{S}}$, and order $D_{\mathrm{X}}$ choose the enumeration
$K \in \operatorname{enums}\left(\left\{G: L \in \mathcal{L}\left(H_{E}\right), G=\{((i, x), S):(i,(x, S)) \in L\}, \operatorname{his}(G)=A\right\}\right)$
where his $=$ histogram. The enumeration of modified histories $K \in \mathcal{H} \rightarrow \mathbf{N}$ is such that
$\exists G \in \operatorname{dom}(K)\left((\{(x, S):((i, x), S) \in G\}=H) \wedge\left(K_{G} \in\left\{1 \ldots Q_{\mathrm{m}}(E, z)(A)\right\}\right)\right)$
where $E=$ histogram $\left(H_{E}\right)$. Any of the modified histories, $G \in \operatorname{dom}(K)$, for which $\{(x, S):((i, x), S) \in G\}=H$, can be chosen to encode $H$. Given $K_{H}$ the decode is $\left\{(x, S):((i, x), S) \in \operatorname{flip}(K)\left(K_{H}\right)\right\}=H$.

Define multinomial distribution space spaceDistributionMultinomial $\in \mathcal{A}_{\mathrm{i}} \times$ $\mathbf{N} \rightarrow\left(\mathcal{A}_{\mathbf{i}} \rightarrow \ln \mathbf{N}_{>0}\right)$ as

$$
\text { spaceDistributionMultinomial }(E, z)(A):=\ln Q_{\mathrm{m}}(E, z)(A)
$$

The space of the multinomial distribution coder is

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{~m}}\right)(H)= & \operatorname{spaceSize}\left(z_{E}\right)+ \\
& \operatorname{spaceCounts}(U)(A)+ \\
& \operatorname{spaceDistributionMultinomial}(E, z)(A)
\end{aligned}
$$

where $z_{E}=\left|H_{E}\right|, E=\operatorname{histogram}\left(H_{E}\right), A=\operatorname{histogram}(H)$ and $z=|H|$. The space of the empty history is defined space $\left(C_{\mathrm{Q}, \mathrm{m}}\right)(\emptyset):=\operatorname{spaceSize}\left(z_{E}\right)$.

The space of a history $H \subseteq H_{E}$ in the multinomial distribution coder is greater than or equal to the space in the historical distribution coder

$$
\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{~m}}\right)(H) \geq \operatorname{space}\left(C_{\mathrm{Q}, \mathrm{~h}}\right)(H)
$$

The space is sometimes larger because

$$
\left|H_{E}^{z}\right|=z_{E}^{z} \geq\left|\left\{H: H \subseteq H_{E},|H|=z\right\}\right|=z_{E}^{\frac{z}{E}} / z!
$$

There are modified histories in the multinomial distribution coder that do not correspond to elements of the coder domain, $\mathrm{P}\left(H_{E}\right)$, because some contain replaced events and because there are up to $z$ ! permutations depending on the number of replaced events. See the discussion, above, comparing historical distributions and multinomial distributions.

In fact, the multinomial distribution would be a more efficient method if the coder domain was $\left\{L: L \in \mathcal{L}\left(H_{E}\right),|L| \leq z_{E}\right\}$ rather than $\mathrm{P}\left(H_{E}\right)$. In this case, each $K_{G} \in\left\{1 \ldots Q_{\mathrm{m}}(E, z)(A)\right\}$ would encode a different element of the coder domain and there would be no unused space.

Also the multinomial distribution could be used to encode lists of cardinality greater than $\left|H_{E}\right|$. In this case the coder domain would be $\{L$ : $\left.L \in \mathcal{L}\left(H_{E}\right),|L| \leq y\right\}$ where $y \in \mathbf{N}$. Here $y$ would be a parameter of the constructor of a multinomial distribution coder, $\left(U, H_{E}, y, D_{\mathrm{V}}, D_{\mathrm{S}}\right)$, and additional space would be required for (i) the length of a limited list, $\ln (y+1)$, or (ii) the termination flag space of an unlimited list.

In order to compare the distribution coders to the classification coders, let $C_{\mathrm{G}, V}$ be a special case of the classification coder of histories, $C_{\mathrm{G}}$, such that the variables, $V$, are fixed. The coder domain is $X \rightarrow V^{\mathrm{CS}}=\{H: H \in$ $\left.\mathcal{H}_{U, X}, \operatorname{vars}(H)=V\right\} \supset \mathrm{P}\left(H_{E}\right)$ where $X=\operatorname{dom}\left(H_{E}\right)$. Thus

$$
\operatorname{space}\left(C_{\mathrm{G}, V}\right)(H)=\operatorname{space}\left(C_{\mathrm{G}}\right)(H)-\operatorname{spaceVariables}(U)(V)
$$

where history $H \subseteq H_{E}$. The space of the substrate classification coder, $C_{\mathrm{G}, V}$, is

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{G}, V}\right)(H)= & \operatorname{spaceIds}\left(z_{E}, z\right)+ \\
& \operatorname{spaceCounts}(U)(A)+ \\
& \operatorname{spaceClassification}(A)
\end{aligned}
$$

where $z_{E}=\left|H_{E}\right|, A=\operatorname{histogram}(H)$ and $z=|H|$. The events classification space of the histogram, spaceClassification $(A)$, is defined as the logarithm of
the multinomial coefficient

$$
\operatorname{spaceClassification}(A):=\ln \frac{z!}{\prod_{S \in A^{\mathrm{s}}} A_{S}!}
$$

As shown above, the events classification space approximates to the sized entropy of the histogram

$$
\operatorname{spaceClassification}(A) \approx z \times \operatorname{entropy}(A)
$$

The space of a history $H \subseteq H_{E}$ in the multinomial distribution coder, space $\left(C_{\mathrm{Q}, \mathrm{m}}\right)(H)$, varies as the frequency $Q_{\mathrm{m}}(E, z)(A)$. This in turn varies as the multinomial coefficient, $z!/ \prod_{S \in A^{\mathrm{S}}} A_{S}$ !. Thus the space of both the classification coder and the multinomial distribution coder varies with the entropy of the histogram, entropy $(A)$. Low entropy histories tends to require less space than high entropy.

However, the frequencies of the multinomial distribution, $Q_{\mathrm{m}}(E, z)$, depend on the permutorial part, $\prod_{S \in A^{S}} E_{S}^{A_{S}}$, as well as the multinomial coefficient, $z!/ \prod_{S \in A^{\mathrm{S}}} A_{S}!$. As shown above, the logarithm of the multinomial probability distribution approximates to the negative sized relative entropy between the complete sample histogram, $A+V^{\mathrm{CZ}}$, and the distribution histogram, $E$,

$$
\begin{aligned}
\ln \hat{Q}_{\mathrm{m}, U}(E, z)\left(A+V^{\mathrm{CZ}}\right) & \approx \sum_{S \in A^{\mathrm{FS}}, P_{S}>0} A_{S} \ln \frac{P_{S}}{N_{S}} \\
& =-z \sum_{S \in A^{\mathrm{FS}}, P_{S}>0} N_{S} \ln \frac{N_{S}}{P_{S}} \\
& =-z \times \text { entropyRelative }(N, P)
\end{aligned}
$$

where $P=\operatorname{resize}(1, E)$ and $N=\operatorname{resize}(1, A)$. So the space of the multinomial distribution coder, space $\left(C_{\mathrm{Q}, \mathrm{m}}\right)(H)$, varies inversely with the relative entropy. In the case of the classification coder, $C_{\mathrm{G}, V}$, there is no distribution histogram. It is equivalent to the multinomial distribution where the distribution histogram is uniform cartesian, $E=V^{\mathrm{C}}$

$$
\begin{aligned}
\operatorname{spaceClassification~}(A) & =\ln Q_{\mathrm{m}}\left(V^{\mathrm{C}}, z\right)(A) \\
& =\ln \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}} 1^{A_{S}} \\
& =\ln \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!}
\end{aligned}
$$

The space of a history in the multinomial distribution coder, space $\left(C_{\mathrm{Q}, \mathrm{m}}\right)(H)$, is maximised when the relative entropy is minimised. That occurs when the sample histogram equals the scaled distribution histogram, $A=\operatorname{scalar}\left(z / z_{E}\right) *$ $E$. In probabilistic terms, this is when the sample histogram equals the mean, $A=\operatorname{mean}\left(\hat{Q}_{\mathrm{m}, U}\left(E+V^{\mathrm{CZ}}, z\right)\right)$. Sample histograms that are far from the mean with respect to the variance, $\operatorname{var}(U)\left(\hat{Q}_{\mathrm{m}, U}\left(E+V^{\mathrm{CZ}}, z\right)\right)$, have lower space. Note that, as shown above, variance varies as the entropy of the distribution histogram, entropy $(E)$.

The space of a history in the multinomial distribution coder in the case of a high entropy uniform cartesian histogram, $A=\operatorname{scalar}(z / v) * V^{\mathrm{C}} \in \mathcal{A}_{\mathrm{i}}$ where $v=\left|V^{\mathrm{C}}\right|$, and a uniform cartesian distribution histogram, $E=\operatorname{scalar}\left(z_{E} / v\right) *$ $V^{\mathrm{C}} \in \mathcal{A}_{\mathrm{i}}$ is

$$
\begin{aligned}
& \text { space }\left(C_{\mathrm{Q}, \mathrm{~m}}\right)(H) \\
& \quad=\ln \left(z_{E}+1\right)+\ln \frac{(z+v-1)!}{z!(v-1)!}+\ln \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}} E_{S}^{A_{S}} \\
& =\ln \left(z_{E}+1\right)+\bar{v} \ln z-\underline{v} \ln v-\ln (z / v)+\underline{z} \ln z-\sum_{S \in A^{\mathrm{S}}} \underline{A_{S}} \ln A_{S}+\sum_{S \in A^{\mathrm{S}}} A_{S} \ln E_{S} \\
& =\ln \left(z_{E}+1\right)+\bar{v} \ln z-\underline{v} \ln v-\ln (z / v)+\underline{z} \ln z-v \underline{(z / v)} \ln (z / v)+z \ln \left(z_{E} / v\right) \\
& \quad<z \ln \left(z_{E} / v\right)+\underline{z} \ln z+\bar{v} \ln z+\ln \left(z_{E}+1\right)
\end{aligned}
$$

It can be seen that even in some high entropy cases the space is less than that for a minimal coder, space $\left(C_{\mathrm{Q}, \mathrm{m}}\right)(H)<z_{E} \ln 2$, if $v \leq z \ll z_{E}$.

The space of a history in the multinomial distribution coder in the low entropy case of a singleton histogram $A=\{(S, z)\}$ and distribution histogram such that $E_{S}=z$ is

$$
\begin{aligned}
& \text { space }\left(C_{\mathrm{Q}, \mathrm{~m}}\right)(H) \\
& \quad=\ln \left(z_{E}+1\right)+\bar{v} \ln z-\underline{v} \ln v-\ln (z / v)+\underline{z} \ln z-\underline{z} \ln z+z \ln z \\
& \quad<z \ln z+\bar{v} \ln z+\ln \left(z_{E}+1\right)
\end{aligned}
$$

For some $v<z$ the space is less than that for an index distribution coder, $\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{m}}\right)(H)<\operatorname{space}\left(C_{\mathrm{Q}, 1}\right)(H)=z \ln z_{E}+\ln \left(z_{E}+1\right)$.

The space of a history in the classification coder is

$$
\begin{aligned}
& \text { space }\left(C_{\mathrm{G}, V}\right)(H) \\
& \quad=\ln \left(z_{E}+1\right)+\ln \frac{z_{E}!}{z!\left(z_{E}-z\right)!}+\ln \frac{(z+v-1)!}{z!(v-1)!}+\ln \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!}
\end{aligned}
$$

The difference between the two coders is

$$
\operatorname{space}\left(C_{\mathrm{G}, V}\right)(H)-\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{~m}}\right)(H)=\ln \frac{z_{E}!}{z!\left(z_{E}-z\right)!}-\ln \prod_{S \in A^{\mathrm{S}}} E_{S}^{A_{S}}
$$

In the case of uniform cartesian histogram, $A=\operatorname{scalar}(z / v) * V^{\mathrm{C}}$, and uniform cartesian distribution histogram, $E=\operatorname{scalar}\left(z_{E} / v\right) * V^{\mathrm{C}} \in \mathcal{A}_{\mathrm{i}}$, the difference is

$$
\operatorname{space}\left(C_{\mathrm{G}, V}\right)(H)-\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{~m}}\right)(H)=\underline{z} \ln z_{E}+z \ln v-\underline{z} \ln z-z \ln z_{E}
$$

Thus the space of the multinomial distribution coder is greater than that of the classification coder, $\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{m}}\right)(H)>\operatorname{space}\left(C_{\mathrm{G}, V}\right)(H)$, in the high entropy case.

Compare the low entropy case of a singleton histogram $A=\{(S, z)\}$ and distribution histogram such that $E_{S}=z$

$$
\operatorname{space}\left(C_{\mathrm{G}, V}\right)(H)-\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{~m}}\right)(H)=\underline{z} \ln z_{E}-\underline{z} \ln z-z \ln z
$$

In the low entropy case the space of the multinomial distribution coder is less than that of the classification coder, space $\left(C_{\mathrm{Q}, \mathrm{m}}\right)(H)<\operatorname{space}\left(C_{\mathrm{G}, V}\right)(H)$, if $z_{E} \gg z^{2}$. Thus the parameterisation of the distribution coders, $C_{\mathrm{Q}, \mathrm{h}}$ and $C_{\mathrm{Q}, \mathrm{m}}$, by the distribution history, $H_{E}$, reduces the space in some cases.

The historical distribution and the multinomial distribution of the distribution coders naturally imply a probability function. For example, let $P=$ $\left\{\left(H, \hat{Q}_{\mathrm{m}, U}(E,|H|)(A)\right): H \subseteq H_{E}, A=\operatorname{his}(H)+V^{\mathrm{CZ}}\right\}$ where $E=\operatorname{his}\left(H_{E}\right)+$ $V^{\mathrm{CZ}}$ then $\hat{P} \in\left(\mathrm{P}\left(H_{E}\right) \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$ is the conditional multinomial probability given the size. Of course, the expected space of the multinomial distribution coder in this implied probability function, expected $(\hat{P})\left(\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{m}}\right)\right) \in$ $\mathrm{Q}_{\geq 0} \ln \mathbf{N}_{>0}$, is high because the space varies with the implied probability, $\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{m}}\right) \sim \hat{P}$, rather than inversely as would be the case in an entropy coder of $\hat{P}$.

In the discussion above the alignment has been derived in terms of relative probability. It may equally be derived in terms of relative space. Let $H_{E}$ be some non-empty distribution history, $H_{E} \in \mathcal{H}_{U, X} \backslash\{\emptyset\}$, of size $z_{E}=\left|H_{E}\right|$ and variables $V=\operatorname{vars}\left(H_{E}\right)$ in system $U$ and event identifiers set $X$. The subset sample history $H \subset H_{E}$, of size $z=|H|$, is drawn from the distribution
history without replacement. Consider the distribution coder domain $\mathrm{P}\left(H_{E}\right)$. The multinomial distribution coder of histories $C_{\mathrm{Q}, \mathrm{m}}$ is defined above, as
$C_{\mathrm{Q}, \mathrm{m}}=\operatorname{coderDistributionMultinomial}\left(U, H_{E}, D_{\mathrm{V}}, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathrm{P}\left(H_{E}\right)\right)$
where $D_{\mathrm{V}}, D_{\mathrm{S}}$ and $D_{\mathrm{X}}$ are orders on the variables, states and event identifiers. The space of the multinomial distribution coder is

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{~m}}\right)(H)= & \operatorname{spaceSize}\left(z_{E}\right)+ \\
& \operatorname{spaceCounts}(U)(A)+ \\
& \operatorname{spaceDistributionMultinomial}(E, z)(A)
\end{aligned}
$$

where $E=\operatorname{histogram}\left(H_{E}\right), A=\operatorname{histogram}(H)$ and multinomial distribution space is

$$
\text { spaceDistributionMultinomial }(E, z)(A):=\ln Q_{\mathrm{m}}(E, z)(A)
$$

Here the sample histogram is trimmed, $A \in\left\{\operatorname{trim}(B): B \in \mathcal{A}_{U, \mathrm{i}, V, z}\right\}$.
In the case where the independent sample histogram is in the histograms of the coder domain, $A^{\mathrm{X}} \in\left\{\operatorname{histogram}(G): G \subseteq H_{E}\right\}$, and is therefore in- $^{\text {n }}$ tegral, $A^{\mathrm{X}} \in \mathcal{A}_{\mathrm{i}}$, then the multinomial distribution coder space of history $H$ may be decomposed into (i) the independent multinomial distribution coder space and (ii) relative dependent multinomial distribution coder space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{~m}}\right)(H)= & \operatorname{space} \operatorname{Size}\left(z_{E}\right)+ \\
& \operatorname{spaceCounts}(U)\left(A^{\mathrm{X}}\right)+ \\
& \operatorname{spaceDistributionMultinomial}(E, z)\left(A^{\mathrm{X}}\right)+ \\
& (\operatorname{spaceDistributionMultinomial}(E, z)(A)- \\
& \text { spaceDistributionMultinomial } \left.(E, z)\left(A^{\mathrm{X}}\right)\right)
\end{aligned}
$$

The counts space of the independent sample equals the counts space of the sample histogram, spaceCounts $(U)\left(A^{\mathrm{X}}\right)=\operatorname{spaceCounts}(U)(A)$, because the counts space only depends on the size, $z$, and volume, $v=\left|V^{\mathrm{C}}\right|$, and the independent is congruent, congruent $\left(A, A^{\mathrm{X}}\right)$.

Let $H_{\mathrm{X}}$ be any history drawn from the distribution history such that it's histogram equals the independent sample histogram,

$$
H_{\mathrm{X}} \in\left\{G: G \subseteq H_{E}, \text { histogram }(G)=A^{\mathrm{X}}\right\}
$$

The independent multinomial distribution coder space equals the space of $H_{\mathrm{X}}$

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{~m}}\right)\left(H_{\mathrm{X}}\right)= & \operatorname{spaceSize}\left(z_{E}\right)+ \\
& \operatorname{spaceCounts}(U)\left(A^{\mathrm{X}}\right)+ \\
& \operatorname{spaceDistributionMultinomial}(E, z)\left(A^{\mathrm{X}}\right)
\end{aligned}
$$

The relative dependent multinomial distribution coder space of history $H$ is

$$
\begin{aligned}
& \text { spaceDistMult }(E, z)(A)-\operatorname{spaceDistMult}(E, z)\left(A^{\mathrm{X}}\right) \\
& \quad=\ln Q_{\mathrm{m}}(E, z)(A)-\ln Q_{\mathrm{m}}(E, z)\left(A^{\mathrm{X}}\right) \\
& \quad=\ln \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \prod_{S \in A^{\mathrm{S}}} E_{S}^{A_{S}}-\ln \frac{z!}{\prod_{S \in A^{\mathrm{XS}}} A_{S}!} \prod_{S \in A^{\mathrm{XS}}} E_{S}^{A_{S}^{\mathrm{X}}}
\end{aligned}
$$

where spaceDistMult $=$ spaceDistributionMultinomial. Thus the negative relative dependent multinomial distribution coder space equals the alignment minus the mis-alignment

$$
\begin{aligned}
& -\left(\text { spaceDistMult }(E, z)(A)-\operatorname{spaceDistMult}(E, z)\left(A^{\mathrm{X}}\right)\right) \\
& \quad=\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!-\sum_{S \in A^{\mathrm{XS}}} \ln A_{S}^{\mathrm{X}}!-\sum_{S \in A^{\mathrm{XS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln E_{S} \\
& \quad=\operatorname{alignment}(A)-\sum_{S \in A^{\mathrm{XS}}}\left(A_{S}-A_{S}^{\mathrm{X}}\right) \ln E_{S}
\end{aligned}
$$

In the case where the sample histogram is independent, $A=A^{\mathrm{X}}$, the negative relative dependent multinomial distribution coder space is 0

$$
-\left(\operatorname{spaceDistMult}(E, z)\left(A^{\mathrm{X}}\right)-\operatorname{spaceDistMult}(E, z)\left(A^{\mathrm{X}}\right)\right)=0
$$

In the case where the distribution history is independent, $E=E^{\mathrm{X}}$, the misalignment is zero and the negative independently-distributed relative dependent multinomial distribution coder space equals the alignment $-\left(\operatorname{spaceDistMult}\left(E^{\mathrm{X}}, z\right)(A)-\operatorname{spaceDistMult}\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)\right)=\operatorname{alignment}(A)$

Similarly, the historical distribution coder of histories $C_{\mathrm{Q}, \mathrm{h}}$ is constructed
$C_{\mathrm{Q}, \mathrm{h}}=\operatorname{coderDistributionHistorical}\left(U, H_{E}, D_{\mathrm{V}}, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathrm{P}\left(H_{E}\right)\right)$
The space of the multinomial distribution coder is

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{~h}}\right)(H)= & \operatorname{spaceSize}\left(z_{E}\right)+ \\
& \operatorname{spaceCounts}(U)(A)+ \\
& \operatorname{spaceDistributionHistorical}(E, z)(A)
\end{aligned}
$$

where $E=\operatorname{histogram}\left(H_{E}\right), A=\operatorname{histogram}(H)$ and historical distribution space is

$$
\text { spaceDistributionHistorical }(E, z)(A):=\ln Q_{\mathrm{h}}(E, z)(A)
$$

In the case where the independent sample histogram is in the histograms of the coder domain, $A^{\mathrm{X}} \in\left\{\operatorname{histogram}(G): G \subseteq H_{E}\right\}$, then the historical distribution coder space of history $H$ may be decomposed into (i) the independent historical distribution coder space and (ii) relative dependent historical distribution coder space

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{Q}, \mathrm{~h}}\right)(H)= & \operatorname{spaceSize}\left(z_{E}\right)+ \\
& \operatorname{space\operatorname {Counts}(U)(A^{\mathrm {X}})+} \\
& \text { spaceDistributionHistorical }(E, z)\left(A^{\mathrm{X}}\right)+ \\
& (\text { spaceDistributionHistorical }(E, z)(A)- \\
& \text { spaceDistributionHistorical } \left.(E, z)\left(A^{\mathrm{X}}\right)\right)
\end{aligned}
$$

The relative dependent historical distribution coder space of history $H$ is

$$
\begin{aligned}
& \text { spaceDistHist }(E, z)(A)-\operatorname{spaceDistHist}(E, z)\left(A^{\mathrm{X}}\right) \\
& \quad=\ln Q_{\mathrm{h}}(E, z)(A)-\ln Q_{\mathrm{h}}(E, z)\left(A^{\mathrm{X}}\right) \\
& \quad=\ln \prod_{S \in A^{\mathrm{S}}} \frac{E_{S}!}{A_{S}!\left(E_{S}-A_{S}\right)!}-\ln \prod_{S \in A^{\mathrm{XS}}} \frac{E_{S}!}{A_{S}^{\mathrm{X}!}!\left(E_{S}-A_{S}^{\mathrm{X}}\right)!} \\
& \quad=\ln \frac{z!}{\prod_{S \in A^{\mathrm{S}}} A_{S}!} \frac{1}{z!} \prod_{S \in A^{\mathrm{S}}} E^{\frac{A_{S}}{S}}-\ln \frac{z!}{\prod_{S \in A^{\mathrm{XS}}} A_{S}^{\mathrm{X}}!} \frac{1}{z!} \prod_{S \in A^{\mathrm{XS}}} E^{\frac{A_{S}^{\mathrm{X}}}{S}}
\end{aligned}
$$

where spaceDistHist $=$ spaceDistributionHistorical. Thus the negative relative dependent historical distribution coder space equals the alignment minus the historical mis-alignment

$$
\begin{aligned}
& -\left(\operatorname{spaceDistHist}(E, z)(A)-\operatorname{space} \operatorname{DistHist}(E, z)\left(A^{\mathrm{X}}\right)\right) \\
& \quad=\sum_{S \in A^{\mathrm{S}}} \ln A_{S}!-\sum_{S \in A^{\mathrm{XS}}} \ln A_{S}^{\mathrm{X}}!-\sum_{S \in A^{\mathrm{xS}}}\left(\underline{A_{S}}-\underline{A_{S}^{\mathrm{X}}}\right) \ln E_{S} \\
& \quad=\operatorname{alignment}(A)-\sum_{S \in A^{\mathrm{XS}}}\left(\underline{A_{S}}-\underline{A_{S}^{\mathrm{X}}}\right) \ln E_{S}
\end{aligned}
$$

where the falling factorial notation is abused such that $\underline{y} \ln x=\ln x \underline{y}$. The historical mis-alignment depends on the distribution histogram, $E$, and its size, $z_{E}$. In the case where the distribution history is independent, $E=E^{\mathrm{X}}$,
conjecture that the historical mis-alignment tends to zero as the distribution history size, $z_{E}$, tends to infinity

$$
\lim _{z_{E} \rightarrow \infty} \sum_{S \in A^{\mathrm{xS}}}\left(\underline{A_{S}}-\underline{A_{S}^{\mathrm{X}}}\right) \ln E_{S}^{\mathrm{X}}=0
$$

Thus in the limit the negative independently-distributed relative dependent historical distribution coder space equals the alignment
$\lim _{z_{E} \rightarrow \infty}-\left(\operatorname{spaceDistHist}\left(E^{\mathrm{X}}, z\right)(A)-\operatorname{spaceDistHist}\left(E^{\mathrm{X}}, z\right)\left(A^{\mathrm{X}}\right)\right)=\operatorname{alignment}(A)$
As shown above the space in the multinomial distribution coder is greater than or equal to that of the space in the historical distribution coder because of the unused codes in the multinomial distribution coder that are not needed to represent the coder domain, $\mathrm{P}\left(H_{E}\right)$. However, for independent distribution histogram, $E=E^{\mathrm{X}}$, in the limit as the size $z_{E}$ tends to infinity, the independently-distributed relative dependent multinomial distribution coder space equals the independently-distributed relative dependent historical distribution coder space which equals the alignment.

## A. 9 Transform and partition space

Let the coder domain $\mathcal{T}_{U, \mathrm{i}, \leq y} \subset \mathcal{A}_{U, \mathrm{i}, \leq y} \times \mathrm{P}\left(\mathcal{V}_{U}\right)$ be the set of transforms in system $U$ having trimmed integral histograms of maximum size $y \in \mathbf{N}$

$$
\mathcal{T}_{U, \mathrm{i}, \leq y}=\left\{(X, W):(X, W) \in \mathcal{T}_{U}, X \in \mathcal{A}_{U, \mathrm{i}, \leq y}\right\}
$$

where the finite set of trimmed integral histograms having size less than or equal to $y$ is

$$
\mathcal{A}_{U, \mathrm{i}, \leq y}=\left\{\operatorname{trim}(A): A \in \mathcal{A}_{U, \mathrm{i}}, \operatorname{size}(A) \leq y\right\}
$$

In the case of a regular system $U$, having dimension $n=|U|$ and such that all the variables have the same valency $d, \forall u \in \operatorname{vars}(U)\left(\left|U_{u}\right|=d\right)$, the cardinality of the coder domain $\mathcal{T}_{U, \mathrm{i}, \leq y}$ is such that $\left|\mathcal{T}_{U, \mathrm{i}, \leq y}\right|<2^{n}\left|\mathcal{A}_{U, \mathrm{i}, \leq y}\right|$. Hence

$$
\left|\mathcal{T}_{U, i, \leq y}\right|<y 2^{2 n} \frac{\left(y+d^{n}-1\right)!}{y!\left(d^{n}-1\right)!}
$$

The coder domain $\mathcal{T}_{U, \mathrm{i}, \leq y}$ is finite so a minimal $\operatorname{coder} C_{\mathrm{T}, \mathrm{m}} \in \operatorname{coders}\left(\mathcal{T}_{U, \mathrm{i}, \leq y}\right)$ can be constructed by enumeration of the coder domain in a similar fashion to the minimal histogram coder, $C_{\mathrm{A}, \mathrm{m}}$, above. The space of the minimal coder is space $\left(C_{\mathrm{T}, \mathrm{m}}\right)(T)=\ln \left|\mathcal{T}_{U, \mathrm{i}, \leq y}\right|$.

Consider the transform coder

$$
C_{\mathrm{T}}=\operatorname{coderTransform}\left(U, y, D_{\mathrm{V}}, D_{\mathrm{S}}\right) \in \operatorname{coders}\left(\mathcal{T}_{U, \mathrm{i}, \leq y}\right)
$$

where $U \in \mathcal{U}$ is a system, $y \in \mathbf{N}$ is the cardinality of the identifier set, $D_{\mathrm{V}}$ and $D_{\mathrm{S}}$ are orders on the variables and states in $U$. The space of the transform coder $C_{\mathrm{T}}$ is that of the trimmed integral histogram coder, $C_{\mathrm{A}}$, plus space required to define the subset of the transform's variables which are the derived variables. This extra space is that of a pair $\mathbf{N} \times \mathbf{N}$, the first of which defines the cardinality of the subset derived variables, $|W|$, and the second of which defines the combination

$$
\operatorname{space}\left(C_{\mathrm{T}}\right)((X, W))=\operatorname{space}\left(C_{\mathrm{A}}\right)(X)+\operatorname{space}(n+1)+\operatorname{spaceSubset}(n,|W|)
$$

where $n=|\operatorname{vars}(X)|$. An alternative method would be to encode the definition of $W$ in a list $\mathcal{L}$ (bits) which would have space $n \ln 2$ instead. A third method is to define all the variables together in a weak composition for the three sets of variables, $V=\operatorname{und}(T), W=\operatorname{der}(T)$ and $\operatorname{dom}(U)$, plus a classification, $\operatorname{spCom}(3,|U|)+\operatorname{spCl}(\{(V,|V|),(W,|W|),(U,|U|-|V|-|W|)\})$, where spCom $=$ spaceCompositionWeak and $\mathrm{spCl}=$ spaceClassification.

Now consider a coder having a subset coder domain which is the unit transforms $C_{\mathrm{T}, \mathrm{U}} \in \operatorname{coders}\left(\mathcal{T}_{U, \mathrm{i}, \leq y} \cap \mathcal{T}_{\mathrm{U}}\right)$. In this special case the space of the weak composition that defines the counts of transform $T$, spaceCounts $(U)(X)$ where $(X, W)=T$, is not needed. Instead the histogram $X$ is simply defined by means of a subset of the volume

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{T}, \mathrm{U}}\right)((X, W))= & \operatorname{spaceVariables}(U)(n)+ \\
& \text { space }(n+1)+\operatorname{spaceSubset}(n,|W|)+ \\
& \text { space }\left(\left|X^{\mathrm{C}}\right|+1\right)+\operatorname{spaceSubset}\left(\left|X^{\mathrm{C}}\right|,\left|X^{\mathrm{F}}\right|\right)
\end{aligned}
$$

where $n=|\operatorname{vars}(X)|$. Again, the subset of the volume could be encoded instead in a list of space $\left|X^{\mathrm{C}}\right| \ln 2$.

To move on to functional transforms, first consider the coder of partitions. The partition coder is constructed

$$
C_{\mathrm{P}}=\operatorname{coderPartition}\left(U, D_{\mathrm{V}}, D_{\mathrm{S}}\right) \in \operatorname{coders}\left(\mathcal{R}_{U}\right)
$$

where $U \in \mathcal{U}$ is a system, $D_{\mathrm{V}}$ and $D_{\mathrm{S}}$ are orders on the variables and states in $U$, and the coder domain $\mathcal{R}_{U}$ is the finite set of all partitions of the variables of the system $U$

$$
\mathcal{R}_{U}=\bigcup\left\{\mathrm{B}\left(W^{\mathrm{CS}}\right): W \in \mathrm{P}(\operatorname{vars}(U))\right\}
$$

where B is the partition function. A partition $P \in \mathcal{R}_{U}$ can be encoded in an intermediate tuple $\left(\left(n, N_{V}\right), R_{P}\right) \in \mathbf{N}^{2} \times \mathbf{N}$. The first element, $\left(n, N_{V}\right)$, encodes the variables in the same way as the history coder $C_{\mathrm{H}}$, above. The space is spaceVariables $(U)(n)$ where $V=\operatorname{vars}(P)$ and $n=|V|$. The last element of the tuple, $R_{P}$, chooses one of the partitions. Given order $D_{\mathrm{S}}$ choose $R \in \operatorname{enums}\left(\mathrm{~B}\left(V^{\mathrm{CS}}\right)\right)$. Then

$$
R_{P} \in\left\{1 \ldots\left|\mathrm{~B}\left(V^{\mathrm{CS}}\right)\right|\right\}=\{1 \ldots \operatorname{bell}(v)\}
$$

where volume $v=\left|V^{\mathrm{C}}\right|$. Define spacePartition $(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \ln \mathbf{N}_{>0}$ as

$$
\operatorname{spacePartition}(U)(V):=\ln \operatorname{bell}(v)
$$

Define spacePartition $(U)(\emptyset):=0$. The space of the partition is

$$
\operatorname{space}\left(C_{\mathrm{P}}\right)(P)=\operatorname{spaceVariables}(U)(|V|)+\operatorname{spacePartition}(U)(V)
$$

where $V=\operatorname{vars}(P)$.
The set of binary partitions is $\mathcal{R}_{U, \mathrm{~b}}=\left\{\left\{C, W^{\mathrm{CS}} \backslash C\right\}: W \in \mathrm{P}(\operatorname{vars}(U)), C \in\right.$ $\left.\mathrm{P}\left(W^{\mathrm{CS}}\right)\right\}=\left\{P: P \in \mathcal{R}_{U},|P|=2\right\}$. The binary partition coder is constructed

$$
C_{\mathrm{P}, \mathrm{~b}}=\operatorname{coderPartitionBinary}\left(U, D_{\mathrm{V}}, D_{\mathrm{S}}\right) \in \operatorname{coders}\left(\mathcal{R}_{U, \mathrm{~b}}\right)
$$

Define spacePartitionBinary $(U) \in \mathrm{P}\left(\mathcal{V}_{U}\right) \rightarrow \ln \mathbf{N}_{>0}$ as

$$
\operatorname{spacePartitionBinary}(U)(V):=v \ln 2
$$

Define spacePartitionBinary $(U)(\emptyset):=0$. The space of the binary partition is

$$
\operatorname{space}\left(C_{\mathrm{P}, \mathrm{~b}}\right)(P)=\operatorname{spaceVariables}(U)(|V|)+\operatorname{spacePartitionBinary}(U)(V)
$$

where $V=\operatorname{vars}(P)$.
The partition transform $T \in \mathcal{T}_{U, \mathrm{P}}=\left\{P^{\mathrm{T}} \in \mathcal{R}_{U}\right\} \subset \mathcal{T}_{U, \mathrm{f}, 1}$ has a single derived partition variable $P$ from which it is constructed, $T=P^{\mathrm{T}}=(\{S \cup\{(P, C)\}$ : $\left.C \in P, S \in C\}^{\mathrm{U}},\{P\}\right)$. The partition variable, $P=T^{\mathrm{P}}$, is not in the system, $P \notin \operatorname{vars}(U)$, but is in the infinite implied system, $P \in \operatorname{vars}(\operatorname{implied}(U))$. The coder of partition transforms

$$
C_{\mathrm{T}, \mathrm{P}}=\operatorname{coder} \operatorname{TransformPartition}\left(U, D_{\mathrm{V}}, D_{\mathrm{S}}\right) \in \operatorname{coders}\left(\mathcal{T}_{U, \mathrm{P}}\right)
$$

is exactly equal to partition coder, $C_{\mathrm{P}}$, after mapping bijectively between the coder domains, $\mathcal{T}_{U, \mathrm{P}}: \leftrightarrow: \mathcal{R}_{U}$. The space is equal, space $\left(C_{\mathrm{T}, \mathrm{P}}\right)(T)=$ $\operatorname{space}\left(C_{\mathrm{P}}\right)\left(T^{\mathrm{P}}\right)$.

Similarly, the space of the binary partition transform coder $C_{\mathrm{T}, \mathrm{P}, \mathrm{b}}$ equals the space of the binary partition coder, $C_{\mathrm{T}, \mathrm{P}, \mathrm{b}}^{\mathrm{s}}(T)=C_{\mathrm{P}, \mathrm{b}}^{\mathrm{s}}\left(T^{\mathrm{P}}\right)$.

To encode a one functional transform $T \in \mathcal{T}_{U, \mathrm{f}, 1}$, where all of the transform's variables are in the system, $\operatorname{vars}(T) \in \operatorname{dom}(U)$, map the transform's subset of the derived variables' cartesian states, $(X \% W)^{\mathrm{S}} \subseteq W^{\mathrm{CS}}$ where $(X, W)=T$, to the components of the partition $P=T^{\mathrm{P}} \in \mathrm{B}\left(V^{\mathrm{CS}}\right)$ of the underlying variables $V=\operatorname{und}(T)$, such that $|X \% W|=|P|$. The space to encode the map between the derived and underlying is spaceSubset $\left(\left|W^{\mathrm{C}}\right|,|P|\right)$ plus the space of the permutation $\ln |P|$ !, or, equivalently, the space of the falling factorial $\ln \left|W^{\mathrm{C}}\right| \underline{\underline{P} \mid}$. The space to define the partition is smaller than for the partition coder because the number of components is fixed by the definition of the derived variables $W$ in the system $U$ and by the functional mapping, $X \% W: \leftrightarrow: P$, of the components to the derived states. Instead use the Stirling number of the second kind stir $\in \mathbf{N}_{>0} \times \mathbf{N} \rightarrow \mathbf{N}_{>0}$ rather than the Bell number. The partition space is $\ln \left(\operatorname{stir}\left(\left|V^{\mathrm{C}}\right|,|P|\right)\right)$. Let

$$
C_{\mathrm{T}, \mathrm{f}, 1}=\operatorname{coderTransformOneFunc}\left(U, D_{\mathrm{V}}, D_{\mathrm{S}}\right) \in \operatorname{coders}\left(\mathcal{T}_{U, \mathrm{f}, 1}\right)
$$

in

```
\(\operatorname{space}\left(C_{\mathrm{T}, \mathrm{f}, 1}\right)(T)=\operatorname{spaceVariables}(U)(n)+\)
    \(\operatorname{space}(n+1)+\operatorname{spaceSubset}(n,|W|)+\)
    space \(\left(\left|W^{\mathrm{C}}\right|\right)+\operatorname{spaceSubset}\left(\left|W^{\mathrm{C}}\right|,\left|T^{\mathrm{P}}\right|\right)+\operatorname{space}\left(\left|T^{\mathrm{P}}\right|!\right)+\)
    space \(\left(\operatorname{stir}\left(\left|V^{\mathrm{C}}\right|,\left|T^{\mathrm{P}}\right|\right)\right)\)
```

where $n=|\operatorname{vars}(T)|, W=\operatorname{der}(T)$ and $V=\operatorname{und}(T)$.
The coder $C_{\mathrm{T}, \mathrm{f}, \mathrm{U}} \in \operatorname{coders}\left(\mathcal{T}_{\mathrm{U}, \mathrm{f}, \mathrm{U}}\right)$ is intermediate between coders $C_{\mathrm{T}, \mathrm{U}} \in$ $\operatorname{coders}\left(\mathcal{T}_{U, \mathrm{i}, \leq y} \cap \mathcal{T}_{\mathrm{U}}\right)$ and $C_{\mathrm{T}, \mathrm{f}, 1} \in \operatorname{coders}\left(\mathcal{T}_{U, \mathrm{f}, 1}\right)$. It requires space to define both the partition and the subset of the volume and so is larger than the one functional coder.

Conjecture that the space of a one functional transform $T \in \mathcal{T}_{U, f, 1}$ having at least one derived variable, $|\operatorname{der}(T)| \geq 1$, must be such that

$$
\operatorname{space}\left(C_{\mathrm{T}, \mathrm{P}}\right)\left(T^{\mathrm{PT}}\right) \leq \operatorname{space}\left(C_{\mathrm{T}, \mathrm{f}, 1}\right)(T) \leq \operatorname{space}\left(C_{\mathrm{T}, \mathrm{f}, \mathrm{U}}\right)(T) \leq \operatorname{space}\left(C_{\mathrm{T}, \mathrm{U}}\right)(T)
$$

Of course, this conjecture depends on the exact definition of $C_{\mathrm{T}, \mathrm{f}, \mathrm{U}}$ which is not made explicit here.

## A. 10 Functional definition set space and Decomposition space

If system $U$ is finite then the set of functional definition sets, $\mathcal{F}_{U} \subseteq$ $\mathrm{P}\left(\mathcal{T}_{U, f, \mathrm{U}}\right)$, in that system is also finite. Therefore there exists a minimal coder
$C_{\mathrm{F}, \mathrm{m}} \in \operatorname{coders}\left(\mathcal{F}_{U}\right)$ such that the space of a member of the coder domain $F \in$ $\mathcal{F}_{U}$ is constant, space $\left(C_{\mathrm{F}, \mathrm{m}}\right)(F)=\ln \left|\mathcal{F}_{U}\right|$. Similarly there can be constructed a minimal coder of the set of one functional definition sets, $\mathcal{F}_{U, 1} \subseteq \mathrm{P}\left(\mathcal{T}_{U, f, 1}\right)$, $C_{\mathrm{F}, 1, \mathrm{~m}} \in \operatorname{coders}\left(\mathcal{F}_{U, 1}\right)$, such that $\operatorname{space}\left(C_{\mathrm{F}, 1, \mathrm{~m}}\right)(F)=\ln \left|\mathcal{F}_{U, 1}\right|$ where $F \in \mathcal{F}_{U, 1}$.

The set of functional definition sets is a subset of the powerset of the set of unit functional transforms in the finite system $U, \mathcal{F}_{U} \subseteq \mathrm{P}\left(\mathcal{T}_{U, \mathrm{f}, \mathrm{U}}\right)$, so a similar method of coder would be to encode the subset of transforms. Let $C_{\mathrm{F}, \mathrm{S}} \in$ $\operatorname{coders}\left(\mathcal{F}_{U}\right)$ and $F \in \mathcal{F}_{U}$, and define the encoding such that space $\left(C_{\mathrm{F}, \mathrm{S}}\right)(F)=$ space $\left(\left|\mathcal{T}_{U, \mathrm{f}, \mathrm{U}}\right|+1\right)+\operatorname{spaceSubset}\left(\left|\mathcal{T}_{U, \mathrm{f}, \mathrm{U}}\right|,|F|\right)$. This coder is not minimal in non-trivial systems because there are members of the powerset of the set of one functional transforms, $\mathrm{P}\left(\mathcal{T}_{U, \mathrm{f}, \mathrm{U}}\right)$, which are not functional definition sets.

It is possible to avoid the necessity of calculating $\mathcal{F}_{U}$ or $\mathcal{T}_{U, \mathrm{f}, \mathrm{U}}$ (or, in the case of one functional fuds and transforms, $\mathcal{F}_{U, 1}$ or $\left.\mathcal{T}_{U, f, 1}\right)$, required by the methods above, by means of list coders (see appendix 'List and tree coders'). List coders encode a list in a generic manner, leaving the details of the encoding of the elements of the list to an underlying coder. Convert the fud $F \in \mathcal{F}_{U}$ to a list of transforms $L \in \mathcal{L}\left(\mathcal{T}_{U, \mathrm{f}, \mathrm{U}}\right)$ and then encode the list in one of the list coders $\operatorname{coders}\left(\mathcal{L}\left(\mathcal{T}_{U, \mathrm{f}, \mathrm{U}}\right)\right)$. The list $L$ is the inverse of one of the enumerations of $F, L=\operatorname{flip}(M)$ where $M \in \operatorname{enums}(F)$. Any ordering of the list may be chosen. In particular, there is no need to order by dependency. If we choose to limit the cardinality of the $f u d,|F| \leq y$, we can use a limited list coder

$$
C_{\mathrm{F}, \mathrm{~L}}=\operatorname{coderListLimited}\left(C_{\mathrm{T}, \mathrm{f}, \mathrm{U}}, y\right) \in \operatorname{coders}\left(\mathcal{L}_{y}\left(\mathcal{T}_{U, \mathrm{f}, \mathrm{U}}\right)\right)
$$

where $\mathcal{L}_{y}\left(\mathcal{T}_{U, \mathrm{f}, \mathrm{U}}\right)$ is the set of lists of unit functional transforms in system $U$ of length less that or equal to $y$. The underlying $\operatorname{coder} C_{\mathrm{T}, \mathrm{f}, \mathrm{U}}$ is described above in the section 'Transform and partition space'. The parameter $y$ need not be greater than the maximum possible cardinality of a fud in the system $U, y \leq\left|\mathcal{T}_{U, \mathrm{f}, \mathrm{U}}\right|$. Fuds which exclude null transforms have at least one derived variable per transform. Non-empty fuds which exclude disjoint transforms have at least one underlying variable. Let $\mathcal{F}_{\mathrm{X}} \subset \mathcal{F}$ be the set of fuds which exclude both special cases, $\forall F \in \mathcal{F}_{\mathrm{X}} \forall T \in F(\operatorname{der}(T) \neq \emptyset \wedge \operatorname{und}(T) \neq \emptyset)$. To encode only fuds in $\mathcal{F}_{\mathrm{X}}$ places a maximum on the list length, $y \leq r-1$ where $r=|\operatorname{vars}(U)|$.

If we do not wish to explicitly limit the cardinality of the $f u d$ we can use the unlimited list coder

$$
C_{\mathrm{F}, \mathrm{U}}=\operatorname{coderListTerminating}\left(C_{\mathrm{T}, \mathrm{f}, \mathrm{U}}\right) \in \operatorname{coders}\left(\mathcal{L}\left(\mathcal{T}_{U, \mathrm{f}, \mathrm{U}}\right)\right)
$$

Neither the limited list coder of functional definition sets, $C_{\mathrm{F}, \mathrm{L}}$, nor the unlimited list coder, $C_{\mathrm{F}, \mathrm{U}}$, are minimal coders, because of the cost of the list overhead space, and because the set of fuds is a proper subset of the powerset of unit functional transforms in non-trivial systems, $\mathcal{F}_{U} \subset \mathrm{P}\left(\mathcal{T}_{U, \mathrm{f}, \mathrm{U}}\right)$.

The space of a transform list coder of a fud is the sum the spaces of the transforms $\sum_{T \in F} \operatorname{space}\left(C_{\mathrm{T}, \mathrm{f}, \mathrm{U}}\right)(T)$ plus the overhead space. The overhead space is a constant, $\ln (y+1)$, in $C_{\mathrm{F}, \mathrm{L}}$, and a linear function of $|F|,(|F|+1) \ln 2$, in $C_{\mathrm{F}, \mathrm{U}}$.

Consider partition functional definition set coders, $\operatorname{coders}\left(\mathcal{F}_{U, \mathrm{P}}\right)$. Partition fuds are a subset of one fuds, $\mathcal{F}_{U, \mathrm{P}} \subset \mathcal{F}_{U, 1}$, and so are a subset of the set of sets of unit functional transforms, $\mathcal{F}_{U, \mathrm{P}} \subset \mathrm{P}\left(\mathcal{T}_{U, \mathrm{f}, \mathrm{U}}\right)$. So a fud $F \in \mathcal{F}_{U, \mathrm{P}}$ could be encoded in list coder such as $C_{\mathrm{F}, \mathrm{L}}$ or $C_{\mathrm{F}, \mathrm{U}}$ with underlying coder $C_{\mathrm{T}, \mathrm{f}, \mathrm{U}}$. However if the system $U$ were to contain all of the partition variables of the partition fuds in $\mathcal{F}_{U, \mathrm{P}}$ then both the system and the set of partition fuds would be necessarily infinite. So an underlying coder cannot be constructed from system $U$ or implied $(U)$. A finite system can be constructed from the partition fuds in finite system $U, U^{\prime}=\left\{(P, P): F \in \mathcal{F}_{U, \mathrm{P}}, P \in \operatorname{dom}(\operatorname{def}(F))\right\} \cup U$. The list coders $C_{\mathrm{F}, \mathrm{U}}, C_{\mathrm{F}, \mathrm{L}} \in \operatorname{coders}\left(\mathcal{L}\left(\mathcal{T}_{U^{\prime}, \mathrm{f}, \mathrm{U}}\right)\right)$ and underlying $\operatorname{coder} C_{\mathrm{T}, \mathrm{f}, \mathrm{U}}$ are then parameterised by the finite system $U^{\prime}$.

A more efficient partition functional definition set coder implementation in a list coder is to use the partition transform coder, $C_{\mathrm{T}, \mathrm{P}}$, as the underlying coder and to construct the system incrementally by looking back at the list of partition transforms so far. In this way, the underlying coder need not choose the underlying variables of the partition from all of the variables in the fuds of $\mathcal{F}_{U, \mathrm{P}}$. That is, instead of using system $U^{\prime}$, the partition transform coder, $C_{\mathrm{T}, \mathrm{P}}$, can use the much smaller system $U$ plus the partition variables previously defined in the list of the fud's transforms. Of course, the list must be ordered by fud dependency so that the references exist. Let

$$
C_{\mathrm{F}, \mathrm{U}, \mathrm{P}}=\operatorname{coderFudPartition}\left(U, D_{\mathrm{V}}, D_{\mathrm{S}}\right) \in \operatorname{coders}\left(\mathcal{F}_{U, \mathrm{P}}\right)
$$

In the non-minimal coders above, the fud has been treated as a unordered collection of transforms, ignoring the definitions constraint on the fud. See appendix 'Functional definition set coders' for the details of the implementation of $C_{\mathrm{F}, \mathrm{U}, \mathrm{P}}$ and a discussion of other fud coders that use the fud constraints to reduce space.

At this stage note that the space of the partition fud coder, $C_{\mathrm{F}, \mathrm{U}, \mathrm{P}}$, is at
least the sum of the space of the set of partitions

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{F}, \mathrm{U}, \mathrm{P}}\right)(F) & >\sum_{T \in F} \operatorname{spacePartition}\left(U^{\prime}\right)(\operatorname{und}(T)) \\
& =\sum_{T \in F} \ln \operatorname{bell}\left(\operatorname{volume}\left(U^{\prime}\right)\left(\operatorname{vars}\left(T^{\mathrm{P}}\right)\right)\right.
\end{aligned}
$$

Consider the partition space of $F=\left\{P_{K}^{\mathrm{T}}, P_{V \backslash K}^{\mathrm{T}}\right\} \in \mathcal{F}_{U, \mathrm{P}}$ where $V \subset \operatorname{vars}(U)$, $K \subset V$ and $P_{X} \in \mathrm{~B}\left(X^{\mathrm{CS}}\right)$. Let $V$ be regular having even dimension $n=|V|$, $n / 2 \in \mathbf{N}$ and valency $\{d\}=\left\{\left|U_{u}\right|: u \in V\right\}$. Let the subset $K$ be such that $|K|=n / 2$. Then the partition space of $F$ is

$$
\operatorname{spacePartition}(U)(K)+\operatorname{spacePartition}(U)(V \backslash K)=2 \ln \operatorname{bell}\left(d^{n / 2}\right)
$$

The partition space of the equivalent transform $F^{\mathrm{TPT}} \in \mathcal{T}_{U, \mathrm{P}}$ is

$$
\operatorname{spacePartition}(U)(V)=\ln \operatorname{bell}\left(d^{n}\right)
$$

Conjecture that $\forall i \in \mathbf{N}\left((\operatorname{bell}(i))^{2} \leq \operatorname{bell}\left(i^{2}\right)\right)$ because the Bell number is $\log$ convex. Therefore conjecture that the partition space of the fud $F$ is less than or equal to the partition space of its equivalent transform, $F^{\mathrm{T}}$, $2 \ln \operatorname{bell}\left(d^{n / 2}\right) \leq \ln \operatorname{bell}\left(d^{n}\right)$.

A coder of multi-partition transforms, $C_{\mathrm{T}, \mathrm{P}^{*}}$, may be implemented as a special case of the partition fud coder, $C_{\mathrm{F}, \mathrm{U}, \mathrm{P}}$, by exploding the contracted transform, explode $\left(T^{\%}\right) \in \mathcal{F}_{U, \mathrm{P}}$ where $T \in \mathcal{T}_{U, \mathrm{P}}{ }^{*}$.

Now consider a coder of partition fud decompositions. The set of partition fud decompositions is defined

$$
\mathcal{D}_{\mathrm{F}, U, \mathrm{P}}=\mathcal{D}_{\mathrm{F}} \cap \operatorname{trees}\left(\mathcal{S}_{U^{\prime}} \times \mathcal{F}_{U, \mathrm{P}}\right)
$$

where the finite system $U^{\prime}$ is defined $U^{\prime}=\left\{(P, P): F \in \mathcal{F}_{U, P}, P \in\right.$ $\operatorname{dom}(\operatorname{def}(F))\} \cup U$. The unlimited partition fud decomposition coder is constructed

$$
C_{\mathrm{D}, \mathrm{~F}, \mathrm{U}, \mathrm{P}}=\operatorname{coderDecompFudPartition}\left(U, D_{\mathrm{V}}, D_{\mathrm{S}}\right) \in \operatorname{coders}\left(\mathcal{D}_{\mathrm{F}, U, \mathrm{P}}\right)
$$

The fud decomposition coder implements the encoding of the decomposition tree of state-fud pairs by means of an unlimited list tree coder, $C_{\mathrm{U}, \mathrm{T}}$, defined in appendix 'List and tree coders'. The fuds of the state-fud pairs are encoded by an unlimited partition fud coder, $C_{\mathrm{F}, \mathrm{U}, \mathrm{P}}$. Let $D \in \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}$. The state $S$ of the pair is in the derived states of the parent $f u d G$ in the tree,
$S \in W^{\mathrm{CS}}$, where $((\cdot, G),(S, \cdot)) \in \operatorname{steps}(D)$ and $W=\operatorname{der}(G)$. So the encoding and decoding of the state, $S$, is preceded by the encoding and decoding of the parent fud, $G$. The state may be encoded by indexing the cartesian of the derived variables of the parent fud. That is, by choosing an enumeration from enums $\left(W^{\mathrm{CS}}\right)$. The space of the state encoding is $\ln \left|W^{\mathrm{C}}\right|$.

The fud decomposition coder space is greater than the space of the partition fud encodings, and so is greater than the total space of the partition transforms of the fuds,

$$
\begin{aligned}
C_{\mathrm{D}, \mathrm{~F}, \mathrm{U}, \mathrm{P}}^{\mathrm{s}}(D) & >\sum_{F \in \operatorname{fuds}(D)} C_{\mathrm{F}, \mathrm{U}, \mathrm{P}}^{\mathrm{s}}(F) \\
& >\sum_{F \in \operatorname{fuds}(D)} \sum_{T \in F} \operatorname{spacePartition}\left(U^{\prime}\right)(\operatorname{und}(T)) \\
& =\sum_{F \in \operatorname{fuds}(D)} \sum_{T \in F} \ln \operatorname{bell}\left(\operatorname{volume}\left(U^{\prime}\right)\left(\operatorname{vars}\left(T^{\mathrm{P}}\right)\right)\right.
\end{aligned}
$$

An unlimited partition transform decomposition coder, $C_{\mathrm{D}, \mathrm{U}, \mathrm{P}}$, is a special case of the unlimited partition fud decomposition coder, $C_{\mathrm{D}, \mathrm{F}, \mathrm{U}, \mathrm{P}}$, constructed

$$
C_{\mathrm{D}, \mathrm{U}, \mathrm{P}}=\operatorname{coderDecompPartition}\left(U, D_{\mathrm{V}}, D_{\mathrm{S}}\right) \in \operatorname{coders}\left(\mathcal{D}_{U, \mathrm{P}}\right)
$$

where $\mathcal{D}_{U, \mathrm{P}}=\mathcal{D} \cap \operatorname{trees}\left(\mathcal{S}_{U^{\prime}} \times \mathcal{T}_{U, \mathrm{P}}\right)$.

## A. 11 Functional definition set coders

Consider the finite coder domain of functional definition sets, $\mathcal{F}_{U} \subseteq \mathrm{P}\left(\mathcal{T}_{U, \mathrm{f}, \mathrm{U}}\right)$, in the finite system $U$. In the section 'Functional definition set space and Decomposition space', above, the non-minimal fud coders treated a fud $F \in \mathcal{F}_{U}$ as a collection of transforms, ignoring the definitions constraint on the fud. That is, that no derived variable of a transform in the fud can be a derived variable in another transform, $\operatorname{ran}(F) \backslash \emptyset \in \mathrm{B}(\operatorname{dom}(\operatorname{def}(F)))$ where $\operatorname{def}(F) \neq \emptyset$ and def $=$ definitions. The space of the fud coder can be reduced by making use of this constraint. The classification definition fud coders $C_{\mathrm{F}, \mathrm{L}, \mathrm{C}} \in \operatorname{coders}\left(\mathcal{F}_{U}\right)$ and $C_{\mathrm{F}, \mathrm{L}, \mathrm{C}, 1} \in \operatorname{coders}\left(\mathcal{F}_{U, 1}\right)$ encode part of the fud in initial space, followed by a limited list coder of the remaining parts of the transforms. Treat the fud as a classification of the derived variables of the transforms. In order to do this first encode the cardinality of the fud, $|F|$. Do this by using a limited list coder of maximum length $y$, in which case the space of the cardinality is the up-front overhead space $\ln (y+1)$. Then the space required to specify the cardinalities of derived variables in the transforms
of $F \in \mathcal{F}_{U}$ is weak composition space spaceCompositionWeak $(|F|+1,|U|)$. If the coder domain is constrained to fuds which exclude null transforms and disjoint transforms, $\mathcal{F}_{U} \cap \mathcal{F}_{\mathrm{X}}$, then $y \leq|U|-1$ and the space of the cardinality of the fud is at most $\ln |U|$. In this case, the space to specify the cardinalities of derived variables is only strong composition space spaceComposition $(|F|+1,|U|)$, where spaceComposition $\in \mathbf{N}_{>0} \times \mathbf{N}_{>0} \rightarrow$ $\ln \mathbf{N}_{>0}$ is defined as spaceComposition $(k, n):=\ln |\mathrm{C}(\{1 \ldots k\}, n)|$. In both cases, $\mathcal{F}_{U}$ and $\mathcal{F}_{U} \cap \mathcal{F}_{\mathrm{X}}$, the space required to specify the classification of derived variables in the transforms is spaceClassification $(\{(T,|\operatorname{der}(T)|)$ : $T \in F\}$ ). The space of the underlying variables in the limited list coder is $\sum($ spaceVariables $(U)(|\operatorname{und}(T)|): T \in F)$. The remaining space of the states of the histograms of the transforms is the same as defined in the respective underlying coders, $C_{\mathrm{T}, \mathrm{f}, \mathrm{U}}$ for fud coder $C_{\mathrm{F}, \mathrm{L}, \mathrm{C}}$ and $C_{\mathrm{T}, \mathrm{f}, 1}$ for one fud coder $C_{\mathrm{F}, \mathrm{L}, \mathrm{C}, 1}$. In the case of one functional definition sets, $F \in \mathcal{F}_{U, 1}$, this space for the limited list coder of each $T \in F$ is space $\left(\left|W^{\mathrm{C}}\right|\right)+\operatorname{spaceSubset}\left(\left|W^{\mathrm{C}}\right|, p\right)+$ $\operatorname{space}(p!)+\operatorname{space}\left(\operatorname{stir}\left(\left|V^{\mathrm{C}}\right|, p\right)\right)$ where $p=|\operatorname{inverse}(T)|, W=\operatorname{der}(T)$ and $V=\operatorname{und}(T)$. The overhead space of the limited list coder of $\ln (y+1)$ performs the dual purpose of defining the length of the list, $|L|$ where $L \in \mathcal{L}_{y}\left(\mathcal{T}_{U, \mathrm{f}, \mathrm{U}}\right)$ or $L \in \mathcal{L}_{y}\left(\mathcal{T}_{U, \mathrm{f}, 1}\right)$, and encoding the cardinality of the fud, $|F|=|L|$, for the definition classification above.

The method of definition classification does not address the space that can be saved in the underlying variables by utilising the depends relations between the transforms of the fud. The underlying variables of a transform $T \in F$ need not be chosen as a subset of the entire system $U$, but only need to be chosen from the underlying variables of the fud and the definition of the underlying depends fud of the transform, und $(F) \cup \operatorname{vars}(\operatorname{depends}(F, \operatorname{der}(T)) \backslash\{T\}) \subseteq$ $\operatorname{vars}(U)$. In this method the space of the underlying variables of transform $T$ in fud $F$ is not $\operatorname{sp} \operatorname{Var}(U)(|\operatorname{und}(T)|)$, but rather $\operatorname{sp} \operatorname{Var}(Q)(|\operatorname{und}(T)|)$ where system $Q \subseteq U$ is defined

$$
Q=\left\{\left(v, U_{v}\right): v \in \operatorname{und}(F) \cup \operatorname{vars}(\operatorname{depends}(F, \operatorname{der}(T)) \backslash\{T\})\right\}
$$

and spVar $=$ spaceVariables. Define system $(U) \in \mathcal{F}_{U} \rightarrow \mathcal{U}$ as

$$
\operatorname{system}(U)(F):=\left\{\left(v, U_{v}\right): v \in \operatorname{vars}(F)\right\}
$$

First encode the underlying variables of the fud in space $\operatorname{sp} \operatorname{Var}(U)(|\operatorname{und}(F)|)$. These underlying variables imply a subset of the system $R \subseteq U$ such that $R=\left\{\left(v, U_{v}\right): v \in \operatorname{und}(F)\right\}$. Then choose a list ordered such that the system $Q$ so far can be implied from a lookback list coder. A finite system cannot be implied where there are fud circularities, so consider only one
functional definition sets $\mathcal{F}_{U, 1}$. Choose a list $L=\operatorname{flip}(M) \in \mathcal{L}\left(\mathcal{T}_{U, \mathrm{f}, 1}\right)$ where $M \in \operatorname{enums}(F)$ ordered such that all of the underlying depends set of any transform precedes the transform

$$
\forall(i, T) \in L(\operatorname{depends}(F, \operatorname{der}(T)) \subseteq\{S:(j, S) \in L, j \leq i\})
$$

Define a variation on the one functional transform coder that takes the underlying variables from system $Q \subseteq U$ and the derived variables from system $U \backslash Q$. Let
$C_{\mathrm{T}, \mathrm{F}, 1, \mathrm{~S}}=\operatorname{coderTransformOneFuncSplitSystem}\left(U, Q, D_{\mathrm{V}}, D_{\mathrm{S}}\right) \in \operatorname{coders}\left(\mathcal{T}_{U, \mathrm{f}, 1}\right)$ in

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{T}, \mathrm{~F}, 1, \mathrm{~S}}\right)(T)= & \operatorname{space}(|U|+1)+\operatorname{space}(n)+ \\
& \text { spaceSubset }(|U \backslash Q|,|W|)+\operatorname{spaceSubset}(|Q|,|V|)+ \\
& \text { space }\left(\left|W^{\mathrm{C}}\right|\right)+\operatorname{spaceSubset}\left(\left|W^{\mathrm{C}}\right|, p\right)+\operatorname{space}(p!)+ \\
& \text { space }\left(\operatorname{stir}\left(\left|V^{\mathrm{C}}\right|, p\right)\right)
\end{aligned}
$$

where $n=|\operatorname{vars}(T)|, p=|\operatorname{inverse}(T)|, W=\operatorname{der}(T)$ and $V=\operatorname{und}(T)$. By splitting the system into $Q$ and $U \backslash Q$ the coder partly addresses the space saved by definitions constraint on the fud. By contrast, the definition classification coders, which also use the definitions constraint to reduce space, do not need to order the underlying list by dependency.

Let $B_{\mathrm{T}, \mathrm{F}, 1, \mathrm{~S}} \in \mathcal{L}\left(\mathcal{T}_{U, \mathrm{f}, 1}\right) \rightarrow \operatorname{coders}\left(\mathcal{T}_{U, \mathrm{f}, 1}\right)$ in

$$
C_{\mathrm{F}, \mathrm{U}, \mathrm{~S}, \mathrm{~B}}=\operatorname{coderListTerminatingLookback}\left(B_{\mathrm{T}, \mathrm{~F}, 1, \mathrm{~S}}\right) \in \operatorname{coders}\left(\mathcal{L}\left(\mathcal{T}_{U, \mathrm{f}, 1}\right)\right)
$$

be defined as

$$
B_{\mathrm{T}, \mathrm{~F}, 1, \mathrm{~S}}(L):=\operatorname{enc}\left(U, \operatorname{system}(U)(\operatorname{ran}(L)) \cup R, D_{\mathrm{V}}, D_{\mathrm{S}}\right)
$$

where enc $=$ coderTransformOneFuncSplitSystem.
The overall space for this coder $C_{\mathrm{F}, \mathrm{U}, \mathrm{S}} \in \operatorname{coders}\left(\mathcal{F}_{U, 1}\right)$, including the upfront encoding of the underlying variables of the fud $F$ and the list coder with an underlying split system one functional transform coder is

$$
\operatorname{space}\left(C_{\mathrm{F}, \mathrm{U}, \mathrm{~S}}\right)(F):=\operatorname{sp} \operatorname{Var}(U)(|\operatorname{und}(F)|)+\operatorname{space}\left(C_{\mathrm{F}, \mathrm{U}, \mathrm{~S}, \mathrm{~B}}\right)(L)
$$

However, the order of the list in the list coder does not necessarily minimise the cardinality of the system $Q$ given to the underlying coder to encode
the transform's underlying variables. Typically there are more underlying variables than derived variables, $|V|>|W|$, in a transform, so we wish to minimise $|Q|$ in order to use the least space. Ideally $|\operatorname{system}(U)(\operatorname{ran}(L))|=$ $|\operatorname{vars}(\operatorname{depends}(F, \operatorname{der}(T)) \backslash\{T\})|$, but sometimes it is larger. A method of minimising $|Q|$ is to use a list tree having the same layout as the fud's variables tree, fudsTreeVariable $(F) \in \operatorname{trees}(\mathcal{V})$. The list tree is encoded using a lookback list tree coder which can construct the underlying variables system $Q$ from the child list tree. If the tree has duplicate nodes then it is a graph and we could use a referencing coder to avoid duplicating the encoding of transforms. Of course, list tree and list graph coders would have additional overhead space.

Now consider partition functional definition set coders, coders $\left(\mathcal{F}_{U, \mathrm{P}}\right)$. Partition fuds are a subset of one fuds, $\mathcal{F}_{U, \mathrm{P}} \subset \mathcal{F}_{U, 1}$, so we could use a coder such as $C_{\mathrm{F}, \mathrm{L}, \mathrm{C}, 1}$ or $C_{\mathrm{F}, \mathrm{U}, \mathrm{S}}$ above. However, the additional constraint imposed on the transforms of partition fuds that the set of derived variables is a singleton set of the partition variable, $\forall T \in F(\operatorname{der}(T)=\{\operatorname{partition}(T)\})$, allows us to both simplify and reduce the space of the coder of a partition fud $F \in \mathcal{F}_{U, \mathrm{P}}$. First, the defined variables of the $f u d \operatorname{dom}(\operatorname{def}(F))$ can imply a system disjoint of the system $R$ where $R$ contains the underlying variables of the fud, $\operatorname{und}(F) \subseteq \operatorname{vars}(R)$. Define system $\in \mathcal{F} \rightarrow \mathcal{U}$ as

$$
\operatorname{system}(F):=\{(P, P): P \in \operatorname{dom}(\operatorname{def}(F))\}
$$

Note that the system function here is defined for all fuds, $F \in \mathcal{F}$, but we are only interested in partition fuds, $F \in \mathcal{F}_{U, \mathrm{P}}$ where system $(F) \cup R \subseteq U$. Second, while encoding the list in the lookback unlimited list coder we do not need to encode the derived variable explicitly because it is encoded in the space defined by the Bell number of the underlying volume rather than the lesser space defined by the Stirling number of the second kind. Let

$$
C_{\mathrm{F}, \mathrm{U}, \mathrm{P}}=\operatorname{coderFudPartition}\left(R, D_{\mathrm{V}}, D_{\mathrm{S}}\right) \in \operatorname{coders}\left(\mathcal{F}_{U, \mathrm{P}}\right)
$$

Again, the subset of the underlying variables of the fud are encoded first before the list encoding takes place, $\operatorname{sp} \operatorname{Var}(R)(|\operatorname{und}(F)|)$. Then choose a list $L=\operatorname{flip}(M) \in \mathcal{L}\left(\mathcal{T}_{U, \mathrm{P}}\right)$ where $M \in \operatorname{enums}(F)$ ordered such that all of the underlying depends set of any transform precedes the transform in the same way as the one fud coder $C_{\mathrm{F}, \mathrm{U}, \mathrm{S}}$ above. Let $B_{\mathrm{T}, \mathrm{F}, \mathrm{P}} \in \mathcal{L}\left(\mathcal{T}_{U, \mathrm{P}}\right) \rightarrow \operatorname{coders}\left(\mathcal{T}_{U, Q, \mathrm{P}}\right)$ in

$$
C_{\mathrm{F}, \mathrm{U}, \mathrm{P}, \mathrm{~B}}=\operatorname{coderListTerminatingLookback}\left(B_{\mathrm{T}, \mathrm{~F}, \mathrm{P}}\right) \in \operatorname{coders}\left(\mathcal{L}\left(\mathcal{T}_{U, \mathrm{P}}\right)\right)
$$

be defined as

$$
B_{\mathrm{T}, \mathrm{~F}, \mathrm{P}}(L):=\operatorname{coder} \operatorname{TransformPartition}\left(\text { system }(\operatorname{ran}(L)) \cup R, D_{\mathrm{V}}, D_{\mathrm{S}}\right)
$$

Here the restricted coder domain, $\mathcal{T}_{U, Q, \mathrm{P}}$ is defined by $Q=\operatorname{system}(\operatorname{ran}(L)) \cup$ $R$. So, strictly speaking, $C_{\mathrm{F}, \mathrm{U}, \mathrm{P}, \mathrm{B}}$ has a coder domain which is a proper subset of $\mathcal{L}\left(\mathcal{T}_{U, \mathrm{P}}\right)$. That is, only the dependency ordered lists of partition transforms.

The overall space of the fud $F$ in this coder $C_{\mathrm{F}, \mathrm{U}, \mathrm{P}} \in \operatorname{coders}\left(\mathcal{F}_{U, P}\right)$, including the up-front encoding of the underlying variables, und $(F)$, and the unlimited list coder $C_{\mathrm{F}, \mathrm{U}, \mathrm{P}, \mathrm{B}}$, with underlying partition transform coder $C_{\mathrm{T}, \mathrm{P}}$, of the list of transforms, $L \in \mathcal{L}\left(\mathcal{T}_{U, \mathrm{P}}\right)$, is

$$
\operatorname{space}\left(C_{\mathrm{F}, \mathrm{U}, \mathrm{P}}\right)(F):=\operatorname{sp} \operatorname{Var}(R)(|\operatorname{und}(F)|)+\operatorname{space}\left(C_{\mathrm{F}, \mathrm{U}, \mathrm{P}, \mathrm{~B}}\right)(L)
$$

The fud space is subject to an inequality which does not depend on $L$

$$
\begin{aligned}
& \operatorname{space}\left(C_{\mathrm{F}, \mathrm{U}, \mathrm{P}}\right)(F) \leq \\
& \quad \operatorname{sp} \operatorname{Var}(R)(|\operatorname{und}(F)|)+\sum_{T \in F} \operatorname{space}\left(C_{\mathrm{T}, \mathrm{P}}\right)(T)+(|F|+1) \ln 2
\end{aligned}
$$

where

$$
C_{\mathrm{T}, \mathrm{P}}=\operatorname{coder} \operatorname{TransformPartition}\left(U, D_{\mathrm{V}}, D_{\mathrm{S}}\right) \in \operatorname{coders}\left(\mathcal{T}_{U, \mathrm{P}}\right)
$$

and system $(F) \cup R \subseteq U$. Now space $\left(C_{\mathrm{T}, \mathrm{P}}\right)(T)=\operatorname{space}\left(C_{\mathrm{P}}\right)(\operatorname{partition}(T))$ so $\operatorname{space}\left(C_{\mathrm{F}, \mathrm{U}, \mathrm{P}}\right)(F) \leq$

$$
\operatorname{sp} \operatorname{Var}(R)\left(\left|V_{F}\right|\right)+\sum_{T \in F}\left(\operatorname{sp} \operatorname{Var}(U)\left(\left|V_{T}\right|\right)+\operatorname{spPart}(U)\left(P_{T}\right)\right)+(|F|+1) \ln 2
$$

where $V=$ und, $P=$ partition, $\mathrm{spVar}=\mathrm{spVar}$ and $\mathrm{spPart}=$ spacePartititon.
The variables space is minimised in the inequality when $U=\operatorname{system}(F) \cup R$. An unlimited list coder minimises the variables space of a fud in the partition fud coder. For example, if a power partition set, $X=\operatorname{power}(U)(V) \in \mathcal{F}_{U, \mathrm{P}}$, has large cardinality and hence a large system, $|U|>|X|$, even small subsets $F \subset X$, where $\operatorname{und}(F) \subseteq V$ and $|F| \ll|X|$, would require large variables space. Conversely, the use of an unlimited list coder also avoids setting a maximum effective limit on the cardinality of the system implied by limited list coders, $y \leq|U|-1$.

## A. 12 Derived history coders and search

The derived history coders discussed in section 'Derived history space', above, such as the specialising derived substrate history coder, $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, are
substrate history coders in that they are given a model such as a transform $T$ as a constructor parameter. The substrate history coder domain is then restricted to the histories in the underlying variables of the transform, $\mathcal{H}_{U, V, X}$, where $V=\operatorname{und}(T)$.

Now consider how the derived substrate history coders may be generalised to the unrestricted history coder domain where the histories may be in any of the system variables, $\mathcal{H}_{U, X}=\bigcup\left\{X \rightarrow V^{\mathrm{CS}}: V \subseteq \operatorname{vars}(U)\right\}$. The generalisation may be accomplished by removing the transform from the parameters altogether and (i) computing a transform, $T_{H}$, at the beginning of the encoding, (ii) encoding the transform, $T_{H}$, in a transform coder, and (iii) encoding the history, $H$, by means of a newly instantiated derived substrate history coder parameterised by the constructed transform, $T_{H}$. A subsequent decoding of the history, $H$, then proceeds by (i) decoding the transform $T_{H}$ in the transform coder, and (ii) decoding the history, $H$, by means of a newly instantiated derived substrate history coder parameterised by the decoded transform, $T_{H}$.

The derived history coders need not be restricted to one functional transforms of a substrate, but can be generalised to any model (i) that can be a model parameter of the history coder and (ii) for which a model coder exists.

In particular, of the substrate models (i) the partition transforms of the base fud, $F_{U, V}=\left\{P^{\mathrm{T}}: P \in \mathrm{~B}\left(V^{\mathrm{CS}}\right)\right\} \subset \mathcal{F}_{U, V} \subset \mathcal{F}_{U, \mathrm{P}}$, can be encoded in a partition transform coder, $C_{\mathrm{T}, \mathrm{P}}$, (ii) the substrate fuds, $\mathcal{F}_{U, V} \subset \mathcal{F}_{U, \mathrm{P}}$, can be encoded in an unlimited partition fud coder, $C_{\mathrm{F}, \mathrm{U}, \mathrm{P}}$, and (iii) the substrate fud decompositions, $\mathcal{D}_{\mathrm{F}, U, V} \subset \mathcal{D}_{\mathrm{F}, U, \mathrm{P}}$, can be encoded in an unlimited partition fud decomposition coder, $C_{\mathrm{D}, \mathrm{F}, \mathrm{U}, \mathrm{P}}$.

The process of computing the model for each encoded history can be generalised also. This is done by defining the computation as a maximisation of a logarithm extended rational valued function of the models for the history. Let $Z \in \mathcal{H} \rightarrow\left(\mathcal{M} \rightarrow\left(\mathbf{Q} \cup \mathbf{Q} \ln \mathbf{Q}_{>0}\right)\right)$ be a search function parameterised by history, where $\mathcal{M}$ is the set of models. The search function, $Z$, is constrained such that the underlying variables of the models equal the history variables, $\forall H \in \operatorname{dom}(Z) \forall M \in \operatorname{dom}(Z(H))(\operatorname{und}(M)=\operatorname{vars}(H))$. Then for history $H \in \mathcal{H}_{U, X}$ the model $M \in \mathcal{M}$ chosen for encoding is such that $M \in \operatorname{maxd}(Z(H))$. If there is more than one model in the maximum function's domain, $|\operatorname{maxd}(Z(H))|>1$, then a model is chosen arbitrarily. For example, $\{M\}=\operatorname{maxd}\left(\operatorname{order}\left(D_{\mathcal{X}}, \operatorname{maxd}(Z(H))\right)\right)$, where $D_{\mathcal{X}} \in \operatorname{enums}(\mathcal{X})$ is
an arbitrary ordering.
In the particular case where a derived history coder is implemented by encoding some subset of the substrate models, $\mathcal{M}_{U, V}$, the search function is constrained $Z(H) \in \mathcal{M}_{U, V} \rightarrow\left(\mathbf{Q} \cup \mathbf{Q} \ln \mathbf{Q}_{>0}\right)$.

An instance of the class of derived history coders may then be constructed by specifying (i) the model coder $C_{\mathrm{M}} \in \operatorname{coders}(\mathcal{M})$, (ii) the model search function $Z \in \mathcal{H} \rightarrow\left(\mathcal{M} \rightarrow\left(\mathbf{Q} \cup \mathbf{Q} \ln \mathbf{Q}_{>0}\right)\right)$, and (iii) the derived substrate history coder function parameterised by model $C_{\mathrm{V}} \in \mathcal{M} \rightarrow \operatorname{coders}(\mathcal{H})$. The parameters of the constructor are constrained $\forall H \in \mathcal{H}_{U, X} \forall M \in \operatorname{dom}(Z(H))(M \in$ domain $\left.\left(C_{\mathrm{M}}\right) \wedge M \in \operatorname{dom}\left(C_{\mathrm{V}}\right)\right)$.

The generic derived history coder is constructed

$$
\begin{aligned}
& C\left(C_{\mathrm{M}}, Z, C_{\mathrm{V}}\right)= \\
& \quad \text { coderHistoryDerivedGeneric }\left(U, X, C_{\mathrm{M}}, Z, C_{\mathrm{V}}, D_{\mathrm{S}}, D_{\mathrm{X}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)
\end{aligned}
$$

A history $H \in \mathcal{H}_{U, X}$ is encoded as a tuple $\left(E_{\mathrm{M}}(M), E_{\mathrm{V}}(H)\right) \in \mathbf{N} \times \mathbf{N}$ where $M \in \operatorname{maxd}(Z(H)),\left(E_{\mathrm{M}}, \cdot, \cdot\right)=\operatorname{def}\left(C_{\mathrm{M}}\right)$ and $\left(E_{\mathrm{V}}, \cdot, \cdot\right)=\operatorname{def}\left(C_{\mathrm{V}}(M)\right)$.

The space of the history in the generic derived history coder, $C\left(C_{\mathrm{M}}, Z, C_{\mathrm{V}}\right)$, is the space of the model, $M$, in the given model coder, $C_{\mathrm{M}}$, plus the space of the history, $H$, in the given derived substrate history coder, $C_{\mathrm{V}}(M)$,

$$
C\left(C_{\mathrm{M}}, Z, C_{\mathrm{V}}\right)^{\mathrm{s}}(H)=C_{\mathrm{M}}^{\mathrm{s}}(M)+C_{\mathrm{V}}(M)^{\mathrm{s}}(H)
$$

Derived history coders require more space to encode a history than their underlying derived substrate history coders do to encode the same history, $C\left(C_{\mathrm{M}}, Z, C_{\mathrm{V}}\right)^{\mathrm{s}}(H)>C_{\mathrm{V}}(M)^{\mathrm{s}}(H)$, because of the necessity of the additional space to encode the model, $C_{\mathrm{M}}^{\mathrm{s}}(M)$. However, derived history coders are more flexible. Not only do they allow histories with arbitrary substrates within the system, but they also allow different models for histories in the same substrate. So vars $\left(H_{1}\right)=\operatorname{vars}\left(H_{2}\right)$, where $H_{1}, H_{2} \in \mathcal{H}_{U, X}$, does not necessarily imply $\operatorname{maxd}\left(Z\left(H_{1}\right)\right)=\operatorname{maxd}\left(Z\left(H_{2}\right)\right)$. That is, a derived substrate history coder of domain $\mathcal{H}_{U, V, X}$ must encode all of the histories of the domain with the same model $M$, where $\operatorname{und}(M)=V$, defined as a parameter at coder instantiation. In contrast, a derived history coder can have different instantiations of its derived substrate history coder depending on the history, possibly with different space.

In addition, the model space typically varies with the volume rather than the size, whereas the substrate history space varies with volume and size. So the proportion of derived history coder space corresponding to the model decreases as the size of the history increases. For example, consider a derived history coder $C\left(C_{\mathrm{T}, \mathrm{P}}, Z, C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$ constructed with a partition transform coder, $C_{\mathrm{T}, \mathrm{P}}$, and index derived substrate history coder $C_{\mathrm{H}, V, T, \mathrm{H}}$. Let $H \in \mathcal{H}_{U, X}$ and $T \in \operatorname{maxd}(Z(H))$. The partition transform coder space is

$$
\operatorname{space}\left(C_{\mathrm{T}, \mathrm{P}}\right)(T)=\operatorname{spaceVariables}(U)(|V|)+\operatorname{spacePartition}(U)(V)
$$

where $V=\operatorname{und}(T)$. The index derived substrate history coder space is

$$
\begin{aligned}
\operatorname{space}\left(C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}\right)(H)= & \operatorname{spaceIds}(|X|,|H|)+ \\
& \operatorname{spaceEventsDerived}(U)(H, T)+ \\
& \operatorname{spaceEventsPartition}(A, T)
\end{aligned}
$$

where $A=\operatorname{histogram}(H)$. So the space is

$$
\begin{aligned}
C\left(C_{\mathrm{T}, \mathrm{P}}, Z, C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}\right)^{\mathrm{s}}(H)= & \text { spaceVariables }(U)(|V|)+ \\
& \text { spaceIds }(|X|,|H|)+ \\
& \text { spacePartition }(U)(V) \\
& \text { spaceEventsDerived }(U)(H, T)+ \\
& \text { spaceEventsPartition }(A, T)
\end{aligned}
$$

Partition space does not depend on size, but varies as $\ln \operatorname{bell}(v)<v \ln v$ where $v=\left|V^{\mathrm{C}}\right|$. The events space is spaceEventsDerived $(U)(H, T):=$ $z \ln w^{\prime}$, where $w^{\prime}=\left|\left(V^{\mathrm{C}} * T\right)^{\mathrm{F}}\right|=\left|T^{-1}\right|$, and the partitioned events space is spaceEventsPartition $(A, T):=\sum_{(R, C) \in T^{-1}}(A * T)_{R} \ln |C|$. Both the events space and the partitioned events space scale with size, $z$. In this example the fraction of space which is model space varies as $v / z$.

A special case of a model search function is the minimum space model search function $Z_{\mathrm{m}}\left(C_{\mathrm{M}}, C_{\mathrm{V}}\right) \in \mathcal{H} \rightarrow\left(\mathcal{M} \rightarrow\left(\mathbf{Q} \cup \mathbf{Q} \ln \mathbf{Q}_{>0}\right)\right)$, which is parameterised by a model coder, $C_{\mathrm{M}}$, and a derived substrate history coder function, $C_{\mathrm{V}}$. Here the model is chosen to minimise the space of the history encoding,

$$
\begin{aligned}
& Z_{\mathrm{m}}\left(C_{\mathrm{M}}, C_{\mathrm{V}}\right)(H)= \\
& \quad\left\{\left(M,-\left(C_{\mathrm{M}}^{\mathrm{s}}(M)+C_{\mathrm{V}}(M)^{\mathrm{s}}(H)\right)\right): M \in \operatorname{domain}\left(C_{\mathrm{M}}\right), \operatorname{und}(M)=\operatorname{vars}(H)\right\}
\end{aligned}
$$

The minimum space model search function is such that for any search function $Z \in \mathcal{H} \rightarrow\left(\mathcal{M} \rightarrow\left(\mathbf{Q} \cup \mathbf{Q} \ln \mathbf{Q}_{>0}\right)\right)$ the minimum space model search function always has least space

$$
\forall H \in \mathcal{H}_{U, X}\left(C\left(C_{\mathrm{M}}, Z, C_{\mathrm{V}}\right)^{\mathrm{s}}(H) \geq C\left(C_{\mathrm{M}}, Z_{\mathrm{m}}\left(C_{\mathrm{M}}, C_{\mathrm{V}}\right), C_{\mathrm{V}}\right)^{\mathrm{s}}(H)\right)
$$

For any generic derived history coder $C\left(C_{\mathrm{M}}, Z, C_{\mathrm{V}}\right)$ there exists a minimum space derived history coder $C\left(C_{\mathrm{M}}, Z_{\mathrm{m}}\left(C_{\mathrm{M}}, C_{\mathrm{V}}\right), C_{\mathrm{V}}\right)$. That is, the search of the models can always be performed by a complete traversal of the finite model set such that the space of the encoding is minimised.

Consider the subset of histories for which a state is uniquely associated with an event identifier. Define the unit histories

$$
\mathcal{H}_{U, X, \mathrm{U}}=\bigcup\left\{X \leftrightarrow V^{\mathrm{CS}}: V \subseteq \operatorname{vars}(U)\right\}
$$

These histories are such that the histograms are unit, $\forall H \in \mathcal{H}_{U, X, \mathrm{U}} \diamond A=$ $\operatorname{histogram}(H)\left(A=A^{\mathrm{F}}\right)$. The size $z$ equals the effective volume, $z=\left|A^{\mathrm{F}}\right| \leq$ $v$, where $z=|H|, V=\operatorname{vars}(H)$ and $v=\left|V^{\mathrm{C}}\right|$.

A minimum space derived history coder of the unit histories may be implemented with the binary partition transform coder, $C_{\mathrm{T}, \mathrm{P}, \mathrm{b}}$, and the specialising derived substrate history coder $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$. Define the binary partition minimum space specialising derived history coder
$C_{\mathrm{P}, \mathrm{b}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}=$
coderHistoryDerivedGeneric $\left(U, X, C_{\mathrm{T}, \mathrm{P}, \mathrm{b}}, Z_{\mathrm{m}}\left(C_{\mathrm{T}, \mathrm{P}, \mathrm{b}}, C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\right), C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}, D_{\mathrm{S}}, D_{\mathrm{X}}\right)$
The space is

$$
\begin{aligned}
C_{\mathrm{P}, \mathrm{~b}, \mathrm{~m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)= & \text { spaceVariables }(U)(|V|)+ \\
& \text { spaceIds }(|X|,|H|)+ \\
& \text { spacePartitionBinary }(U)(V) \\
& \text { spaceCountsDerived }(U)(A, T)+ \\
& \text { spaceClassification }(A * T)+ \\
& \text { spaceEventsPartition }(A, T)
\end{aligned}
$$

where $V=\operatorname{vars}(H)$ and $A=$ histogram $(H)$. The minimum space binary partition is always $\left\{A^{\mathrm{FS}}, V^{\mathrm{CS}} \backslash A^{\mathrm{FS}}\right\}$. So the space is $C_{\mathrm{P}, \mathrm{b}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}^{\mathrm{s}}(H)=$ $\operatorname{sp} \operatorname{Var}(U)(|V|)+\operatorname{spIds}(|X|,|H|)+v \ln 2+\ln (z+1)+z \ln z$. Compare the
space to the canonical history coders. The difference in space for the index history coder, $C_{\mathrm{H}}$, is

$$
C_{\mathrm{P}, \mathrm{~b}, \mathrm{~m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{H}}^{\mathrm{s}}(H)=v \ln 2+\ln (z+1)+z \ln z-z \ln v
$$

The difference is necessarily positive. Similarly, the difference in space for the classification history coder, $C_{\mathrm{G}}$, is

$$
C_{\mathrm{P}, \mathrm{~b}, \mathrm{~m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)-C_{\mathrm{G}}^{\mathrm{s}}(H)=v \ln 2+\ln (z+1)+z \ln z-\bar{z} \ln v
$$

which is also always positive. That is, the binary partition minimum space specialising derived history coder, $C_{\mathrm{P}, \mathrm{b}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$, always requires more space to encode a unit history than both of the canonical coders, $C_{\mathrm{H}}$ and $C_{\mathrm{G}}$, even though the search is the minimum space search. This is because the model space, $v \ln 2$, varies with the volume, as is typical, while the canonical coder space, $z \ln v$ and $\bar{z} \ln v$, varies with the size.

For fixed volume the coder space, $C_{\mathrm{P}, \mathrm{b}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}^{\mathrm{s}}(H)$, varies with the size, $z$, which equals the component cardinality, $\left|A^{\mathrm{F}}\right|$. So the space varies against the component size cardinality relative entropy.

In order to construct a minimum space specialising derived history coder that requires a smaller space to encode a unit history than the canonical coders, a model $M$ is needed such that its encoding space in coder $C_{\mathrm{M}}$ is approximately constrained

$$
C_{\mathrm{M}}^{\mathrm{s}}(M)<z \ln \frac{v+z}{2 z}
$$

Note that the discussion above of the process of encoding in derived history coders does not address the computational tractability or practicability. Especially in the case of the minimum space search, where the entire set of the model coder domain is traversed, the computation may be infeasible. The discussion in later sections below considers search functions that (i) traverse only subsets of the model set, and (ii) have different metrics, not necessarily an encoding space valued function of the models.

Given a system $U$ and event identifiers $X$, a history coder domain probability function $P \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$ is defined as entropic with respect to history coder $C \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$ if the coder is an entropy coder. See appendix 'Coders and entropy' for the definition of the entropy coder. The coder is an entropy history coder if and only if the space of a history equals
the negative logarithm of the non-zero probability, $\forall H \in \mathcal{H}_{U, X}\left(P_{H}>0 \Longrightarrow\right.$ $C^{\mathrm{s}}(H)=-\ln P_{H}$ ). Then the expected space of the coder equals the entropy of the history probability function.

$$
\begin{aligned}
\operatorname{expected}(P)\left(C^{\mathrm{s}}\right) & =\sum_{H \in \mathcal{H}_{U, X}} P_{H} \times C^{\mathrm{s}}(H) \\
& =-\sum\left(P_{H} \ln P_{H}: H \in \mathcal{H}_{U, X}, P_{H}>0\right) \\
& =\operatorname{entropy}(P)
\end{aligned}
$$

An entropy coder has the smallest expected space of all coders given the probability function.

Similar to the definition of entropic history probability functions, a history coder domain probability function $P \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$ is defined as structured with respect to derived history coder $C\left(C_{\mathrm{M}}, Z, C_{\mathrm{V}}\right) \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$, if the expected space of the derived history coder is less than the expected lesser space of the canonical history coders, (i) index history coder, $C_{\mathrm{H}}$, and (ii) classification history coder, $C_{\mathrm{G}}$,

$$
\operatorname{expected}(P)\left(C\left(C_{\mathrm{M}}, Z, C_{\mathrm{V}}\right)^{\mathrm{s}}\right)<\operatorname{expected}(P)\left(\operatorname{minimum}\left(C_{\mathrm{H}}^{\mathrm{s}}, C_{\mathrm{G}}^{\mathrm{s}}\right)\right)
$$

where minimum $\left(C_{\mathrm{H}}^{\mathrm{s}}, C_{\mathrm{G}}^{\mathrm{s}}\right) \in \mathcal{H}_{U, X} \rightarrow \ln \mathbf{N}_{>0}$. That is, history $H \in \mathcal{H}_{U, X}$ in structured history probability function $P$ with respect to derived history coder $C\left(C_{\mathrm{M}}, Z, C_{\mathrm{V}}\right)$ has a model $M \in \operatorname{mind}(Z(H))$ for which it is expected that $C_{\mathrm{M}}^{\mathrm{s}}(M)+C_{\mathrm{V}}(M)^{\mathrm{s}}(H)<\operatorname{minimum}\left(C_{\mathrm{H}}^{\mathrm{s}}(H), C_{\mathrm{G}}^{\mathrm{s}}(H)\right)$, where minimum $(x, y)=$ if $(x<y, x, y)$.

The degree of structure is defined structure $(U, X) \in\left(\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}\right) \times$ $\operatorname{coders}\left(\mathcal{H}_{U, X}\right) \rightarrow \mathbf{Q} \ln \mathbf{Q}_{>0} / \ln \mathbf{Q}_{>0}$ as

$$
\operatorname{structure}(U, X)(P, C):=\frac{\operatorname{canonical}(U, X)(P)-\operatorname{expected}(P)\left(C^{\mathrm{s}}\right)}{\operatorname{canonical}(U, X)(P)-\operatorname{entropy}(P)}
$$

where canonical $(U, X) \in\left(\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}\right) \rightarrow \mathbf{Q}_{\geq 0} \ln \mathbf{N}_{>0}$ is defined

$$
\operatorname{canonical}(U, X)(P):=\operatorname{expected}(P)\left(\operatorname{minimum}\left(C_{\mathrm{H}}^{\mathrm{s}}, C_{\mathrm{G}}^{\mathrm{s}}\right)\right)
$$

The degree of structure is undefined if the canonical coders are already entropic, canonical $(U, X)(P)=\operatorname{entropy}(P)$. The degree of structure is defined for all history coders, not just derived history coders.

Define the compression of coder $C$ with respect to probability function $P$
as a synonym for the degree of structure of probability function $P$ with respect to the coder $C$.

The degree of structure is always less than or equal to one,

$$
\forall P \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}(\text { structure }(U, X)(P, C) \leq 1)
$$

If the degree of structure equals one, structure $(U, X)(P, C)=1$, the coder, $C$, is an entropy coder of the probability function, $P$, $\operatorname{expected}(P)\left(C^{\mathbf{s}}\right)=$ entropy $(P)$.

If the degree of structure less than or equal to zero, structure $(U, X)(P, C) \leq 0$, the probability function, $P$, is structureless with respect to the coder, $C$, or, equivalently, the coder, $C$, is non-compressing with respect to the probability function, $P$. For example, the theoretical variable-width history coder, $C_{\mathrm{E}}$, is non-compressing with respect to all probability functions for which it can be defined, because the space is always greater than or equal to the space of the classification coder, $C_{\mathrm{E}}^{\mathrm{s}}(H) \geq C_{\mathrm{G}}^{\mathrm{s}}(H)$.

Structured history probability functions are less strongly constrained than entropic history probability functions because entropy coders have least expected space, $0<\operatorname{structure}(U, X)(P, C) \leq 1$.

Histories that are structured with respect to derived history coders,

$$
\text { structure }(U, X)\left(P, C\left(C_{\mathrm{M}}, Z, C_{\mathrm{V}}\right)\right)>0
$$

are expected to be lawlike in that the structures can be encapsulated in a model such that encoding space of the history plus the additional space of the model is less than the cost of encoding the history in the structureless canonical coders. If a history probability function is structured with respect to some derived history coder $C\left(C_{\mathrm{M}}, Z, C_{\mathrm{V}}\right)$, then it is also at least as structured with respect to the minimum space derived history $\operatorname{coder} C\left(C_{\mathrm{M}}, Z_{\mathrm{m}}\left(C_{\mathrm{M}}, C_{\mathrm{V}}\right), C_{\mathrm{V}}\right)$,
structure $(U, X)\left(P, C\left(C_{\mathrm{M}}, Z_{\mathrm{m}}\left(C_{\mathrm{M}}, C_{\mathrm{V}}\right), C_{\mathrm{V}}\right)\right) \geq \operatorname{structure}(U, X)\left(P, C\left(C_{\mathrm{M}}, Z, C_{\mathrm{V}}\right)\right)$
Structured histories are not necessarily assumed to be each encoded with the same model, $\exists M \in \operatorname{dom}(Z) \forall H \in \mathcal{H}_{U, X}(\operatorname{maxd}(Z(H))=\{M\})$, only that there exists some model for some histories such that the expected space is smaller than the canonical space, $\exists H \in \mathcal{H}_{U, X} \exists M \in \operatorname{maxd}(Z(H))\left(C_{\mathrm{M}}^{\mathrm{s}}(M)+\right.$ $\left.C_{\mathrm{V}}(M)^{\mathrm{s}}(H)<\operatorname{minimum}\left(C_{\mathrm{H}}^{\mathrm{s}}(H), C_{\mathrm{G}}^{\mathrm{s}}(H)\right)\right)$.

There is no structured probability function of unit histories, $\mathcal{H}_{U, X, \mathrm{U}}$, with respect to the binary partition minimum space specialising derived history coder, $C_{\mathrm{P}, \mathrm{b}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$,

$$
\forall P \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}\left(\text { structure }(U, X)\left(P, C_{\mathrm{P}, \mathrm{~b}, \mathrm{~m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}\right)<0\right)
$$

because the space of any non-empty history is always greater than in both canonical coders

$$
\forall H \in \mathcal{H}_{U, X, \mathrm{U}} \backslash\{\emptyset\}\left(C_{\mathrm{P}, \mathrm{~b}, \mathrm{~m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}^{\mathrm{s}}(H)>\operatorname{minimum}\left(C_{\mathrm{H}}^{\mathrm{s}}(H), C_{\mathrm{G}}^{\mathrm{s}}(H)\right)\right)
$$

A history coder $C_{\min (\mathrm{H}, \mathrm{G})}$ of the lesser space of the canonical history coders can be implemented with a flag to indicate which of the canonical coders was chosen. The space is $C_{\min (\mathrm{H}, \mathrm{G})}^{\mathrm{s}}(H)=\operatorname{minimum}\left(C_{\mathrm{H}}^{\mathrm{s}}(H), C_{\mathrm{G}}^{\mathrm{s}}(H)\right)+\ln 2$. The lesser canonical history coder, $C_{\min (\mathrm{H}, \mathrm{G})}$, is necessarily structureless,

$$
\forall P \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}\left(\text { structure }(U, X)\left(P, C_{\min (\mathrm{H}, \mathrm{G})}\right)<0\right)
$$

because of the additional space of the flag.
Conjecture that there is no coder such that the uniform history probability function, $\hat{\mathcal{H}}_{U, X}=\mathcal{H}_{U, X} \times\left\{1 /\left|\mathcal{H}_{U, X}\right|\right\} \in \mathcal{P}$, has structure,

$$
\forall C \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)\left(\operatorname{structure}(U, X)\left(\hat{\mathcal{H}}_{U, X}, C\right)<0\right)
$$

where canonical $(U, X)\left(\hat{\mathcal{H}}_{U, X}\right) \neq \operatorname{entropy}\left(\hat{\mathcal{H}}_{U, X}\right)$.
The degree of structure has two arguments, (i) the probability function $P \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$, and (ii) the coder $C \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$. The function can be viewed as (i) a measure of the structure of the histories of the probability function, $P$, with respect to a fixed coder, $C$, or (ii) a measure of the compression, or canonical-entropic relative space, of the coder, $C$, given a probability function, $P$.

In the first case, probability functions may be compared by structure given the partition minimum space specialising derived history coder,

```
C C,m,G,T,H}
    coderHistoryDerivedGeneric}(U,X,\mp@subsup{C}{\textrm{T},\textrm{P}}{},\mp@subsup{Z}{\textrm{m}}{}(\mp@subsup{C}{\textrm{T},\textrm{P}}{},\mp@subsup{C}{\textrm{G},V,\textrm{T},\textrm{H}}{}),\mp@subsup{C}{\textrm{G},V,\textrm{T},\textrm{H}}{},\mp@subsup{D}{\textrm{S}}{},\mp@subsup{D}{\textrm{X}}{}
```

The speciality is the degree of structure of probability function $P$ with respect to the partition minimum space specialising derived history coder. Define $\operatorname{speciality}(U, X) \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P} \rightarrow \mathbf{Q} \ln \mathbf{Q}_{>0} / \ln \mathbf{Q}_{>0}$ as

$$
\operatorname{speciality}(U, X)(P):=\operatorname{structure}(U, X)\left(P, C_{\mathrm{P}, \mathrm{~m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}\right)
$$

For an example of comparison by structure, let $P_{1}, P_{2} \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap$ $\mathcal{P}$. Then $P_{1}$ is more specially structured than $P_{2}$ if speciality $(U, X)\left(P_{1}\right)>$ speciality $(U, X)\left(P_{2}\right)$. Here the given coder, $C_{\mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$, has a simply defined model space, requiring only that the partition be encoded. The minimum search function, $Z_{\mathrm{m}}\left(C_{\mathrm{T}, \mathrm{P}}, C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\right)$, does a brute force search over the partition transforms, domain $\left(C_{\mathrm{T}, \mathrm{P}}\right) \subset \mathcal{T}_{U, \mathrm{P}}$, choosing the transform with the least encoding space of the history, so the speciality structure is maximised with respect to search function.

Similarly, the generality is the degree of structure of probability function $P$ with respect to the partition minimum space generalising derived history coder. Define generality $(U, X) \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P} \rightarrow \mathbf{Q} \ln \mathbf{Q}_{>0} / \ln \mathbf{Q}_{>0}$ as

$$
\text { generality }(U, X)(P):=\operatorname{structure}(U, X)\left(P, C_{\mathrm{P}, \mathrm{~m}, \mathrm{H}, \mathrm{~T}, \mathrm{G}}\right)
$$

In the second case, coders may be compared by compression given the probability function, $P$. For example, let $C_{1}, C_{2} \in \operatorname{coders}\left(\mathcal{H}_{U, X}\right)$. Then $C_{1}$ is more compressing than $C_{2}$ if structure $(U, X)\left(P, C_{1}\right)>\operatorname{structure}(U, X)\left(P, C_{2}\right)$.

A probability function $P$ can be characterised by the relative compression of coders that differ only in model. The generic minimum space specialising derived history coder is parameterised by model $C_{\mathrm{M}}$,

$$
\begin{aligned}
& C_{\mathrm{m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(C_{\mathrm{M}}\right)= \\
& \quad \text { coderHistoryDerivedGeneric }\left(U, X, C_{\mathrm{M}}, Z_{\mathrm{m}}\left(C_{\mathrm{M}}, C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\right), C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}, D_{\mathrm{S}}, D_{\mathrm{X}}\right)
\end{aligned}
$$

Similarly, define (i) the generic minimum space specialising fud history coder $C_{\mathrm{m}, \mathrm{G}, \mathrm{F}, \mathrm{H}}\left(C_{\mathrm{M}}\right)$, (ii) the generic minimum space specialising decomposition history coder $C_{\mathrm{m}, \mathrm{G}, \mathrm{D}, \mathrm{H}}\left(C_{\mathrm{M}}\right)$ and (iii) the generic minimum space specialising fud decomposition history coder $C_{\mathrm{m}, \mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}\left(C_{\mathrm{M}}\right)$.

The relative redundant speciality of the probability function $P$ is the relative compression between the multi-partition transform coder, $C_{\mathrm{T}, \mathrm{P}^{*}}$, and the partition transform coder, $C_{\mathrm{T}, \mathrm{P}}$,

$$
\operatorname{structure}(U, X)\left(P, C_{\mathrm{m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(C_{\mathrm{T}, \mathrm{P}^{*}}\right)\right)-\operatorname{structure}(U, X)\left(P, C_{\mathrm{m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(C_{\mathrm{T}, \mathrm{P}}\right)\right)
$$

The relative layered redundant speciality of the probability function $P$ is the relative compression between the unlimited partition fud coder, $C_{\mathrm{F}, \mathrm{U}, \mathrm{P}}$, and the multi-partition transform coder, $C_{\mathrm{T}, \mathrm{P}^{*}}$,

$$
\operatorname{structure}(U, X)\left(P, C_{\mathrm{m}, \mathrm{G}, \mathrm{~F}, \mathrm{H}}\left(C_{\mathrm{F}, \mathrm{U}, \mathrm{P}}\right)\right)-\operatorname{structure}(U, X)\left(P, C_{\mathrm{m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(C_{\mathrm{T}, \mathrm{P}^{*}}\right)\right)
$$

The relative contingent speciality of the probability function $P$ is the relative compression between the unlimited partition transform decomposition coder, $C_{\mathrm{D}, \mathrm{U}, \mathrm{P}}$, and the partition transform coder, $C_{\mathrm{T}, \mathrm{P}}$,

$$
\operatorname{structure}(U, X)\left(P, C_{\mathrm{m}, \mathrm{G}, \mathrm{D}, \mathrm{H}}\left(C_{\mathrm{D}, \mathrm{U}, \mathrm{P}}\right)\right)-\operatorname{structure}(U, X)\left(P, C_{\mathrm{m}, \mathrm{G}, \mathrm{~T}, \mathrm{H}}\left(C_{\mathrm{T}, \mathrm{P}}\right)\right)
$$

The relative layered redundant contingent speciality of the probability function $P$ is the relative compression between the unlimited partition fud decomposition coder, $C_{\mathrm{D}, \mathrm{F}, \mathrm{U}, \mathrm{P}}$, and the unlimited partition transform decomposition coder, $C_{\mathrm{D}, \mathrm{U}, \mathrm{P}}$,
$\operatorname{structure}(U, X)\left(P, C_{\mathrm{m}, \mathrm{G}, \mathrm{D}, \mathrm{F}, \mathrm{H}}\left(C_{\mathrm{D}, \mathrm{F}, \mathrm{U}, \mathrm{P}}\right)\right)-\operatorname{structure}(U, X)\left(P, C_{\mathrm{m}, \mathrm{G}, \mathrm{D}, \mathrm{H}}\left(C_{\mathrm{D}, \mathrm{U}, \mathrm{P}}\right)\right)$
Note that, while the partition transform coder, $C_{T, P}$, is straightforwardly implemented by encoding the partition $T^{\mathrm{P}}$ in space spacePartition $(U)\left(T^{\mathrm{P}}\right):=$ $\ln \operatorname{bell}(v)$, where $v=\left|V^{\mathrm{C}}\right|$ and $V=\operatorname{und}(T)$, the other model coders require the encoding of the structure in lists and trees, and so there are various implementations. This includes the multi-partition transform coder, $C_{\mathrm{T}, \mathrm{P}^{*}}$, which is implemented by encoding the exploded contracted transform, explode $\left(T^{\%}\right) \in \mathcal{F}_{U, \mathrm{P}}$ in a partition fud coder such as the unlimited partition fud coder, $C_{\mathrm{F}, \mathrm{U}, \mathrm{P}}$.

A probability function $P$ can also be characterised by the relative compression of coders that differ only in derived substrate history coder. The generic partition minimum space history coder is parameterised by substrate history coder $C_{\mathrm{V}}$,

$$
\begin{aligned}
& C_{\mathrm{P}, \mathrm{~m}}\left(C_{\mathrm{V}}\right)= \\
& \quad \text { coderHistoryDerivedGeneric }\left(U, X, C_{\mathrm{T}, \mathrm{P}}, Z_{\mathrm{m}}\left(C_{\mathrm{T}, \mathrm{P}}, C_{\mathrm{V}}\right), C_{\mathrm{V}}, D_{\mathrm{S}}, D_{\mathrm{X}}\right)
\end{aligned}
$$

The midity of the probability function $P$ is the difference in compression between (a) the sum of (i) the index derived substrate history coder $C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}$, and (ii) the classification derived substrate history coder $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}$, and (b) the sum of (iii) the specialising derived substrate history coder $C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}$, and (iv) the generalising derived substrate history coder $C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{G}}$. Define $\operatorname{midity}(U, X) \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P} \rightarrow \mathbf{Q} \ln \mathbf{Q}_{>0} / \ln \mathbf{Q}_{>0}$ as

$$
\operatorname{midity}(U, X)(P):=
$$

$$
\begin{aligned}
& \left(\operatorname{structure}(U, X)\left(P, C_{\mathrm{P}, \mathrm{~m}}\left(C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}\right)\right)+\operatorname{structure}(U, X)\left(P, C_{\mathrm{P}, \mathrm{~m}}\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}\right)\right)\right) \\
- & \left(\operatorname{structure}(U, X)\left(P, C_{\mathrm{P}, \mathrm{~m}}\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{H}}\right)\right)+\operatorname{structure}(U, X)\left(P, C_{\mathrm{P}, \mathrm{~m}}\left(C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{G}}\right)\right)\right) \\
= & \left(\operatorname{structure}(U, X)\left(P, C_{\mathrm{P}, \mathrm{~m}}\left(C_{\mathrm{H}, V, \mathrm{~T}, \mathrm{H}}\right)\right)+\operatorname{structure}(U, X)\left(P, C_{\mathrm{P}, \mathrm{~m}}\left(C_{\mathrm{G}, V, \mathrm{~T}, \mathrm{G}}\right)\right)\right) \\
- & (\operatorname{speciality}(U, X)(P)+\text { generality }(U, X)(P))
\end{aligned}
$$

Consider a history probability function which is defined in terms of a historical distribution, $Q_{\mathrm{h}}$. The historical distribution is defined for sample histogram $A$ of size $z$ drawn from distribution histogram $E$ as

$$
Q_{\mathrm{h}}(E, z)(A)=\prod_{S \in A^{\mathrm{S}}}\binom{E_{S}}{A_{S}}=\prod_{S \in A^{\mathrm{S}}} \frac{E_{S}!}{A_{S}!\left(E_{S}-A_{S}\right)!} \in \mathbf{N}_{>0}
$$

The historical probability distribution is normalised,

$$
\hat{Q}_{\mathrm{h}}(E, z)(A)=Q_{\mathrm{h}}(E, z)(A) /\binom{z_{E}}{z}
$$

where $z_{E}=\operatorname{size}(E)$.
Let $H_{E} \subseteq \mathcal{H}_{U, X}$ be a distribution history and $E$ be its distribution histogram, $E=$ histogram $\left(H_{E}\right)$. The distribution history, $H_{E}$, has substrate $V_{E}$ equal to the system variables, $V_{E}=\operatorname{vars}(E)=\operatorname{vars}(U)$. Its volume is $v_{E}=\left|V_{E}^{\mathrm{C}}\right|$. Its domain is the entire set of event identifiers, $\operatorname{ids}\left(H_{E}\right)=X$, so that the distribution history is a left total function, $H_{E} \in X: \rightarrow V_{E}^{\text {CS }}$, and its size $z_{E}$ equals the cardinality of the event identifiers, $z_{E}=\operatorname{size}(E)=|X|$. The historically distributed history probability function $P_{U, X, H_{E}} \in\left(\mathcal{H}_{U, X}: \rightarrow \mathbf{Q}_{\geq 0}\right) \cap \mathcal{P}$ is defined

$$
\begin{aligned}
P_{U, X, H_{E}}:= & \left\{\left(H, 1 /\left(z_{E} 2^{v_{E}}\binom{z_{E}}{z_{H}}\right)\right): H \in \mathcal{H}_{U, X}, H \subseteq H_{E} \% V_{H}, H \neq \emptyset\right\} \cup \\
& \left\{(H, 0): H \in \mathcal{H}_{U, X}, H \nsubseteq H_{E} \% V_{H}\right\} \cup\{(\emptyset, 0)\}
\end{aligned}
$$

where $V_{H}=\operatorname{vars}(H)$ and $z_{H}=|H|$. The historically distributed history probability, $P_{U, X, H_{E}}(H)$, is independent of the event identifiers, ids $(H) \subseteq X$, because the probability depends only on the history size, $z_{H}$. The historically distributed history probability function, $P_{U, X, H_{E}}$, is uniform with respect to the substrate subset of the system variables, $V_{H} \subseteq V_{E}$, and the draw size, $z_{H} \leq z_{E}$. That is,

$$
\begin{aligned}
P_{U, X, H_{E}}= & \left\{\left(H, 1 /\binom{z_{E}}{z}\right): V \subseteq V_{E}, z \in\left\{1 \ldots z_{E}\right\}, H \subseteq H_{E} \% V,|H|=z\right\}^{\wedge} \cup \\
& \left\{(H, 0): H \in \mathcal{H}_{U, X}, H \nsubseteq H_{E} \% V_{H}\right\} \cup\{(\emptyset, 0)\}
\end{aligned}
$$

where $\hat{Y}=(Y)^{\wedge}=\operatorname{normalise}(Y)$. Or

$$
\begin{aligned}
\forall V & \subseteq V_{E} \forall z \in\left\{1 \ldots z_{E}\right\} \\
& \left(\sum\left(P_{U, X, H_{E}}(H): H \in \mathcal{H}_{U, X}, V_{H}=V,|H|=z\right)=1 /\left(z_{E} 2^{v_{E}}\right)\right)
\end{aligned}
$$

The historically distributed history probability function, $P_{U, X, H_{E}}$, is the probability function of the first drawn history $H \subseteq H_{E} \% V_{H}$ of arbitrary variables
$V_{H} \subseteq V_{E}$ and size $z_{H} \in\left\{1 \ldots z_{E}\right\}$ from distribution history $H_{E} \subseteq \mathcal{H}_{U, X}$.
Now for arbitrary drawn history $H \subseteq H_{E} \% V_{H}$, the historical probability of drawing without replacement its histogram $A_{H}=\operatorname{histogram}(H)$ from the distribution histogram, $E=$ histogram $\left(H_{E}\right)$, is the expected historically distributed history probability of the histogram, $A_{H}$, times the normalising factor,

$$
\hat{Q}_{\mathrm{h}}\left(E \% V_{H}, z_{H}\right)\left(A_{H}\right)=z_{E} 2^{v_{E}} \sum\left(P_{U, X, H_{E}}(G): G \in \mathcal{H}_{U, X}, A_{G}=A_{H}\right)
$$

The set of sized cardinal substrate histograms $\mathcal{A}_{z}$, defined above in section 'Distinct geometry sized cardinal substrate histograms', is the set of complete integral cardinal substrate histograms of size $z$ and dimension less than or equal to the size such that the independent is completely effective

$$
\mathcal{A}_{z}=\left\{A: A \in \mathcal{A}_{\mathrm{c}} \cap \mathcal{A}_{\mathrm{i}}, \operatorname{size}(A)=z,\left|V_{A}\right| \leq z, A^{\mathrm{U}}=A^{\mathrm{XF}}=A^{\mathrm{C}}\right\}
$$

Each substrate histogram $A \in \mathcal{A}_{z}$ has $\left|V_{A}\right|!\prod_{w \in V_{A}}\left|U_{A}(w)\right|!$ cardinal substrate permutations. These frame mappings partition the substrate histograms into equivalence classes having the same geometry. Let $P_{z}$ be the partition, $P_{z} \in$ $\mathrm{B}\left(\mathcal{A}_{z}\right)$, such that the components of $P_{z}$ are the equivalence classes by cardinal substrate permutation, $\forall C \in P_{z} \forall A \in C\left(|C|=\left|V_{A}\right|!\prod_{w \in V_{A}}\left|U_{A}(w)\right|\right)$.

Each of the substrate histograms in a component of $P_{z}$, that are equivalent by cardinal substrate permutation, have the same entropy, $\forall C \in P_{z} \forall A, B \in$ $C(\operatorname{entropy}(A)=\operatorname{entropy}(B))$.

The expected function of the renormalised geometry-weighted probability function, $\hat{R}_{z}$, that operates on real-valued functions of the sized cardinal substrate histograms, $\mathcal{A}_{z} \rightarrow \mathbf{R}$, is defined $\operatorname{ex}(z)(F):=\operatorname{expected}\left(\hat{R}_{z}\right)(F)$ where $\hat{R}_{z}=\operatorname{normalise}\left(\left\{\left(A, 1 /\left(\left|V_{A}\right|!\prod_{w \in V_{A}}\left|U_{A}(w)\right|!\right)\right): A \in \operatorname{dom}(F)\right\}\right)$.

The set of non-trivially ideal sized cardinal substrate histograms $\mathcal{A}_{z, \dagger}$ is a subset defined

$$
\begin{aligned}
\mathcal{A}_{z, \uparrow}=\{A: A & \in \mathcal{A}_{z}, z>\left|V_{A}^{\mathrm{C}}\right| \\
& \left.\exists T \in \mathcal{T}_{U_{A}, V_{A}}\left(T^{\mathrm{P}} \notin\left\{V_{A}^{\mathrm{CS}\{ \}},\left\{V_{A}^{\mathrm{CS}}\right\}\right\} \wedge A=A * T * T^{\dagger A}\right)\right\}
\end{aligned}
$$

where $V_{A}=\operatorname{vars}(A)$ and $U_{A}=\operatorname{implied}(A)$. Each non-trivially ideal histogram $A \in \mathcal{A}_{z, \dagger}$ has an ideal transform such that the transform's partition is neither (i) the self partition, $V_{A}^{\mathrm{CS}\{ \}}$, nor (ii) the unary partition, $\left\{V_{A}^{\mathrm{CS}}\right\}$. Thus (i) the partition cannot be a reframe, and (ii) the histogram is not necessarily
independent. The size is constrained to be greater than the volume, $z>$ $v$, so at least one component of the partition has a size greater than one, $\exists(\cdot, C) \in T^{-1}(\operatorname{size}(A * C)>1)$. Therefore a trimmed non-trivially ideal histogram cannot be the histogram of a unit history $H \notin \mathcal{H}_{U, X, \mathrm{U}}$ where $A=\operatorname{histogram}(H) \in \operatorname{trim}\left(\mathcal{A}_{z, \dagger}\right)$.

The historically distributed history probability function $P_{U, X, H_{E}} \in\left(\mathcal{H}_{U, X}: \rightarrow\right.$ $\left.\mathrm{Q}_{\geq 0}\right) \cap \mathcal{P}$ is a function only of the distribution histogram $E$ if (i) the system is the implied system, $U=\operatorname{implied}(E)$, (ii) the distribution history is constructed from the distribution histogram, $H_{E}=$ history $(E)$, and (iii) the set of event identifiers is the domain of the constructed history, $X=$ $\operatorname{ids}\left(H_{E}\right) \in \mathcal{S} \times \mathbf{N}_{>0}$. So the degree of structure of the historically nontrivially ideal distributed history probability function with respect to the partition minimum space specialising derived history coder is the speciality, $\operatorname{speciality}(U, X)\left(P_{U, X, H_{E}}\right)$ where $E \in \operatorname{trim}\left(\mathcal{A}_{z_{E}, \dagger}\right)$.

Conjecture that the expected geometry-permutation-weighted speciality varies with distribution history size
$\operatorname{ex}\left(z_{E}\right)\left(\left\{\left(E^{\prime}, \operatorname{speciality}\left(U_{E}, X_{E}\right)\left(P_{U, X, H_{E}}\right)\right): E^{\prime} \in \mathcal{A}_{z_{E}, t}, E=\operatorname{trim}\left(E^{\prime}\right)\right\}\right) \sim z_{E}$
where $U_{E}=\operatorname{implied}(E)$ and $X_{E}=\operatorname{ids}(\operatorname{history}(E))$.
That is, conjecture that as the size of the non-trivially ideal distribution histogram, $E$, increases, the corresponding historically distributed history probability function, $P_{U, X, H_{E}}$, tends to have increasing degree of structure with respect to the specialising coder, $C_{\mathrm{P}, \mathrm{m}, \mathrm{G}, \mathrm{T}, \mathrm{H}}$.

## A. 13 Computers

The set of computers, computers, is a type class that formalises computation time and representation space. Define the application of a computer, apply $\in$ computers $\rightarrow(\mathcal{X} \rightarrow \mathcal{Y})$, where $\mathcal{X}$ and $\mathcal{Y}$ are universal sets. Define the domain of the application of a computer, domain $\in$ computers $\rightarrow \mathrm{P}(\mathcal{X})$, and the range of the application of a computer, range $\in$ computers $\rightarrow \mathrm{P}(\mathcal{Y})$, such that

$$
\forall I \in \operatorname{computers}(\operatorname{apply}(I) \in \operatorname{domain}(I) \rightarrow \operatorname{range}(I))
$$

and

$$
\forall I \in \operatorname{computers}(\operatorname{dom}(\operatorname{apply}(I))=\operatorname{domain}(I))
$$

Define the shorthand $I^{*}:=\operatorname{apply}(I)$. The definition here of the application is left total, but not necessarily right total, so the application of a subsequent computer, $J^{*}\left(I^{*}(x)\right)$, requires the domain of $J$ to be a superset of the range of $I$, domain $(J) \supseteq \operatorname{range}(I)$. In the cases where the range of $I$ is a subset of its own domain, range $(I) \subseteq$ domain $(I)$, the computer $I$ may be applied to itself recursively, $I^{*} \circ I^{*}, I^{*} \circ I^{*} \circ I^{*}$, and so on.

An inverse computer $J \in$ computer of a computer $I$ is such that domain $(J)=$ range $(I)$, range $(J)=\operatorname{domain}(I)$ and $\forall x \in \operatorname{domain}(I)\left(J^{*}\left(I^{*}(x)\right)=x\right)$. Note that if an inverse computer $J$ exists, the computer I must be right total.

The computation or application time is defined as time $\in$ computers $\rightarrow$ $\left(\mathcal{X} \rightarrow \mathbf{N}_{>0}\right)$. Define the shorthand $I^{\mathrm{t}}:=\operatorname{time}(I)$. If the time of some given argument $x$ is finite, $I^{\mathrm{t}}(x)<\infty$, then $x$ is computable.

Note that the range is available to the compute time calculation via apply. If it is necessary to perform the application in order to calculate the computation time then the computation is non-deterministic and the time of the time calculation itself must be greater than the application time. For example, let $I, J \in$ computers, domain $(J)=\{I\} \times$ domain $(I)$, range $(J)=\mathbf{N}_{>0}$ and $\forall x \in \operatorname{domain}(I)(\operatorname{apply}(J)((I, x))=\operatorname{time}(I)(x))$. Let $I$ and $J$ be such that time $(J)$ depends on apply $(I)$, then $\forall x \in \operatorname{domain}(I)(\operatorname{time}(J)((I, x))>$ time $(I)(x))$.

The representation space is defined as space $\in$ computers $\rightarrow\left(\mathcal{X} \rightarrow \ln \mathbf{N}_{>0}\right)$. Define the shorthand $I^{\mathrm{s}}:=\operatorname{space}(I)$. If the space of some given argument $x$ is finite, $I^{\mathrm{s}}(x)<\infty$, then $x$ is representable.

A computer is tractable if both the time complexity and the space complexity is no worse than polynomial with respect to any underlying variable.

A possible definition of a computer could be in terms of a Turing Machine. For example, the tuple (in, out, step, term) of (i) an input function, in $\in \mathcal{X} \rightarrow$ $\mathbf{N}$, (ii) an output function, out $\in \mathbf{N} \rightarrow \mathcal{X}$, (iii) a transition function, step $\in$ $\mathbf{N} \rightarrow \mathbf{N}$, and (iv) a set of terminating states, term $\subset \mathbf{N}$. Let $L \in \mathcal{L}(\mathbf{N}) \backslash\{\emptyset\}$ be the list of the states such that $L_{1}=\operatorname{in}(x), \forall i \in\{1 \ldots t-1\}\left(L_{i} \notin\right.$ term $\wedge$ $\left.L_{i+1}=\operatorname{step}\left(L_{i}\right)\right)$ and $L_{t} \in \operatorname{term}$ where $t=|L|$. Then $I^{*}(x)=\operatorname{out}\left(L_{t}\right)$ and the time to compute $x$ is the number of states in the sequence, $I^{t}(x)=t$. The time cannot be zero, because the conversion from and to the representation, $\mathbf{N}$, is treated as a step. The space to represent $x$ is $\ln (\operatorname{maxr}(L)+1)$. The
space is zero if $L=\{(1,0)\}$.
Define $I_{+}=$adder $\in$ computers such that domain $\left(I_{+}\right)=\mathbf{Q} \times \mathbf{Q}$ and range $\left(I_{+}\right)=\mathbf{Q}$, such that

$$
\forall(a, b) \in \operatorname{domain}\left(I_{+}\right)\left(\operatorname{apply}\left(I_{+}\right)((a, b))=a+b\right)
$$

The adder is also constrained such that the self addition of zero has least time, $\forall q_{1}, q_{2} \in \operatorname{domain}\left(I_{+}\right)\left(I_{+}^{\mathrm{t}}\left(\left(q_{1}, q_{2}\right)\right) \geq I_{+}^{\mathrm{t}}((0,0))\right.$.

Define $I_{\times}=$multiplier $\in$ computers such that domain $\left(I_{\times}\right)=\mathbf{Q} \times \mathbf{Q}$ and range $\left(I_{\times}\right)=\mathbf{Q}$, such that

$$
\forall(a, b) \in \operatorname{domain}\left(I_{\times}\right)\left(\operatorname{apply}\left(I_{\times}\right)((a, b))=a b\right)
$$

The multiplier is also constrained such that the self multiplication of one has least time, $\forall q_{1}, q_{2} \in \operatorname{domain}\left(I_{\times}\right)\left(I_{\times}^{\mathrm{t}}\left(\left(q_{1}, q_{2}\right)\right) \geq I_{\times}^{\mathrm{t}}((1,1))\right.$.

Define $I_{0}=$ resetter $\in$ computers such that domain $\left(I_{0}\right)=\operatorname{range}\left(I_{0}\right)=\mathbf{Q}$, such that

$$
\forall a \in \operatorname{domain}\left(I_{0}\right)\left(\operatorname{apply}\left(I_{0}\right)(a)=0\right)
$$

Define $I_{\mathrm{L}, \mathrm{s}}=$ listSetter $(X) \in$ computers such that domain $\left(I_{\mathrm{L}, \mathrm{s}}\right)=\{(L,(i, x))$ : $L \in \mathcal{L}(X), i \in\{1 \ldots|L|\}, x \in X\}$, range $\left(I_{\mathrm{L}, \mathrm{s}}\right)=\mathcal{L}(X)$, such that

$$
\forall(L,(i, x)) \in \operatorname{domain}\left(I_{\mathrm{L}, \mathrm{~s}}\right)\left(\operatorname{apply}\left(I_{\mathrm{L}, \mathrm{~s}}\right)((L,(i, x)))=L \backslash\left\{\left(i, L_{i}\right)\right\} \cup\{(i, x)\}\right)
$$

Define $I_{\mathrm{L}, \mathrm{g}}=$ listGetter $(X) \in$ computers such that domain $\left(I_{\mathrm{L}, \mathrm{g}}\right)=\{(L, i)$ : $L \in \mathcal{L}(X), i \in\{1 \ldots|L|\}\}$, range $\left(I_{\mathrm{L}, \mathrm{g}}\right)=X$, such that

$$
\forall(L, i) \in \operatorname{domain}\left(I_{\mathrm{L}, \mathrm{~g}}\right)\left(\operatorname{apply}\left(I_{\mathrm{L}, \mathrm{~g}}\right)((L, i))=L_{i}\right)
$$

The time complexity of the list get and set operations is constant

$$
\exists m \in \mathbf{N}_{>0}\left(I_{\mathrm{L}, \mathrm{~s}}^{\mathrm{t}} \in \mathrm{O}\left(\text { domain }\left(I_{\mathrm{L}, \mathrm{~s}}\right) \times\{1\}, m\right)\right)
$$

and

$$
\exists m \in \mathbf{N}_{>0}\left(I_{\mathrm{L}, \mathrm{~g}}^{\mathrm{t}} \in \mathrm{O}\left(\operatorname{domain}\left(I_{\mathrm{L}, \mathrm{~g}}\right) \times\{1\}, m\right)\right)
$$

The space complexity of the list get and set operations varies as the length of the list, assuming the space of the elements of the list is constant
$\exists m \in \mathbf{N}_{>0}\left(I_{\mathrm{L}, \mathrm{s}}^{\mathrm{s}} \in \mathrm{O}\left(\left\{((L,(i, x)), n):(L,(i, x)) \in \operatorname{domain}\left(I_{\mathrm{L}, \mathrm{s}}\right), n=|L|\right\}, m\right)\right)$ and

$$
\exists m \in \mathbf{N}_{>0}\left(I_{\mathrm{L}, \mathrm{~g}}^{\mathrm{s}} \in \mathrm{O}\left(\left(\{((L, i), n)):(L, i) \in \operatorname{domain}\left(I_{\mathrm{L}, \mathrm{~g}}\right), n=|L|\right\}, m\right)\right)
$$

Define $I_{\mathrm{B}, \mathrm{s}}=$ mapBinarySetter $(X) \in$ computers such that domain $\left(I_{\mathrm{B}, \mathrm{s}}\right)=$ $\{(B,(i, x)): B \in \mathcal{B}(X), i \in \operatorname{domain}(B), x \in X\}$, range $\left(I_{\mathrm{B}, \mathrm{s}}\right)=\mathcal{B}(X)$, such that

$$
\forall(B,(i, x)) \in \operatorname{domain}\left(I_{\mathrm{B}, \mathrm{~s}}\right)\left((i, x) \in \operatorname{function}\left(\operatorname{apply}\left(I_{\mathrm{B}, \mathrm{~s}}\right)((B,(i, x)))\right)\right)
$$

Define $I_{\mathrm{B}, \mathrm{g}}=$ mapBinaryGetter $(X) \in$ computers such that domain $\left(I_{\mathrm{B}, \mathrm{g}}\right)=$ $\{(B, i): B \in \mathcal{B}(X), i \in \operatorname{domain}(B)\}$, range $\left(I_{\mathrm{B}, \mathrm{g}}\right)=X$, such that

$$
\forall(B, i) \in \operatorname{domain}\left(I_{\mathrm{B}, \mathrm{~g}}\right)\left(\operatorname{apply}\left(I_{\mathrm{B}, \mathrm{~g}}\right)((B, i))=\operatorname{find}(B, i)\right)
$$

The time complexity of the binary map accessors is that of the find operation which is $\ln n$ where $n=\mid$ function $(B) \mid$
$\exists m \in \mathbf{N}_{>0}$

$$
\left(I_{\mathrm{B}, \mathrm{~s}}^{\mathrm{t}} \in \mathrm{O}\left(\left\{((B,(i, x)), \ln n):(B,(i, x)) \in \operatorname{domain}\left(I_{\mathrm{B}, \mathrm{~s}}\right), n=|\mathrm{f}(B)|\right\}, m\right)\right)
$$

and

$$
\begin{aligned}
& \exists m \in \mathbf{N}_{>0} \\
& \quad\left(I_{\mathrm{B}, \mathrm{~g}}^{\mathrm{t}} \in \mathrm{O}\left(\left\{((B, i), \ln n):(B, i) \in \operatorname{domain}\left(I_{\mathrm{B}, \mathrm{~g}}\right), n=|\mathrm{f}(B)|\right\}, m\right)\right)
\end{aligned}
$$

where $\mathrm{f}=$ function.
The space complexity of the binary map accessors is $n \ln n$ where $n=$ |function( $B$ )|

$$
\begin{aligned}
& \exists m \in \mathbf{N}_{>0} \\
& \quad\left(I_{\mathrm{B}, \mathrm{~s}}^{\mathrm{t}} \in \mathrm{O}\left(\left\{((B,(i, x)), n \ln n):(B,(i, x)) \in \operatorname{domain}\left(I_{\mathrm{B}, \mathrm{~s}}\right), n=|\mathrm{f}(B)|\right\}, m\right)\right)
\end{aligned}
$$

and

$$
\begin{aligned}
& \exists m \in \mathbf{N}_{>0} \\
& \quad\left(I_{\mathrm{B}, \mathrm{~g}}^{\mathrm{t}} \in \mathrm{O}\left(\left\{((B, i), n \ln n):(B, i) \in \operatorname{domain}\left(I_{\mathrm{B}, \mathrm{~g}}\right), n=|\mathrm{f}(B)|\right\}, m\right)\right)
\end{aligned}
$$

Set operations on a domain $X \subset \mathcal{X}$ can be implemented in a binary map given some coder $C \in$ coders such that domain $(C)=X$. For example, define $I_{\mathrm{B}, \mathrm{S}, \mathrm{i}}=\operatorname{setBinaryInserter}(C) \in$ computers such that range $\left(I_{\mathrm{B}, \mathrm{S}, \mathrm{i}}\right)=\{B: B \in$ $\mathcal{B}(X)$, flip $($ function $(B)) \subseteq E\}$ and domain $\left(I_{\mathrm{B}, \mathrm{S}, \mathrm{i}}\right)=\operatorname{range}\left(I_{\mathrm{B}, \mathrm{S}, \mathrm{i}}\right) \times X$ where $(E, \cdot, \cdot)=\operatorname{def}(C)$

$$
\forall(B, x) \in \operatorname{domain}\left(I_{\mathrm{B}, \mathrm{~S}, \mathrm{i}}\right)\left(\left(E_{x}, x\right) \in \text { function }\left(\operatorname{apply}\left(I_{\mathrm{B}, \mathrm{~S}, \mathrm{i}}\right)((B, x))\right)\right)
$$

Again, the time complexity is that of the find function, $\ln n$, assuming that the encode opertion has constant time complexity. The space complexity is also that of the binary map accessors, $n \ln n$.

Given a coder $C \in$ coders such that domain $(C)=X$ nested in coder $C^{\prime} \in$ coders having a domain which is the powerset, domain $\left(C^{\prime}\right)=\mathrm{P}(X)$, the powersetter can be defined $I_{\mathrm{B}, \mathrm{S}, \mathrm{P}}=\operatorname{setBinaryPowersetter}\left(C^{\prime}, C\right) \in$ computers such that domain $\left(I_{\mathrm{B}, \mathrm{S}, \mathrm{P}}\right)=\{B: B \in \mathcal{B}(X)$, flip(function $\left.(B)) \subseteq E\right\}$ and range $\left(I_{\mathrm{B}, \mathrm{S}, \mathrm{P}}\right)=\left\{B: B \in \mathcal{B}(X)\right.$, flip $($ function $\left.(B)) \subseteq E^{\prime}\right\}$ where $(E, \cdot, \cdot)=$ $\operatorname{def}(C)$ and $\left(E^{\prime}, \cdot, \cdot\right)=\operatorname{def}\left(C^{\prime}\right)$

$$
\begin{aligned}
& \forall B \in \operatorname{domain}\left(I_{\mathrm{B}, \mathrm{~S}, \mathrm{P}}\right) \\
& \quad\left(\bigcup\left\{\operatorname{range}(Q): Q \in \operatorname{range}\left(\operatorname{apply}\left(I_{\mathrm{B}, \mathrm{~S}, \mathrm{P}}\right)(B)\right)\right\}=\mathrm{P}(\operatorname{range}(B))\right)
\end{aligned}
$$

In other words, the application $I_{\mathrm{B}, \mathrm{S}, \mathrm{P}}^{*}(B)$ on a binary set $B$ of set $Y \subseteq X$, range $(B)=Y$, is equivalent to computing $\mathrm{P}(Y)$. Implementation of the powersetter can be done by folding over the given binary set with the current accumulated powerset, creating a singleton and adding the current element to each of the sets in the current powerset. The list of cardinalities of the powersets is such that $L_{i+1}=2 L_{i}+1$ where $L \in \mathcal{L}(\mathbf{N})$. Thus $\operatorname{sum}(L)<n 2^{n}$ where $n=|L|=|Y|$. The time complexity of the powersetter is $n 2^{n} \ln n$.

Similarly, given $C^{\prime \prime} \in$ coders having a domain which is the powerset of the powerset, domain $\left(C^{\prime \prime}\right)=\mathrm{P}(\mathrm{P}(X))$, the partitioner can be defined $I_{\mathrm{B}, \mathrm{S}, \mathrm{B}}=$ setBinaryPartitioner $\left(C^{\prime \prime}, C^{\prime}, C\right) \in$ computers which is such that the application $I_{\mathrm{B}, \mathrm{S}, \mathrm{B}}^{*}(B)$ on a binary set $B$ of set $Y \subseteq X$, range $(B)=Y$, is equivalent to computing $\mathrm{B}(Y)$. Implementation of the partitioner can be done by folding over the given binary set with the current accumulated set of partitions. The list of cardinalities of the sets of partitions is such that $L_{i+1}=(i+1) L_{i}$ where $L \in \mathcal{L}(\mathbf{N})$. Thus $\operatorname{sum}(L)<n n!$ where $n=|L|=|Y|$. The time complexity of the partitioner is $n n!\ln n$.

Contrast the computation of the natural number binary map setter to the poset binary map setter. Define $I_{\mathrm{B}, \mathrm{P}, \mathrm{s}}=$ mapBinaryPosetSetter $\left(I_{ \pm}, Y, X\right) \in$ computers such that

$$
\operatorname{domain}\left(I_{\mathrm{B}, \mathrm{P}, \mathrm{~s}}\right)=\{(B,(y, x)): B \in \operatorname{mapBinaryPosets}(Y, X), y \in Y, x \in X\}
$$

and range $\left(I_{\mathrm{B}, \mathrm{P}, \mathrm{s}}\right)=\operatorname{mapBinaryPosets}(Y, X)$, such that

$$
\forall(B,(y, x)) \in \operatorname{domain}\left(I_{\mathrm{B}, \mathrm{P}, \mathrm{~s}}\right) \quad\left((y, x) \in \text { function }\left(\operatorname{apply}\left(I_{\mathrm{B}, \mathrm{P}, \mathrm{~s}}\right)((B,(y, x)))\right)\right)
$$

The find computation of the poset binary map setter is implemented with a nested computer, comparator $I_{ \pm} \in$ computers, which is such that domain $\left(I_{ \pm}\right)=$ $Y \times Y$, range $\left(I_{ \pm}\right)=\{-1,0,1\}$, and $\forall y_{1}, y_{2} \in Y\left(\left(y_{1}<y_{2} \Longrightarrow I_{ \pm}^{*}\left(\left(y_{1}, y_{2}\right)\right)=\right.\right.$ $\left.-1) \wedge\left(y_{1}=y_{2} \Longrightarrow I_{ \pm}^{*}\left(\left(y_{1}, y_{2}\right)\right)=0\right) \wedge\left(y_{1}>y_{2} \Longrightarrow I_{ \pm}^{*}\left(\left(y_{1}, y_{2}\right)\right)=1\right)\right)$.

Define $I_{\mathrm{B}, \mathrm{P}, \mathrm{g}}=$ mapBinaryPosetGetter $\left(I_{ \pm}, Y, X\right) \in$ computers such that domain $\left(I_{\mathrm{B}, \mathrm{P}, \mathrm{g}}\right)=\{(B, y): B \in \operatorname{mapBinaryPosets}(Y, X), y \in \operatorname{domain}(B)\}$, range $\left(I_{\mathrm{B}, \mathrm{P}, \mathrm{g}}\right)=X$, such that

$$
\forall(B, y) \in \operatorname{domain}\left(I_{\mathrm{B}, \mathrm{P}, \mathrm{~g}}\right)\left(\operatorname{apply}\left(I_{\mathrm{B}, \mathrm{P}, \mathrm{~g}}\right)((B, y))=\operatorname{find}(B, y)\right)
$$

The time of the poset binary map getter is at least that of the time of the self comparison in the comparator of the given index, $I_{\mathrm{B}, \mathrm{P}, \mathrm{g}}^{\mathrm{t}}((B, y))>$ $I_{ \pm}^{\mathrm{t}}((y, y))$. If it is the case that self comparison has the greatest time, $\forall\left(y_{1}, y_{2}\right) \in Y\left(I_{ \pm}^{\mathrm{t}}\left(\left(y_{1}, y_{1}\right)\right) \geq I_{ \pm}^{\mathrm{t}}\left(\left(y_{1}, y_{2}\right)\right)\right)$, then the time complexity of the poset binary map accessors is that of the find operation, which is $\ln n$ where $n=\mid$ function $(B) \mid$, times the self comparison time of the comparator

$$
\begin{aligned}
& \exists m \in \mathbf{N}_{>0}\left(I _ { \mathrm { B } , \mathrm { P } , \mathrm { s } } ^ { \mathrm { t } } \in \mathrm { O } \left(\left\{\left((B,(y, x)), I_{ \pm}^{\mathrm{t}}((y, y)) \times \ln n\right):\right.\right.\right. \\
& \left.\left.\left.\quad(B,(y, x))) \in \operatorname{domain}\left(I_{\mathrm{B}, \mathrm{P}, \mathrm{~s}}\right), n=\mid \text { function }(B) \mid\right\}, m\right)\right)
\end{aligned}
$$

and

$$
\begin{aligned}
& \exists m \in \mathbf{N}_{>0}\left(I _ { \mathrm { B } , \mathrm { P } , \mathrm { g } } ^ { \mathrm { t } } \in \mathrm { O } \left(\left\{\left((B, y), I_{ \pm}^{\mathrm{t}}((y, y)) \times \ln n\right):\right.\right.\right. \\
& \left.\left.\left.\quad(B, y) \in \operatorname{domain}\left(I_{\mathrm{B}, \mathrm{P}, \mathrm{~g}}\right), n=\mid \text { function }(B) \mid\right\}, m\right)\right)
\end{aligned}
$$

## A. 14 Search and optimisation

Searchers, searchers $(\mathcal{X})$, encapsulate partial or complete traversal of some search set by neighbourhood. There are two sub-types of searcher, (i) tree searchers

$$
\operatorname{searchTreers}(\mathcal{X}) \subset \operatorname{searchers}(\mathcal{X})
$$

and (ii) list searchers

$$
\operatorname{searchListers}(\mathcal{X}) \subset \operatorname{searchers}(\mathcal{X})
$$

Both types have (i) some set $X \subset \mathcal{X}$ to search, (ii) an initial subset of the search set $R \subseteq X$, and (iii) a total neighbourhood function on the search set. Tree searchers have a total neighbourhood function having a domain equal to the search set and a range of subsets of the search set, $N \in X: \rightarrow \mathrm{P}(X)$ where $\operatorname{dom}(N)=X$. List searchers have a neighbourhood function having a domain equal to the powerset of the search set and a range of subsets of
the search set, $P \in \mathrm{P}(X): \rightarrow \mathrm{P}(X)$ where $\operatorname{dom}(P)=\mathrm{P}(X)$. Define the constructor of a tree searcher as
searchTreer $\in$

$$
\mathrm{P}(\mathcal{X}) \times(\mathcal{X} \rightarrow \mathrm{P}(\mathcal{X})) \times \mathrm{P}(\mathcal{X}) \rightarrow \text { searchTreers }(\mathcal{X})
$$

such that searchTreer $(X, N, R) \in \operatorname{searchTreers}(X) \subset \operatorname{searchers}(X)$.
Define the constructor of a list searcher as
searchLister $\in$

$$
\mathrm{P}(\mathcal{X}) \times(\mathrm{P}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X})) \times \mathrm{P}(\mathcal{X}) \rightarrow \operatorname{searchListers}(\mathcal{X})
$$

such that searchLister $(X, P, R) \in \operatorname{searchListers}(X) \subset \operatorname{searchers}(X)$.

Given a tree searcher $Z=\operatorname{search} \operatorname{Treer}(X, N, R)$ the function tree returns a tree of elements of the search set, $\operatorname{tree}(Z) \in \operatorname{trees}(X)$, of all possible noncircular partial or complete traverses of $X$ from $R$ via successive neighbouring elements of $X$. Define

$$
\text { tree } \in \operatorname{searchTreers}(\mathcal{X}) \rightarrow \operatorname{trees}(\mathcal{X})
$$

as $\operatorname{tree}(Z):=\operatorname{ts}(R, \emptyset)$ where searchTreer $(X, N, R)=Z$ and $\mathrm{ts} \in \mathrm{P}(\mathcal{X}) \times$ $\mathrm{P}(\mathcal{X}) \rightarrow \operatorname{trees}(\mathcal{X})$ is defined

$$
\operatorname{ts}(Y, J):=\{(y, \operatorname{ts}(N(y) \backslash(J \cup\{y\}), J \cup\{y\})): y \in Y\}
$$

Define elements $\in \operatorname{searchTreers}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X})$ as

$$
\operatorname{elements}(Z):=\operatorname{elements}(\operatorname{tree}(Z))
$$

The elements of the search tree $T=\operatorname{tree}(Z)$ form a subset of the search set, elements $(Z)=\operatorname{elements}(T) \subseteq X$. If the elements equals the search set, elements $(Z)=X$, then the search is said to be a complete traversal. Otherwise the search is a partial traversal, elements $(Z) \neq X$. The roots of the search tree equal the initial subset, $\operatorname{roots}(T)=R$. If the search set, $X$, is finite then the neighbourhood function, $N$, and the initial subset, $R$, are finite, and hence the search tree is finite, $|\operatorname{leaves}(T)|<\infty, \operatorname{depth}(T)<\infty$ and $\mid$ elements $(T) \mid<\infty$.

The paths of the trees exclude circularities and thus contain each element no more than once, $\forall L \in \operatorname{paths}(T)(|\operatorname{set}(L)|=|L|)$. The first element of
each path is in the subset $R, \forall L \in \operatorname{paths}(T)\left(L_{1} \in R\right)$. The successive element of each element in a path must be in the neighbourhood of the element excluding the elements of the path up to that point, $\forall L \in \operatorname{paths}(T) \forall i \in$ $\{1 \ldots|L|-1\}\left(L_{i+1} \in N\left(L_{i}\right) \backslash \operatorname{set}\left(L_{\{1 \ldots i\}}\right)\right)$.

In the case where the tree neighbourhood function returns $X$ for all elements and the initial set is $X, Z=\operatorname{searchTreer}(X, X \times\{X\}, X)$, then the paths of the search form the set of all permutations, $\mid$ paths $(\operatorname{tree}(Z))|=|X|$ !. In the case where the neighbourhood function returns the empty set, $Z=$ search $\operatorname{Treer}(X, X \times\{\emptyset\}, X)$, then the search tree nodes equals the roots, tree $(Z)=X \times\{\emptyset\}$, and the cardinality of the paths equals that of the initial set, $\mid$ paths $(\operatorname{tree}(Z))|=|X|$.

An example of a tree neighbourhood function returns decremented cardinality parent partitions given a partition of some set $J, X=\mathrm{B}(J)$, and $N=$ $\{(Q,\{P: P \in X, \operatorname{parent}(P, Q),|P|=|Q|-1\}): Q \in X\} \in X: \rightarrow \mathrm{P}(X)$.

Given a list searcher $Z=\operatorname{searchLister}(X, P, R)$ the function list returns a list of subsets of the search set, $\operatorname{list}(Z) \in \mathcal{L}(\mathrm{P}(X))$. The list, list $(Z)$, is a noncircular partial or complete traverse of $X$ from $R$ via successive neighbouring subsets of $X$. Define

$$
\text { list } \in \operatorname{searchListers}(\mathcal{X}) \rightarrow \mathcal{L}(\mathrm{P}(X))
$$

as $\operatorname{list}(Z):=\operatorname{list}(\operatorname{ls}(R, \emptyset))$ where $\operatorname{searchLister}(X, P, R)=Z$ and $\mathrm{ls} \in \mathrm{P}(\mathcal{X}) \times$ $\mathrm{P}(\mathcal{X}) \rightarrow \mathcal{K}(\mathrm{P}(\mathcal{X}))$ is defined

$$
\begin{aligned}
\operatorname{ls}(Y, K) & :=(Y, \operatorname{ls}(P(Y) \backslash(K \cup Y), K \cup Y)) \\
\operatorname{ls}(\emptyset, \cdot) & :=\emptyset
\end{aligned}
$$

Define elements $\in \operatorname{searchListers}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X})$ as

$$
\operatorname{elements}(Z):=\bigcup \operatorname{set}(\operatorname{list}(Z))
$$

The elements of the search list $L=\operatorname{list}(Z)$ form a subset of the search set, elements $(Z)=\bigcup \operatorname{set}(L) \subseteq X$. If the elements equals the search set, elements $(Z)=X$, then the search is said to be a complete traversal. Otherwise the search is a partial traversal, elements $(Z) \neq X$. The first element of the list is the initial subset, $L_{1}=R$. If the search set, $X$, is finite then the neighbourhood function, $P$, and the initial subset, $R$, are finite, and hence the search list is finite, $|L|<\infty$ and $|\operatorname{set}(L)|<\infty$.

The list excludes circularities and thus contains each element no more than once, $\forall i \in\{1 \ldots|L|-1\}\left(\bigcup \operatorname{set}\left(L_{\{1 \ldots i\}}\right) \cap L_{i+1}=\emptyset\right)$.

In the case where the initial set is $X, Z=\operatorname{searchLister}(X, P, X)$, then the list is a singleton, list $(Z)=\{(1, X)\}$, whatever the neighbourhood function, $P$. In the case where the list neighbourhood function returns $X$ for all subsets of the search set, $Z=\operatorname{searchLister}(X, \mathrm{P}(X) \times\{X\}, R)$, and the initial set is a proper subset of the search set, $R \neq X$, then the list has a length of two, $\operatorname{list}(Z)=\{(1, R),(2, X \backslash R)\}$. In the case where the neighbourhood function returns the empty set, $Z=\operatorname{searchLister}(X, \mathrm{P}(X) \times\{\emptyset\}, R)$, then the list is a singleton, $\operatorname{list}(Z)=\{(1, R)\}$.

The set of optimisers optimisers $(\mathcal{X})$ is a subset of searchers,

$$
\operatorname{optimisers}(\mathcal{X}) \subset \operatorname{searchers}(\mathcal{X})
$$

which constrain the application of the neighbourhood function by post-applying an inclusion function. On a search set $X$ the inclusion function $I \in \mathrm{P}(X): \rightarrow$ $\mathrm{P}(X)$ returns a subset of the argument, $\forall Y \subseteq X(I(Y) \subseteq Y)$. Given an extensive tree neighbourhood function $N \in X: \rightarrow \mathrm{P}(X)$ the application of the inclusion function results in a new neighbourhood function $M=\{(x, I(N(x))): x \in X\} \in X: \rightarrow \mathrm{P}(X)$, so that $\forall x \in X(M(x) \subseteq N(x))$. Given an extensive list neighbourhood function $P \in \mathrm{P}(X): \rightarrow \mathrm{P}(X)$ the application of the inclusion function results in a new neighbourhood function $Q=\{(Y, I(P(Y))): Y \subseteq X\} \in \mathrm{P}(X): \rightarrow \mathrm{P}(X)$, so that $\forall Y \subseteq X(Q(Y) \subseteq$ $P(Y))$.

Consider two sub-types of optimisers, (i) tree optimisers

$$
\operatorname{optimise} \operatorname{Treer}(\mathcal{X}) \subset \operatorname{optimisers}(\mathcal{X})
$$

and (ii) list optimisers

$$
\operatorname{optimiseListers}(\mathcal{X}) \subset \operatorname{optimisers}(\mathcal{X})
$$

Define the constructor of a tree optimiser
optimiseTreer $\in$

$$
\mathrm{P}(\mathcal{X}) \times(\mathcal{X} \rightarrow \mathrm{P}(\mathcal{X})) \times(\mathrm{P}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X})) \times \mathrm{P}(\mathcal{X}) \rightarrow \text { optimiseTreers }(\mathcal{X})
$$

such that optimiseTreer $(X, N, I, R) \in \operatorname{optimise} \operatorname{Tr} e e r s(X) \subset \operatorname{optimisers}(X)$.

Define the constructor of a list optimiser
optimiseLister $\in$
$\mathrm{P}(\mathcal{X}) \times(\mathrm{P}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X})) \times(\mathrm{P}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X})) \times \mathrm{P}(\mathcal{X}) \rightarrow$ optimiseListers $(\mathcal{X})$
such that optimiseLister $(X, P, I, R) \in \operatorname{optimiseListers}(X) \subset \operatorname{optimisers}(X)$.
Re-define the tree optimiser tree function

$$
\operatorname{tree} \in \operatorname{optimise} \operatorname{Treers}(\mathcal{X}) \rightarrow \operatorname{trees}(\mathcal{X})
$$

as tree $(Z):=\operatorname{tree}($ search $\operatorname{Treer}(X, M, I(R)))$ where optimiseTreer $(X, N, I, R)=$ $Z$ and $M=\{(x, I(N(x))): x \in X\}$.

Re-define the list optimiser list function

$$
\text { list } \in \operatorname{optimiseListers}(\mathcal{X}) \rightarrow \mathcal{L}(\mathrm{P}(X))
$$

as list $(Z):=\operatorname{list}(\operatorname{searchLister}(X, Q, I(R)))$ where $\operatorname{optimiseLister}(X, P, I, R)=$ $Z$ and $Q=\{(Y, I(P(Y))): Y \subseteq X\}$.

Define the tree optimiser searched set as the union of the extensive neighbourhoods searched $\in$ optimiseTreers $(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X})$ as

$$
\operatorname{searched}(Z):=\bigcup\{N(x): x \in \operatorname{elements}(Z)\} \cup R
$$

Define the list optimiser searched set as the union of the extensive neighbourhoods searched $\in$ optimiseListers $(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X})$ as

$$
\operatorname{searched}(Z):=\bigcup\{P(Y): Y \in \operatorname{set}(\operatorname{list}(Z))\} \cup R
$$

Define the traversable set as the elements of the search of the extensive neighbourhoods traversable $\in$ optimise $\operatorname{Treers}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X})$ as

$$
\operatorname{traversable}(Z):=\operatorname{elements}(\operatorname{searchTreer}(X, N, R))
$$

and traversable $\in \operatorname{optimiseListers}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X})$ as

$$
\operatorname{traversable}(Z):=\operatorname{elements}(\operatorname{searchLister}(X, P, R))
$$

An optimiser is potentially traversable if traversable $(Z)=X$.
Thus, for all $Z \in \operatorname{optimisers}(X)$

$$
I(\operatorname{elements}(Z)) \subseteq \operatorname{elements}(Z) \subseteq \operatorname{searched}(Z) \subseteq \operatorname{traversable}(Z) \subseteq X
$$

Consider a variation in which the optimisers do not apply the inclusion function to the initial set. Consider two sub-types of optimisers, (i) tree tail optimisers

$$
\operatorname{optimiseTailTreers}(\mathcal{X}) \subset \operatorname{optimisers}(\mathcal{X})
$$

and (ii) list tail optimisers

$$
\operatorname{optimiseTailListers}(\mathcal{X}) \subset \operatorname{optimisers}(\mathcal{X})
$$

Define the constructor of a tree tail optimiser
optimiseTailTreer $\in$

$$
\mathrm{P}(\mathcal{X}) \times(\mathcal{X} \rightarrow \mathrm{P}(\mathcal{X})) \times(\mathrm{P}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X})) \times \mathrm{P}(\mathcal{X}) \rightarrow \text { optimiseTailTreers }(\mathcal{X})
$$

Define the constructor of a list tail optimiser
optimiseTailLister $\in$

$$
\mathrm{P}(\mathcal{X}) \times(\mathrm{P}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X})) \times(\mathrm{P}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X})) \times \mathrm{P}(\mathcal{X}) \rightarrow \text { optimiseTailListers }(\mathcal{X})
$$

Re-define the tree tail optimiser tree function

$$
\text { tree } \in \operatorname{optimise} \text { TailTreers }(\mathcal{X}) \rightarrow \operatorname{trees}(\mathcal{X})
$$

as tree $(Z):=\operatorname{tree}($ searchTreer $(X, M, R))$ where optimiseTailTreer $(X, N, I, R)=$ $Z$ and $M=\{(x, I(N(x))): x \in X\}$.

Re-define the list tail optimiser list function

$$
\text { list } \in \operatorname{optimise} \text { TailListers }(\mathcal{X}) \rightarrow \mathcal{L}(\mathrm{P}(X))
$$

as list $(Z):=\operatorname{list}(\operatorname{searchLister}(X, Q, R))$ where optimiseTailLister $(X, P, I, R)=$ $Z$ and $Q=\{(Y, I(P(Y))): Y \subseteq X\}$.

Consider the optimisation of some real-valued total function on the search set $F \in X: \rightarrow \mathbf{R}$. In particular, consider the maximisation inclusion function, $I=\{(Y, \operatorname{maxd}(\{(y, F(y)): y \in Y\})): Y \subseteq X\}$, applied to some tree neighbourhood function $N \in X: \rightarrow \mathrm{P}(X)$. The true maximum value is $\operatorname{maxr}(\{(y, F(y)): y \in \operatorname{dom}(F)\})$ and the optimised maximum value from initial set $R$ of optimiser $Z=$ optimiseTreer $(X, N, I, R)$ is $\operatorname{maxr}(\{(y, F(y))$ : $y \in \operatorname{elements}(Z)\})$.

Computationally it is inefficient to apply the function $F$ to each element of the searched neighbourhoods, $\operatorname{searched}(Z)$, and then to re-apply it to the
maximum subsets of these, elements $(Z)$. If the function $F$ is the search set rather than $X$ then the values, $\operatorname{ran}(F)$, are carried around in the search tree. Let $Z^{\prime}=\operatorname{optimiseTreer}\left(F, N^{\prime}, \max , R^{\prime}\right)$ where $N^{\prime}:=\{((x, r),\{(y, F(y)): y \in$ $N(x)\}):(x, r) \in F\}=\{((x, r)$, filter $(N(x), F)):(x, r) \in F\} \in F \rightarrow \mathrm{P}(F)$ and $R^{\prime}=\operatorname{filter}(R, F) \subseteq F$. The application of function $F$ need only be done once for the set dom (searched $\left.\left(Z^{\prime}\right)\right)$. The true maximum value is $\operatorname{maxr}(F)$ and the optimised maximum value is maxr (elements $\left(Z^{\prime}\right)$ ).

The maximisers maximisers $(\mathcal{X})$ is a subset of the optimisers,

$$
\operatorname{maximisers}(\mathcal{X}) \subset \text { optimisers }(\mathcal{X} \times \mathbf{R})
$$

which constrain the search set to real-valued functions.
Consider two sub-types of maximisers, (i) tree maximisers

$$
\operatorname{maximise} \operatorname{Treers}(\mathcal{X}) \subset \operatorname{maximisers}(\mathcal{X})
$$

and (ii) list maximisers

$$
\text { maximiseListers }(\mathcal{X}) \subset \text { maximisers }(\mathcal{X})
$$

Define the constructor of a tree maximiser
maximiseTreer $\in$

$$
\begin{aligned}
& (\mathcal{X} \rightarrow \mathbf{R}) \times((\mathcal{X} \times \mathbf{R}) \rightarrow(\mathcal{X} \rightarrow \mathbf{R})) \times((\mathcal{X} \rightarrow \mathbf{R}) \rightarrow(\mathcal{X} \rightarrow \mathbf{R})) \times(\mathcal{X} \rightarrow \mathbf{R}) \rightarrow \\
& \quad \text { maximiseTreers }(\mathcal{X})
\end{aligned}
$$

such that maximise $\operatorname{Treer}(X, N, I, R)=\operatorname{optimise} \operatorname{Treer}(X, N, I, R)$.
Define the constructor of a list maximiser
maximiseLister $\in$

$$
\begin{aligned}
& (\mathcal{X} \rightarrow \mathbf{R}) \times((\mathcal{X} \rightarrow \mathbf{R}) \rightarrow(\mathcal{X} \rightarrow \mathbf{R})) \times((\mathcal{X} \rightarrow \mathbf{R}) \rightarrow(\mathcal{X} \rightarrow \mathbf{R})) \times(\mathcal{X} \rightarrow \mathbf{R}) \rightarrow \\
& \quad \text { maximiseListers }(\mathcal{X})
\end{aligned}
$$

such that maximiseLister $(X, P, I, R)=\operatorname{optimiseLister}(X, P, I, R)$.
Consider two sub-types of maximisers, (i) tree tail maximisers

$$
\operatorname{maximise} \text { TailTreers }(\mathcal{X}) \subset \operatorname{maximisers}(\mathcal{X})
$$

and (ii) list tail maximisers

$$
\text { maximiseTailListers }(\mathcal{X}) \subset \text { maximisers }(\mathcal{X})
$$

Define the constructor of a tree tail maximiser
maximiseTailTreer $\in$

$$
\begin{aligned}
& (\mathcal{X} \rightarrow \mathbf{R}) \times((\mathcal{X} \times \mathbf{R}) \rightarrow(\mathcal{X} \rightarrow \mathbf{R})) \times((\mathcal{X} \rightarrow \mathbf{R}) \rightarrow(\mathcal{X} \rightarrow \mathbf{R})) \times(\mathcal{X} \rightarrow \mathbf{R}) \rightarrow \\
& \quad \text { maximiseTailTreers }(\mathcal{X})
\end{aligned}
$$

such that maximiseTailTreer $(X, N, I, R)=\operatorname{optimiseTailTreer}(X, N, I, R)$.
Define the constructor of a list tail maximiser
maximiseTailLister $\in$

$$
(\mathcal{X} \rightarrow \mathbf{R}) \times((\mathcal{X} \rightarrow \mathbf{R}) \rightarrow(\mathcal{X} \rightarrow \mathbf{R})) \times((\mathcal{X} \rightarrow \mathbf{R}) \rightarrow(\mathcal{X} \rightarrow \mathbf{R})) \times(\mathcal{X} \rightarrow \mathbf{R}) \rightarrow
$$ maximiseTailListers $(\mathcal{X})$

such that maximiseTailLister $(X, P, I, R)=\operatorname{optimiseTailLister}(X, P, I, R)$.
Define the constructor of a single maximiser which is a special case of a list maximiser with an empty neighbourhood function

$$
\begin{aligned}
& \text { maximiseSingler } \in \\
& \qquad(\mathcal{X} \rightarrow \mathbf{R}) \times((\mathcal{X} \rightarrow \mathbf{R}) \rightarrow(\mathcal{X} \rightarrow \mathbf{R})) \times(\mathcal{X} \rightarrow \mathbf{R}) \rightarrow \\
& \quad \text { maximiseListers }(\mathcal{X})
\end{aligned}
$$

such that maximiseSingler $(X, I, R)=\operatorname{optimiseLister}(X, \mathrm{P}(X) \times\{\emptyset\}, I, R)$.
Note that although the maximiser functions are defined in terms of the max aggregation function below, the inclusion function need not be equal to the $\max$ function. For example, $I=\operatorname{top}(n)$. The inclusion function could also terminate a search by returning the empty set.

The true value is the maximum value of the search set. Define true $\epsilon$ maximisers $(\mathcal{X}) \rightarrow \mathbf{R}$ as

$$
\operatorname{true}(Z):=\operatorname{maxr}(X)
$$

where maximise $\operatorname{Treer}(X, N, I, R)=Z$ or maximiseLister $(X, P, I, R)=Z$.
The optimum is the maximum value of the elements. Define optimum $\in$ maximisers $(\mathcal{X}) \rightarrow \mathbf{R}$ as

$$
\operatorname{optimum}(Z):=\operatorname{maxr}(\operatorname{elements}(Z))
$$

The optimum value is not necessarily a leaf value in the case of tree maximisers, $\operatorname{maxr}(\operatorname{leaves}(\operatorname{tree}(Z))) \leq \operatorname{optimum}(Z)$. Nor is the optimum value necessarily in the last element in the case of list maximisers, $\operatorname{maxr}\left(L_{|L|}\right) \leq$ $\operatorname{optimum}(Z)$ where $L=\operatorname{list}(Z)$.

The error value is the difference between the true value and the optimum value. Define error $\in \operatorname{maximisers}(\mathcal{X}) \rightarrow \mathbf{R}$

$$
\operatorname{error}(Z):=\operatorname{true}(Z)-\operatorname{optimum}(Z)
$$

The arbitrary value is the expected maximum of arbitrarily chosen subsets of the search set, $Y \subseteq X$, having cardinality equal to that of the searched set, $|Y|=|\operatorname{searched}(Z)|$. Define arbitrary $\in \operatorname{maximisers}(\mathcal{X}) \rightarrow \mathbf{R}$ as

$$
\operatorname{arbitrary}(Z):=\operatorname{average}(\{(Y, \operatorname{maxr}(Y)): Y \subseteq X,|Y|=|\operatorname{searched}(Z)|\})
$$

The difference between the optimum value and the arbitrary value is the gain. Define gain $\in$ maximisers $(\mathcal{X}) \rightarrow \mathbf{R}$ as

$$
\operatorname{gain}(Z):=\operatorname{optimum}(Z)-\operatorname{arbitrary}(Z)
$$

Note that the gain value is not necessarily positive. If the gain is zero then the maximiser is equivalent to a brute force search. The gain rate is the gain per cardinality of the searched set. Define rate $\in \operatorname{maximisers}(\mathcal{X}) \rightarrow \mathbf{R}$ as

$$
\operatorname{rate}(Z):=\operatorname{gain}(Z) /|\operatorname{searched}(Z)|
$$

The rate is undefined if the search set is empty, $\operatorname{searched}(Z)=\emptyset$.
The gain may be conjectured to depend on several factors. First, the gain is conjectured to increase with the difference between (i) the expected maximum of a neighbourhood and (ii) the expected maximum of an arbitrarily chosen neighbourhood. For tree maximisers that is

```
average \((\{(x, \operatorname{maxr}(N(x))): x \in X\})-\)
    average \((\{(x\), average \((\{(Y, \operatorname{maxr}(Y)): Y \subseteq X,|Y|=|N(x)|\})): x \in X\})\)
```

where maximise $\operatorname{Treer}(X, N, I, R)=Z$. Secondly, the optimisation gain is conjectured to increase with the difference between (i) the expected maximum of a neighbourhood per cardinality of the neighborhood and (ii) the expected maximum of an arbitrarily chosen neighbourhood per cardinality

$$
\begin{aligned}
& \text { average }(\{(x, \operatorname{maxr}(N(x)) /|N(x)|): x \in X\})- \\
& \quad \text { average }(\{(x, \text { average }(\{(Y, \operatorname{maxr}(Y) /|Y|): Y \subseteq X,|Y|=|N(x)|\})): x \in X\})
\end{aligned}
$$

Conjecture that smaller neighbourhoods require longer paths and deeper trees, and therefore more elements to traverse the searched set, searched $(Z)$. Similarly for list maximisers smaller neighbourhoods require a longer list, and therefore more elements to traverse the searched set.

Thirdly, the gain is conjectured to increase with the cardinality of the initial set, $|R|$. Larger initial sets allow more paths to be searched in a tree maximiser or larger subsets of the search set in a list maximiser, increasing the cardinality of the searched set, $|\operatorname{searched}(Z)|$.

## A. 15 Likelihood functions and Fisher information

Let the m-parameter n-dimensional parameterised probability density functions

$$
\operatorname{ppdfs}(m, n) \subset \mathbf{R}^{m} \rightarrow\left(\mathbf{R}^{n}: \rightarrow \mathbf{R}_{[0,1]}\right)
$$

be such that for all $P \in \operatorname{ppdfs}(m, n)$ and for all $\theta \in \operatorname{dom}(P)$, the probability density function, $P(\theta) \in \mathbf{R}^{n}: \rightarrow \mathbf{R}_{[0,1]}$ is continuous and

$$
\int_{X \in \mathbf{R}^{n}} P(\theta)(X) d X=1
$$

The corresponding set of n-dimensional m-parameter likelihood functions

$$
\operatorname{lfs}(n, m) \subset \mathbf{R}^{n}: \rightarrow\left(\mathbf{R}^{m} \rightarrow \mathbf{R}_{[0,1]}\right)
$$

is such that for all $L \in \operatorname{lfs}(n, m)$ and for all $X \in \mathbf{R}^{n}$, the likelihood function, $L(X) \in \operatorname{dom}(L(X)) \rightarrow \mathbf{R}_{[0,1]}$ is continuous and

$$
\begin{aligned}
& \operatorname{lfs}(n, m):= \\
& \qquad \bigcup\left\{\left\{(X,\{(\theta, P(\theta)(X)): \theta \in \operatorname{dom}(P)\}): X \in \mathbf{R}^{n}\right\}: P \in \operatorname{ppdfs}(m, n)\right\}
\end{aligned}
$$

So the likelihood functions are such that $\forall P \in \operatorname{ppdfs}(m, n) \forall \theta \in \operatorname{dom}(P) \exists L \in$ lfs $(n, m) \forall X \in \mathbf{R}^{n}(L(X)(\theta)=P(\theta)(X))$.

Given a parameterised probability density function $P \in \operatorname{ppdfs}(m, n)$ and its corresponding likelihood function $L \in \operatorname{lfs}(n, m)$, the maximum likelihood estimate of the parameters $\tilde{\theta} \in \mathbf{R}^{m}$, under certain regularity conditions, at observation coordinate $X_{\mathrm{o}} \in \mathbf{R}^{n}$ is the mode of the likelihood function,

$$
\{\tilde{\theta}\}=\operatorname{maxd}\left(L\left(X_{\mathrm{o}}\right)\right)
$$

At $\tilde{\theta}$ the gradient of the likelihood function is zero,

$$
\forall j \in\{1 \ldots m\}\left(\partial_{j}\left(L\left(X_{\circ}\right)\right)(\tilde{\theta})=0\right)
$$

where $\partial_{j} \in(\mathcal{L}(\mathbf{R}) \rightarrow \mathbf{R}) \rightarrow(\mathcal{L}(\mathbf{R}) \rightarrow \mathbf{R})$ is defined $\partial_{i}(F):=\left\{\left(Z, \partial F(Z) / \partial Z_{i}\right):\right.$ $Z \in \operatorname{dom}(F)\}$ and $F$ is a continuous function.

At $\tilde{\theta}$ the curvature of the likelihood function is negative,

$$
\forall j \in\{1 \ldots m\}\left(\partial_{j}^{2}\left(L\left(X_{\circ}\right)\right)(\tilde{\theta})<0\right)
$$

so the set of modes of the likelihood function at $X$ is a singleton, $\left|\operatorname{maxd}\left(L\left(X_{\mathrm{o}}\right)\right)\right|=$ 1.

The score of the $j$-th parameter at coordinate $X \in \mathbf{R}^{n}$ is the gradient of the likelihood function per likelihood or probability density, which equals the gradient of the log-likelihood,

$$
\left\{\left(\theta, \frac{\partial_{j}(L(X))(\theta)}{L(X)(\theta)}\right): \theta \in \operatorname{dom}(L(X))\right\}=\partial_{j}(\ln \circ L(X))
$$

which is undefined where $L(X)(\theta)=0$.
The expected value of the score is always zero,

$$
\begin{aligned}
& \forall \theta \in \operatorname{dom}(P) \forall j \in\{1 \ldots m\} \\
& \int\left(\partial_{j}(\ln \circ L(X))(\theta) \times P(\theta)(X) d X: X \in \mathbf{R}^{n}, P(\theta)(X)>0\right) \\
&= \int\left(\frac{\partial_{j}(L(X))(\theta)}{L(X)(\theta)} \times P(\theta)(X) d X: X \in \mathbf{R}^{n}, P(\theta)(X)>0\right) \\
&= \int_{X \in \mathbf{R}^{n}} \partial_{j}(L(X))(\theta) d X \\
&= \partial_{j}\left(\left\{\left(\theta^{\prime}, \int_{X \in \mathbf{R}^{n}} L(X)\left(\theta^{\prime}\right) d X\right): \theta^{\prime} \in \operatorname{dom}(P)\right\}\right)(\theta) \\
&= \partial_{j}\left(\left\{\left(\theta^{\prime}, 1\right): \theta^{\prime} \in \operatorname{dom}(P)\right\}\right)(\theta)=0
\end{aligned}
$$

That is, the expected first order sensitivity of the probability density function, $P$, to the parameters is zero.

The Fisher information of the $j$-th parameter on the diagonal $I_{P, j} \in \operatorname{dom}(P) \rightarrow$ $\mathbf{R}_{\geq 0}$ is defined as the second moment,

$$
I_{P, j}(\theta):=\int\left(\partial_{j}(\ln \circ L(X))(\theta)\right)^{2} \times P(\theta)(X) d X: X \in \mathbf{R}^{n}, P(\theta)(X)>0
$$

Under the regularity conditions, the Fisher information is always greater than zero, $I_{P, j}(\theta)>0$. Under certain further conditions the Fisher information is the negative of the second derivative,

$$
I_{P, j}(\theta)=-\int \partial_{j}^{2}(\ln \circ L(X))(\theta) \times P(\theta)(X) d X: X \in \mathbf{R}^{n}, P(\theta)(X)>0
$$

Given some observation coordinate $X_{\mathrm{o}} \in \mathbf{R}^{n}$ the maximum likelihood estimate is also the mode of log-likelihood function, $\{\tilde{\theta}\}=\operatorname{maxd}\left(\ln \circ L\left(X_{\mathrm{o}}\right)\right)=$ $\operatorname{maxd}\left(L\left(X_{o}\right)\right)$, because the natural logarithm function, $\ln$, is monotonic, $\forall j \in\{1 \ldots m\}\left(\partial_{j}\left(\ln \circ L\left(X_{\circ}\right)\right)(\tilde{\theta})=0\right)$. Thus the second derivative of the $j$-th parameter at the maximum likelihood estimate, $\tilde{\theta}$, is the curvature of the loglikelihood function, $\partial_{j}^{2}\left(\ln \circ L\left(X_{\circ}\right)\right)(\tilde{\theta})$, which is negative under the conditions.

In the case where (i) the modal probability density parameterised by the maximum likelihood estimate occurs at the observation coordinate, $X_{\mathrm{o}} \in$ $\operatorname{maxd}(P(\tilde{\theta}))$, and (ii) the sum negative curvature of the probability density function at the maximum likelihood estimate, $-\sum_{i \in\{1 \ldots n\}} \partial_{i}^{2}(P(\tilde{\theta}))\left(X_{\mathrm{o}}\right)$, is high, the Fisher information of the $j$-th parameter at the maximum likelihood estimate of the parameters, $I_{P, j}(\tilde{\theta})$, approximates to the negative curvature of the log-likelihood at the maximum likelihood estimate times the modal likelihood,

$$
\begin{aligned}
I_{P, j}(\tilde{\theta}) & =-\int \partial_{j}^{2}(\ln \circ L(X))(\tilde{\theta}) \times P(\tilde{\theta})(X) d X: X \in \mathbf{R}^{n}, P(\tilde{\theta})(X)>0 \\
& \approx-\partial_{j}^{2}\left(\ln \circ L\left(X_{\circ}\right)\right)(\tilde{\theta}) \times \operatorname{maxr}(P(\tilde{\theta})) \\
& =-\partial_{j}^{2}\left(\ln \circ L\left(X_{\circ}\right)\right)(\tilde{\theta}) \times L\left(X_{\circ}\right)(\tilde{\theta})
\end{aligned}
$$

Therefore the Fisher information for arbitrary probability density function would be expected to vary with the log-likelihood, $I_{P, j}(\tilde{\theta}) \sim \ln L\left(X_{\mathrm{o}}\right)(\tilde{\theta})$. That is, in some cases, the sensitivity of the probability density function to parameter at the maximum likelihood estimate varies with the log-likelihood.

The modal probability density, $P(\tilde{\theta})\left(X_{\mathrm{o}}\right)$, varies with the sum negative curvature of the probability density function, so the Fisher information varies with the sum negative curvature,

$$
I_{P, j}(\tilde{\theta}) \sim-\sum_{i \in\{1 \ldots n\}} \partial_{i}^{2}(P(\tilde{\theta}))\left(X_{\mathrm{o}}\right)
$$

For those centrally organised probability density functions which have a definition of variance $\operatorname{var}(n) \in\left(\mathbf{R}^{n}: \rightarrow \mathbf{R}\right) \rightarrow \mathbf{R}$, the variance varies against the
sum negative curvature at the maximum likelihood estimate, so the Fisher information would be expected to vary against the variance of the probability density function, at least in the case of low variance,

$$
I_{P, j}(\tilde{\theta}) \sim-\operatorname{var}(n)(P(\tilde{\theta}))
$$

That is, in some cases, the sensitivity of the probability density function to parameter at the maximum likelihood estimate varies against the variance of the probability density function.

The binomial distribution is the discrete probability function defined

$$
\begin{aligned}
\operatorname{bpmf} & \in \mathbf{N}_{>0} \rightarrow\left(\mathbf{Q}_{(0,1)} \rightarrow\left(\left(\mathbf{N} \rightarrow \mathbf{Q}_{(0,1)}\right) \cap \mathcal{P}\right)\right) \\
\operatorname{bpmf}(n) & \in \mathbf{Q}_{(0,1)} \rightarrow\left(\left(\{0 \ldots n\}: \rightarrow \mathbf{Q}_{(0,1)}\right) \cap \mathcal{P}\right) \\
\operatorname{bpmf}(n)(p)(k) & :=\binom{n}{k} p^{k}(1-p)^{n-k} \in \mathbf{Q}_{(0,1)}
\end{aligned}
$$

The binomial distribution can be generalised to a parameterised probability density function defined in terms of the unit-translated gamma function, $\Gamma!x=\Gamma(x+1)$,

$$
\begin{aligned}
\operatorname{bppdf} & \in \mathbf{N}_{>0} \rightarrow \operatorname{ppdfs}(1,1) \\
\operatorname{bppdf}(n) & \in \mathbf{R}_{(0,1)} \rightarrow\left(\mathbf{R}: \rightarrow \mathbf{R}_{[0,1)}\right) \\
\operatorname{bppdf}(n)(p)(k) & :=\frac{n!}{\Gamma_{!} k \Gamma_{!}(n-k)} p^{k}(1-p)^{n-k} \in \mathbf{R}_{(0,1)}
\end{aligned}
$$

where $0 \leq k \leq n$ and $0<p<1$, otherwise if $0<p<1, \operatorname{bppdf}(n)(p)(k):=0$, otherwise $\operatorname{bppdf}(n)(p)(k)$ is undefined. Note that, strictly speaking, the $b i-$ nomial parameterised probability density function, $\operatorname{bppdf}(n)(p)$, is only coninuous in the limit as $n$ tends to infinity.

The corresponding likelihood function $\operatorname{blf}(n) \in \operatorname{lfs}(1,1)$ is defined $\operatorname{blf}(n)(k)(p):=$ $\operatorname{bppdf}(n)(p)(k)$. The likelihood, $\operatorname{blf}(n)(k)(p)$, and log-likelihood, $\ln (\operatorname{blf}(n)(k)(p))$, are defined if and only if $0<p<1$.

Given observation coordinate $k_{\mathrm{o}} \in \mathbf{R}_{(0, n)}$ the maximum likelihood estimate for the parameter of the probability density function is $\tilde{p}=k_{0} / n$, where $\{\tilde{p}\}=\operatorname{maxd}\left(\operatorname{blf}(n)\left(k_{\mathrm{o}}\right)\right)$. The Fisher information of the parameter $p \in \mathbf{R}_{(0,1)}$ is

$$
I_{\mathrm{bppdf}(n)}(p)=\frac{n}{p(1-p)}
$$

which is minimised where $p=0.5$. That is, the Fisher information of the maximum likelihood estimate of the parameter, $I_{\mathrm{bppdf}(n)}(\tilde{p})$, is minimised if $k_{\mathrm{o}}=n / 2$, where $\operatorname{blf}(n)(n / 2)$ is expected to be least sensitive to $\tilde{p}$. The Fisher information of the maximum likelihood estimate varies against the variance, $n \tilde{p}(1-\tilde{p})$.

The multiple binomial parameterised probability density function $\operatorname{mbppdf}(n) \in$ $\operatorname{ppdfs}(v, v)$, where $v \in \mathbf{N}_{>0}$, is defined

$$
\begin{aligned}
& \operatorname{mbppdf}(n)(P):= \\
& \quad\left\{\left(K, \prod_{i \in\{1 . . . v\}} \frac{n!}{\Gamma_{!} K_{i} \Gamma_{!}\left(n-K_{i}\right)} P_{i}^{K_{i}}\left(1-P_{i}\right)^{n-K_{i}}\right): K \in \mathbf{R}_{[0, n]}^{v}\right\} \cup \\
& \quad\left(\mathbf{R}^{v} \backslash \mathbf{R}_{[0, n]}^{v}\right) \times\{0\}
\end{aligned}
$$

where $n \in \mathbf{N}_{>0}$ and $P \in \mathbf{R}_{(0,1)}^{v}$, otherwise $\operatorname{mbppdf}(n)(P)$ is undefined.
The multiple binomial likelihood function $\operatorname{mblf}(z) \in \operatorname{lfs}(v, v)$ is defined

$$
\operatorname{mblf}(n)(K):=\left\{(P, \operatorname{mbppdf}(n)(P)(K)): P \in \mathbf{R}_{(0,1)}^{v}\right\}
$$

where $K \in \mathbf{R}^{v}$.
Given observation coordinate $K_{\mathrm{o}} \in \mathbf{R}_{[0, n]}^{v}$ the maximum likelihood estimate for the parameter of the probability density function is $\tilde{P}=\left\{\left(i, K_{\mathrm{o}}(i) / n\right)\right.$ : $i \in\{1 \ldots v\}\}$, where $\{\tilde{P}\}=\operatorname{maxd}\left(\operatorname{mblf}(n)\left(K_{\mathrm{o}}\right)\right)$. The Fisher information of the parameter $P_{j} \in \mathbf{R}_{(0,1)}$ is

$$
I_{\operatorname{mbppdf}(n), j}\left(P_{j}\right)=\frac{n}{P_{j}\left(1-P_{j}\right)}
$$

The multinomial parameterised probability density function $\operatorname{mppdf}(n) \in$ $\operatorname{ppdfs}(v, v)$, where $v \in \mathbf{N}_{>0}$, is defined

$$
\begin{aligned}
& \operatorname{mppdf}(n)(P):= \\
& \quad\left\{\left(K, \frac{n!}{\prod_{i \in\{1 \ldots v\}} \Gamma_{!} K_{i}} \prod_{i \in\{1 \ldots v\}} P_{i}^{K_{i}}\right): K \in \mathbf{R}_{[0, n]}^{v}, \sum_{i \in\{1 \ldots v\}} K_{i}=n\right\} \cup \\
& \quad\left\{(K, 0): K \in \mathbf{R}_{[0, n]}^{v}, \sum_{i \in\{1 \ldots v\}} K_{i} \neq n\right\} \cup \\
& \quad\left(\mathbf{R}^{v} \backslash \mathbf{R}_{[0, n]}^{v}\right) \times\{0\}
\end{aligned}
$$

where $n \in \mathbf{N}_{>0}, P \in \mathbf{R}_{(0,1)}^{v}$ and $\sum_{i \in\{1 \ldots v\}} P_{i}=1$, otherwise $\operatorname{mppdf}(n)(P)$ is undefined.

The multinomial likelihood function $\operatorname{mlf}(z) \in \operatorname{lfs}(v, v)$ is defined

$$
\operatorname{mlf}(n)(K):=\left\{(P, \operatorname{mppdf}(n)(P)(K)): P \in \mathbf{R}_{(0,1)}^{v}\right\}
$$

where $K \in \mathbf{R}^{v}$. Note that the multinomial likelihood function only requires that each parameter is in the open set between zero and one, $P \in \mathbf{R}_{(0,1)}^{v}=$ $\{r: r \in \mathbf{R}, 0<r<1\}^{v}$, so $P$ is not necessarily a probability function. That is, in some cases $P \notin \mathcal{P}$ or $\sum_{i \in\{1 \ldots v\}} P_{i} \neq 1$. This is to allow well defined partial derivatives in free parameters. So $\partial_{i}(\operatorname{mlf}(n)(K))(P)$ is the sensitivity of the likelihood to the $i$-th parameter at $P$, where $\partial_{j} \in(\mathcal{L}(\mathbf{R}) \rightarrow \mathbf{R}) \rightarrow$ $(\mathcal{L}(\mathbf{R}) \rightarrow \mathbf{R})$ is defined $\partial_{j}(F):=\left\{\left(Z, \partial F(Z) / \partial Z_{j}\right): Z \in \operatorname{dom}(F)\right\}$ and $F$ is a continuous function.

Given observation coordinate $K_{\mathrm{o}} \in \mathbf{R}_{[0, n]}^{v}$, where $\sum_{i \in\{1 \ldots v\}} K_{\mathrm{o}}(i)=n$, the maximum likelihood estimate for the parameter of the probability density function is $\tilde{P}=\left\{\left(i, K_{\mathrm{o}}(i) / n\right): i \in\{1 \ldots v\}\right\}$. That is, although the multinomial parameterised probability density function is constrained in the sum of the coordinates, $\sum_{i \in\{1 \ldots v\}} K_{i}=n$, a Lagrangian multiplier can be used to prove that the maximum likelihood estimate is equal to that for the parameter of the multiple binomial parameterised probability density function, $\{\tilde{P}\}=\operatorname{maxd}\left(\operatorname{mlf}(n)\left(K_{\mathrm{o}}\right)\right)=\operatorname{maxd}\left(\operatorname{mblf}(n)\left(K_{\mathrm{o}}\right)\right)$. Similarly, along the diagonal the Fisher information of the parameter $P_{j} \in \mathbf{R}_{(0,1)}$ is also equal to that for the parameter of the multiple binomial parameterised probability density function

$$
I_{\operatorname{mppdf}(n), j}\left(P_{j}\right)=I_{\operatorname{mbppdf}(n), j}\left(P_{j}\right)=\frac{n}{P_{j}\left(1-P_{j}\right)}
$$

## B Useful functions

## B. 1 Entropy and Gibbs' inequality

Define entropy $\in\left(\mathcal{X} \rightarrow \mathbf{Q}_{\geq 0}\right) \rightarrow \mathrm{Q}_{\geq 0} \ln \mathrm{Q}_{>0}$

$$
\operatorname{entropy}(N):=-\sum\left(\hat{N}_{x} \ln \hat{N}_{x}: x \in \operatorname{dom}(N), N_{x}>0\right)
$$

where $\operatorname{sum}(N)>0$ and normalised $\hat{N}=\{(x, q / \operatorname{sum}(N)):(x, q) \in N\}$. Define entropy $(\emptyset):=0$. Here entropy is defined such that it is independent of $\operatorname{sum}(N)$.

Define entropyCross $\in\left(\mathcal{X} \rightarrow \mathbf{Q}_{\geq 0}\right) \times\left(\mathcal{X} \rightarrow \mathbf{Q}_{\geq 0}\right) \rightarrow \mathbf{Q}_{\geq 0} \ln \mathbf{Q}_{>0}$

$$
\text { entropy } \operatorname{Cross}(N, M):=-\sum\left(\hat{N}_{x} \ln \hat{M}_{x}: x \in \operatorname{dom}(N), M_{x}>0\right)
$$

where $\operatorname{sum}(N)>0, \operatorname{sum}(M)>0$ and $\operatorname{dom}(N) \subseteq \operatorname{dom}(M)$.
Gibbs' inequality states that
$-\sum\left(P_{x} \ln P_{x}: x \in \operatorname{dom}(P), P_{x}>0\right) \leq-\sum\left(P_{x} \ln Q_{x}: x \in \operatorname{dom}(P), Q_{x}>0\right)$
where $P, Q \in \mathcal{X} \rightarrow \mathbf{Q}_{\geq 0}, \operatorname{sum}(P)=1, \operatorname{dom}(Q) \supseteq \operatorname{dom}(P)$ and $\operatorname{sum}(Q) \leq 1$. $P$ is a probability function, $P \in \mathcal{P}$, but $Q$ is not necessarily a probability function.

Define entropyRelative $\in\left(\mathcal{X} \rightarrow \mathbf{Q}_{\geq 0}\right) \times\left(\mathcal{X} \rightarrow \mathbf{Q}_{\geq 0}\right) \rightarrow \mathbf{Q}_{\geq 0} \ln \mathbf{Q}_{>0}$

$$
\text { entropyRelative }(N, M):=\sum\left(\hat{N}_{x} \ln \frac{\hat{N}_{x}}{\hat{M}_{x}}: x \in \operatorname{dom}(N), N_{x}>0, M_{x}>0\right)
$$

where $\operatorname{sum}(N)>0, \operatorname{sum}(M)>0$ and $\operatorname{dom}(N) \subseteq \operatorname{dom}(M)$. The relative entropy equals the cross entropy minus the entropy,

$$
\operatorname{entropyRelative}(N, M)=\operatorname{entropyCross}(N, M)-\operatorname{entropy}(N)
$$

By Gibbs' inequality the relative entropy is positive, entropyRelative( $N, M) \geq$ 0 . So the cross entropy is greater than or equal to the entropy,

$$
\operatorname{entropy} \operatorname{Cross}(N, M) \geq \operatorname{entropy}(N)
$$

## B. 2 Probability functions

The set of probability functions $\mathcal{P}$ is the set of rational valued functions such that the values are bounded $[0,1]$ and sum to 1 ,

$$
\mathcal{P} \subset \mathcal{X} \rightarrow\{q: q \in \mathbf{Q}, 0 \leq q \leq 1\}
$$

and

$$
\forall P \in \mathcal{P}(\operatorname{sum}(P)=1)
$$

A probability function cannot be empty, $\emptyset \notin \mathcal{P}$. Note that the events of a probability definition, $\operatorname{dom}(P)$ where $P \in \mathcal{P}$, are defined here as elementary events or outcomes. That is, the events are exclusive and do not form a
$\sigma$-field.
Any non-empty, finite $\mathcal{X}$-valued function of $\mathcal{Y}$ implies a distribution of $\mathcal{Y}$ over $\mathcal{X}$ and hence a probability function by normalisation,

$$
\forall R \in \mathcal{Y} \rightarrow \mathcal{X}\left(0<|R|<\infty \Longrightarrow\left\{(x,|C|):(x, C) \in R^{-1}\right\}^{\wedge} \in \mathcal{P}\right)
$$

where ()$^{-1}:=$ inverse and ()$^{\wedge}:=$ normalise. Conversely, any probability function implies the existence of at least one non-empty, finite $\mathcal{X}$-valued function of integer,

$$
\begin{aligned}
& \forall P \in \mathcal{P} \exists R \in \mathbf{N} \rightarrow \mathcal{X} \\
& \quad\left(0<|R|<\infty \wedge\left\{(x,|C|):(x, C) \in R^{-1}\right\}^{\wedge}=\{(x, p):(x, p) \in P, p>0\}\right)
\end{aligned}
$$

The set of weak probability functions $\mathcal{P}^{\prime}$ is superset of probability functions, $\mathcal{P}^{\prime} \supset \mathcal{P}$, that weakens the summation constraint such that the sum is less than or equal to 1 ,

$$
\mathcal{P}^{\prime} \subset \mathcal{X} \rightarrow\{q: q \in \mathbf{Q}, 0 \leq q \leq 1\}
$$

and

$$
\forall P^{\prime} \in \mathcal{P}^{\prime}\left(\operatorname{sum}\left(P^{\prime}\right) \leq 1\right)
$$

The empty function is a weak probability function, $\emptyset \in \mathcal{P}^{\prime}$.
The expected or mean of a probability function $P \in \mathcal{P}$ applied to a given function $F \in \mathcal{X} \rightarrow \mathbf{R}$ is defined expected $\in \mathcal{P} \rightarrow((\mathcal{X} \rightarrow \mathbf{R}) \rightarrow \mathbf{R})$, and $\operatorname{expected}(P) \in(\operatorname{dom}(P) \rightarrow \mathbf{R}) \rightarrow \mathbf{R}$ as

$$
\operatorname{expected}(P)(F):=\sum_{x \in \operatorname{dom}(F)} P_{x} F_{x}
$$

Define $\operatorname{expected}(P)(\emptyset):=0$. If $F \in \mathcal{X} \rightarrow \mathbf{Q}$ then $\operatorname{expected}(P)(F) \in \mathbf{Q}$. If $F \in \mathcal{X} \rightarrow \mathbf{Q}_{\geq 0}$ then $\operatorname{expected}(P)(F) \in \mathbf{Q}_{\geq 0}$.

The covariance of given functions $F, G \in \mathcal{X} \rightarrow \mathbf{R}$ is defined covariance $\in$ $\mathcal{P} \rightarrow((\mathcal{X} \rightarrow \mathbf{R}) \times(\mathcal{X} \rightarrow \mathbf{R}) \rightarrow \mathbf{R})$, and covariance $(P) \in(\operatorname{dom}(P) \rightarrow$ $\mathbf{R}) \times(\operatorname{dom}(P) \rightarrow \mathbf{R}) \rightarrow \mathbf{R}$ as
covariance $(P)(F, G):=$ $\operatorname{expected}(P)(\{(x, F(x) G(x)): x \in \operatorname{dom}(F) \cap \operatorname{dom}(G)\})-$ $\operatorname{expected}(P)(\operatorname{filter}(\operatorname{dom}(G), F)) \times \operatorname{expected}(P)(\operatorname{filter}(\operatorname{dom}(F), G))$

The variance of given function $F \in \mathcal{X} \rightarrow \mathbf{R}$ is defined variance $\in \mathcal{P} \rightarrow$ $((\mathcal{X} \rightarrow \mathbf{R}) \rightarrow \mathbf{R})$, and variance $(P) \in(\operatorname{dom}(P) \rightarrow \mathbf{R}) \rightarrow \mathbf{R}$ as

$$
\text { variance }(P)(F):=\operatorname{covariance}(P)(F, F)
$$

Note that in the case of uniform probability function, $P=\operatorname{dom}(F) \times\{1 /|F|\}$, the variance, variance $(P)(F)$, is the population variance, not the sample variance.

The correlation of given functions $F, G \in \mathcal{X} \rightarrow \mathbf{R}$ is defined correlation $\in$ $\mathcal{P} \rightarrow((\mathcal{X} \rightarrow \mathbf{R}) \times(\mathcal{X} \rightarrow \mathbf{R}) \rightarrow \mathbf{R})$, and correlation $(P) \in(\operatorname{dom}(P) \rightarrow$ $\mathbf{R}) \times(\operatorname{dom}(P) \rightarrow \mathbf{R}) \rightarrow \mathbf{R}$ as

$$
\begin{aligned}
& \text { correlation }(P)(F, G):= \\
& \qquad \frac{\text { covariance }(P)(F, G)}{\sqrt{\operatorname{var}(P)(\text { filter }(\operatorname{dom}(G), F))} \times \sqrt{\operatorname{var}(P)(\text { filter }(\operatorname{dom}(F), G))}}
\end{aligned}
$$

where var $=$ variance. The correlation is undefined if either variance is zero.
The moment generating function of given function $F \in \mathcal{X} \rightarrow \mathbf{R}$ and moment parameter $t \in \mathbf{R}$ is defined $\mathrm{mgf} \in \mathcal{P} \rightarrow((\mathcal{X} \rightarrow \mathbf{R}) \rightarrow(\mathbf{R} \rightarrow \mathbf{R}))$, and $\operatorname{mgf}(P) \in(\operatorname{dom}(P) \rightarrow \mathbf{R}) \rightarrow(\mathbf{R} \rightarrow \mathbf{R})$ as

$$
\operatorname{mgf}(P)(F)(t):=\operatorname{expected}(P)\left(\left\{\left(x, e^{t F_{x}}\right): x \in \operatorname{dom}(F)\right\}\right)
$$

The expression $F \sim G$, where $F, G \in \mathcal{X} \rightarrow \mathbf{R}$ and $\operatorname{dom}(F)=\operatorname{dom}(G)$, can be formalised in terms of the covariance of the functions in a uniform probability function

$$
F \sim G \Longleftrightarrow \text { covariance }(\operatorname{dom}(F) \times\{1 /|F|\})(F, G)>0
$$

## B. 3 Function composition

A pair of functions, $F_{1}, F_{2} \in \mathcal{X} \rightarrow \mathcal{X}$ can be composed in an outer join $F_{2} \circ F_{1}$. Define compose $\in(\mathcal{X} \rightarrow \mathcal{X}) \times(\mathcal{X} \rightarrow \mathcal{X}) \rightarrow(\mathcal{X} \rightarrow \mathcal{X})$ as

$$
\begin{aligned}
& \operatorname{compose}\left(F_{1}, F_{2}\right):= \\
& \\
& \quad\left\{\left(x_{1}, y_{2}\right):\left(x_{1}, y_{1}\right) \in F_{1},\left(x_{2}, y_{2}\right) \in F_{2}, x_{2}=y_{1}\right\} \cup \\
& \\
& \quad\left\{\left(x_{1}, y_{1}\right):\left(x_{1}, y_{1}\right) \in F_{1}, y_{1} \notin \operatorname{dom}\left(F_{2}\right)\right\} \cup \\
& \quad\left\{\left(x_{2}, y_{2}\right):\left(x_{2}, y_{2}\right) \in F_{2}, x_{2} \notin \operatorname{dom}\left(F_{1}\right)\right\}
\end{aligned}
$$

Define $F_{2} \circ F_{1}:=\operatorname{compose}\left(F_{1}, F_{2}\right)$. The domain of a composition is the union of the domains of the arguments, $\operatorname{dom}\left(F_{2} \circ F_{1}\right)=\operatorname{dom}\left(F_{1}\right) \cup \operatorname{dom}\left(F_{2}\right)$. A
sequence of compositions of functions is right associative, $F_{3} \circ F_{2} \circ F_{1}=$ $F_{3} \circ\left(F_{2} \circ F_{1}\right)$. A list of functions, $L \in \mathcal{L}(\mathcal{X} \rightarrow \mathcal{X})$, can be composed recursively from right to left. Define compose $\in \mathcal{L}(\mathcal{X} \rightarrow \mathcal{X}) \rightarrow(\mathcal{X} \rightarrow \mathcal{X})$ as compose $(L):=\operatorname{compose}($ sequence $($ reverse $(L)))$ and compose $\in \mathcal{K}(\mathcal{X} \rightarrow$ $\mathcal{X}) \rightarrow(\mathcal{X} \rightarrow \mathcal{X})$ as

$$
\begin{aligned}
\operatorname{compose}((F, X)) & :=F \circ \operatorname{compose}(X) \\
\operatorname{compose}(\emptyset) & :=\emptyset
\end{aligned}
$$

A composition $L \in \mathcal{L}(\mathcal{X} \rightarrow \mathcal{X})$ is non-circular where no source subsequently appears as a target, $\forall i \in\{1 \ldots|L|\}\left(\operatorname{dom}\left(L_{i}\right) \cap \operatorname{ran}(\bigcup \operatorname{set}(\operatorname{drop}(i-1, L)))=\right.$ $\emptyset$ ). A composition $L$ is functional where unioned list is functional, $\bigcup \operatorname{set}(L) \in$ $\mathcal{X} \rightarrow \mathcal{X}$.

## B. 4 Monoidal product

The product of a monoidal set $\left(\prod\right) \in \mathrm{P}(\mathcal{X}) \rightarrow \mathcal{X}$ requires a product operator $(*) \in \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{X}$ which is commutative, $\forall x, y \in \mathcal{X}(x * y=y * x)$. The monoidal product $\Pi X$ is defined by choosing some enumeration $Q \in$ enums $(X)$ and then folding over the list, flip $(Q) \in \mathcal{L}(X)$

$$
\prod X=\operatorname{fold} 1((*), \operatorname{flip}(Q))
$$

The product of the empty set, $\Pi \emptyset$, is undefined.
In the case of sets of sets, $(\Pi) \in \mathrm{P}(\mathrm{P}(\mathcal{X})) \rightarrow \mathrm{P}(\mathcal{X})$, and in the absence of an explicit monoidal operator, the operator is taken to be the union of the self. Given argument $Q \in \mathrm{P}(\mathrm{P}(\mathcal{X}))$, let $S=\{\operatorname{self}(P): P \in Q\}$. Then let the operator be $X * Y:=\{x \cup y: x \in X, y \in Y\}$. Then $\prod Q=\prod S$. Alternatively the product can be calculated from the product of a list of sets. Choose some arbitrary enumeration of the argument $Q, X \in \operatorname{enums}(Q)$. Then the product of a list of sets is a set of lists, $\prod$ flip $(X) \in \mathrm{P}(\mathcal{L}(\mathcal{X}))$. Then $\Pi Q=\left\{\operatorname{set}(R): R \in \prod \operatorname{flip}(X)\right\}$.

## B. 5 Lists, tuples and sequences

A list is defined $\mathcal{L}(\mathcal{X}) \subset \mathbf{N} \rightarrow \mathcal{X}$, where $\mathcal{X}$ is the universal set (or type variable), such that $\forall L \in \mathcal{L}(\mathcal{X})(L \neq \emptyset \Longrightarrow \operatorname{dom}(L)=\{1 \ldots|L|\})$. If a list is a bijection $L \in \mathbf{N} \leftrightarrow \mathcal{X} \subset \mathcal{L}(\mathcal{X})$ then this constraint can also be expressed flip $(L) \in \operatorname{enums}(\operatorname{ran}(L))$, which highlights the connection with enumerations.

For the subset of tuples which have elements of type $\mathcal{X}$ define list $\in\left\{\mathcal{X}^{i}\right.$ : $i \in \mathbf{N}\} \rightarrow \mathcal{L}(\mathcal{X})$ as list ()$:=\emptyset, \operatorname{list}(x):=\{(1, x)\}, \operatorname{list}(x, y):=\{(1, x),(2, y)\}$, and so on. The inverse function is defined tuple $\in \mathcal{L}(\mathcal{X}) \rightarrow\left\{\mathcal{X}^{i}: i \in \mathbf{N}\right\}$ as tuple $(\emptyset):=()$, tuple $(\{(1, x)\}):=(x)$, tuple $(\{(1, x),(2, y)\}):=(x, y)$, and so on.

The set of head/tail sequences is recursively defined in terms of null terminated pairs

$$
\mathcal{K}(\mathcal{X}):=((\mathcal{X} \backslash\{\emptyset\}) \times \mathcal{K}(\mathcal{X})) \cup\{\emptyset\}
$$

Define list $\in \mathcal{K}(\mathcal{X}) \rightarrow \mathcal{L}(\mathcal{X})$ as

$$
\begin{aligned}
\operatorname{list}(\emptyset) & :=\emptyset \\
\operatorname{list}((x, \emptyset)) & :=\{(1, x)\} \\
\operatorname{list}((x, X)) & :=\{(1, x)\} \cup\{(i+1, y):(i, y) \in \operatorname{list}(X)\}
\end{aligned}
$$

Similarly, define sequence $\in \mathcal{L}(\mathcal{X}) \rightarrow \mathcal{K}(\mathcal{X})$ as

$$
\begin{aligned}
\text { sequence }(\emptyset) & :=\emptyset \\
\text { sequence }(\{(i, x)\}) & :=(x, \emptyset)
\end{aligned}
$$

And

$$
\text { sequence }(L):=(x, \text { sequence }(L \backslash\{(i, x)\}))
$$

where $\{(x, i)\} \in \min (f l i p(L))$.
Define set $\in \mathcal{L}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X})$ as

$$
\operatorname{set}(L):=\operatorname{ran}(L)
$$

We define the constructor of a list from a set as list $\in \mathrm{P}(\mathcal{X}) \rightarrow \mathcal{L}(\mathcal{X})$ without defining the method, except to say that the order is arbitrary and it is constrained such that $\operatorname{set}(\operatorname{list}(X))=X$. Also define sequence $\in \mathrm{P}(\mathcal{X}) \rightarrow \mathcal{K}(\mathcal{X})$ as sequence $(X)=$ sequence $(\operatorname{list}(X))$.

Define map $\in(\mathcal{X} \rightarrow \mathcal{Y}) \times \mathcal{K}(\mathcal{X}) \rightarrow \mathcal{K}(\mathcal{Y})$ as

$$
\begin{aligned}
\operatorname{map}(F, \emptyset) & :=\emptyset \\
\operatorname{map}(F,(x, X)) & :=\left(F_{x}, \operatorname{map}(F, X)\right)
\end{aligned}
$$

Define filter $\in(\mathcal{X} \rightarrow \mathbf{B}) \times \mathcal{K}(\mathcal{X}) \rightarrow \mathcal{K}(\mathcal{X})$ as

$$
\begin{aligned}
\text { filter }(F, \emptyset) & :=\emptyset \\
\text { filter }(F,(x, X)) & :=\operatorname{if}(F(x),(x, \text { filter }(F, X)), \text { filter }(F, X))
\end{aligned}
$$

Define map $\in(\mathcal{X} \rightarrow \mathcal{Y}) \times \mathcal{L}(\mathcal{X}) \rightarrow \mathcal{L}(\mathcal{Y})$ as

$$
\operatorname{map}(F, L):=\left\{\left(i, F_{x}\right):(i, x) \in L\right\}
$$

where $\forall(F, L) \in \operatorname{dom}($ map $)(\operatorname{ran}(L) \in \operatorname{dom}(F))$.
Define right associative fold $\in(\mathcal{X} \times \mathcal{Y} \rightarrow \mathcal{Y}) \times \mathcal{Y} \times \mathcal{K}(\mathcal{X}) \rightarrow \mathcal{Y}$ as

$$
\begin{aligned}
\operatorname{fold}(F, y, \emptyset) & :=y \\
\operatorname{fold}(F, y,(x, X)) & :=F(x, \operatorname{fold}(F, y, X))
\end{aligned}
$$

Define fold $1 \in(\mathcal{X} \times \mathcal{Y} \rightarrow \mathcal{Y}) \times \mathcal{K}(\mathcal{X}) \rightarrow \mathcal{Y}$ as

$$
\operatorname{fold} 1(F,(x, X))=\operatorname{fold}(F, x, X)
$$

which is defined for an non-empty sequence. Define fold $\in(\mathcal{X} \times \mathcal{Y} \rightarrow$ $\mathcal{Y}) \times \mathcal{Y} \times \mathcal{L}(\mathcal{X}) \rightarrow \mathcal{Y}$ as fold $(F, y, L):=$ fold $(F, y$, sequence $(L))$ and fold $1 \in$ $(\mathcal{X} \times \mathcal{Y} \rightarrow \mathcal{Y}) \times \mathcal{L}(\mathcal{X}) \rightarrow \mathcal{Y}$ as fold1 $(F, L):=$ fold1 $(F$, sequence $(L))$.

Define reverse $\in \mathcal{L}(\mathcal{X}) \rightarrow \mathcal{L}(\mathcal{X})$ as

$$
\operatorname{reverse}(L):=\{(|L|+1-i, x):(i, x) \in L\}
$$

Define concat $\in \mathcal{K}(\mathcal{X}) \times \mathcal{K}(\mathcal{X}) \rightarrow \mathcal{K}(\mathcal{X})$ as

$$
\begin{aligned}
\operatorname{concat}(\emptyset, Y) & :=Y \\
\operatorname{concat}((x, X), Y) & :=(x, \operatorname{concat}(X, Y))
\end{aligned}
$$

Define concat $\in \mathcal{L}(\mathcal{X}) \times \mathcal{L}(\mathcal{X}) \rightarrow \mathcal{L}(\mathcal{X})$ as

$$
\operatorname{concat}(L, M):=L \cup\{(|L|+i, x):(i, x) \in M\}
$$

Define concat $\in \mathcal{L}(\mathcal{L}(\mathcal{X})) \rightarrow \mathcal{L}(\mathcal{X})$ as

$$
\operatorname{concat}(N):=\text { fold }(\text { concat }, \emptyset, \text { sequence }(N))
$$

Define head $\in \mathcal{L}(\mathcal{X}) \backslash\{\emptyset\} \rightarrow \mathcal{X}$ as

$$
\operatorname{head}(L):=x
$$

where $(1, x) \in L . \operatorname{head}(\emptyset)$ is undefined.
Define last $\in \mathcal{L}(\mathcal{X}) \backslash\{\emptyset\} \rightarrow \mathcal{X}$ as

$$
\operatorname{last}(L):=x
$$

where $(|L|, x) \in L . \operatorname{last}(\emptyset)$ is undefined.
Define tail $\in \mathcal{L}(\mathcal{X}) \rightarrow \mathcal{L}(\mathcal{X})$ as

$$
\operatorname{tail}(L):=\{(i-1, x):(i, x) \in L, i>1\}
$$

Define take $\in \mathbf{N} \times \mathcal{L}(\mathcal{X}) \rightarrow \mathcal{L}(\mathcal{X})$ as

$$
\operatorname{take}(j, L):=\{(i, x):(i, x) \in L, i \leq j\}
$$

Define drop $\in \mathbf{N} \times \mathcal{L}(\mathcal{X}) \rightarrow \mathcal{L}(\mathcal{X})$ as

$$
\operatorname{drop}(j, L):=\{(i-j, x):(i, x) \in L, i>j\}
$$

A selection of a list is defined select $\in \mathrm{P}\left(\mathbf{N}_{>0}\right) \times \mathcal{L}(\mathcal{X}) \rightarrow \mathcal{L}(\mathcal{X})$ as

$$
\operatorname{select}(Q, L):=\left\{\left(|\{j: j \in Q, j \leq i\}|, L_{i}\right): i \in Q, i \leq|L|\right\}
$$

Define shorthand $L_{Q}:=\operatorname{select}(Q, L)$ where $Q \subset \mathbf{N}_{>0}$. Then $\operatorname{take}(j, L)=$ $L_{\{1 \ldots j\}}$ and $\operatorname{drop}(j, L)=L_{\{j+1 \ldots|L|\}}$.

Define sublists $\in \mathcal{L}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{L}(\mathcal{X}))$ as

$$
\operatorname{sublists}(L):=\{\operatorname{take}(i, L): i \in\{1 \ldots|L|\}\} \cup\{\emptyset\}
$$

There are $|L|+1$ sublists, $\mid$ sublists $(L)|=|L|+1$. The empty list, $\emptyset$, is a sublist of all lists. The immediate sublist is take $(|L|-1, L) \in \operatorname{sublists}(L)$ where $L \neq \emptyset$.

A pair of lists may be zipped together as far as the shorter list. Define zip $\in \mathcal{L}(\mathcal{X}) \times \mathcal{L}(\mathcal{Y}) \rightarrow \mathcal{L}(\mathcal{X} \times \mathcal{Y})$ as

$$
\operatorname{zip}(L, M):=\left\{\left(i,\left(L_{i}, M_{i}\right)\right): i \in\{1 \ldots \operatorname{minimum}(|L|,|M|)\}\right\}
$$

The product of a list of sets is a set of lists, $(\Pi) \in \mathcal{L}(\mathrm{P}(\mathcal{X})) \rightarrow \mathrm{P}(\mathcal{L}(\mathcal{X}))$. See 'Monoidal product', above. Let mul $\in \mathrm{P}(\mathcal{X}) \times \mathrm{P}(\mathcal{L}(\mathcal{X})) \rightarrow \mathrm{P}(\mathcal{L}(\mathcal{X}))$ be defined as

$$
\operatorname{mul}(Q, R):=\{\operatorname{concat}(J,\{(1, x)\}): J \in R, x \in Q\}
$$

Then

$$
\prod L:=\operatorname{fold}(\operatorname{mul},\{\emptyset\}, L)
$$

The product of the empty set is a set of the empty list, $\Pi \emptyset=\{\emptyset\}$. The product of sequences, $\left(\prod\right) \in \mathcal{K}(\mathrm{P}(\mathcal{X})) \rightarrow \mathrm{P}(\mathcal{K}(\mathcal{X}))$, and the product of tuples, $(\Pi) \in \operatorname{tuples}(\mathrm{P}(\mathcal{X})) \rightarrow \mathrm{P}($ tuples $(\mathcal{X}))$, are similarly defined.

The power of a set is the product of a list of the set such that the length of the list equals the power, $X^{n}=\prod(\{1 \ldots n\} \times\{X\}) \subset\{L: L \in \mathcal{L}(X),|L|=n\}$.

## B. 6 Trees

Trees, as defined here, are unordered functional relations between objects and trees

$$
\operatorname{trees}(\mathcal{X})=\mathcal{X} \rightarrow \operatorname{trees}(\mathcal{X})
$$

The function nodes $\in \operatorname{trees}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X} \times \operatorname{trees}(\mathcal{X}))$ is defined

$$
\operatorname{nodes}(T):=T \cup \bigcup\{\operatorname{nodes}(R):(x, R) \in T\}
$$

where nodes $(\emptyset):=\emptyset$.
The elements of the tree is defined elements $\in \operatorname{trees}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X})$

$$
\operatorname{elements}(T):=\operatorname{dom}(\operatorname{nodes}(T))
$$

The function roots $\in \operatorname{trees}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X})$ is defined

$$
\operatorname{roots}(T):=\operatorname{dom}(T)
$$

The function leaves $\in \operatorname{trees}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X})$ is defined

$$
\operatorname{leaves}(T):=\{x:(x, R) \in \operatorname{nodes}(T), R=\emptyset\}
$$

The set of pairs of elements of the tree is defined steps $\in \operatorname{trees}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X} \times$ $\mathcal{X})$

$$
\operatorname{steps}(T):=\{(x, y):(x, R) \in \operatorname{nodes}(T), y \in \operatorname{roots}(R)\}
$$

Define map $\in(\mathcal{X} \rightarrow \mathcal{Y}) \times \operatorname{trees}(\mathcal{X}) \rightarrow \operatorname{trees}(\mathcal{Y})$ as

$$
\operatorname{map}(F, T):=\{(F(x), \operatorname{map}(F, R)):(x, R) \in T\}
$$

where $F$ is such that elements $(T) \subseteq \operatorname{dom}(F)$.
Define mapNode $\in(\mathcal{X} \times \operatorname{trees}(\mathcal{X}) \rightarrow \mathcal{Y}) \times \operatorname{trees}(\mathcal{X}) \rightarrow \operatorname{trees}(\mathcal{Y})$ as

$$
\operatorname{mapNode}(F, T):=\{(F(x, R), \operatorname{mapNode}(F, R)):(x, R) \in T\}
$$

where $F$ is such that elements $(T) \times \operatorname{trees}(\operatorname{elements}(T)) \subseteq \operatorname{dom}(F)$.
Define mapAccum $\in(\mathcal{L}(\mathcal{X}) \rightarrow \mathcal{Y}) \times \operatorname{trees}(\mathcal{X}) \rightarrow \operatorname{trees}(\mathcal{Y})$ as

$$
\operatorname{mapAccum}(F, T):=\operatorname{mapAccum}(F, \emptyset, T)
$$

and mapAccum $\in(\mathcal{L}(\mathcal{X}) \rightarrow \mathcal{Y}) \times \mathcal{L}(\mathcal{X}) \times \operatorname{trees}(\mathcal{X}) \rightarrow \operatorname{trees}(\mathcal{Y})$ as

$$
\begin{aligned}
& \operatorname{mapAccum}(F, L, T):= \\
& \qquad\{(F(M), \operatorname{mapAccum}(F, M, R)):(x, R) \in T, M=\operatorname{concat}(L,\{(1, x)\})\}
\end{aligned}
$$

where $F$ is such that $\operatorname{paths}(T) \subset \operatorname{dom}(F)$.
Define mapNodeAccum $\in(\mathcal{L}(\mathcal{X}) \times \operatorname{trees}(\mathcal{X}) \rightarrow \mathcal{Y}) \times \operatorname{trees}(\mathcal{X}) \rightarrow \operatorname{trees}(\mathcal{Y})$ as mapNodeAccum $(F, T):=$ mapNodeAccum $(F, \emptyset, T)$
and mapNodeAccum $\in(\mathcal{L}(\mathcal{X}) \times \operatorname{trees}(\mathcal{X}) \rightarrow \mathcal{Y}) \times \mathcal{L}(\mathcal{X}) \times \operatorname{trees}(\mathcal{X}) \rightarrow \operatorname{trees}(\mathcal{Y})$ as
mapNodeAccum $(F, L, T):=$
$\{(F(M, R), \operatorname{mapNodeAccum}(F, M, R)):(x, R) \in T, M=\operatorname{concat}(L,\{(1, x)\})\}$
where $F$ is such that elements $(T) \times \operatorname{trees}($ elements $(T)) \subseteq \operatorname{dom}(F)$.
Given a pair of trees, $\operatorname{dot} \in \operatorname{trees}(\mathcal{X}) \times \operatorname{trees}(\mathcal{Y}) \rightarrow \operatorname{trees}(\mathcal{X} \times \mathcal{Y})$, returns the zipped tree of pairs,

$$
\operatorname{dot}(S, T):=\left\{\left((x, y), \operatorname{dot}\left(S_{x}, T_{y}\right)\right):(x, y) \in \operatorname{dom}(S) \cdot \operatorname{dom}(T)\right\}
$$

where $\operatorname{dot}(\emptyset, \cdot):=\{\emptyset\}$ and $\operatorname{dot}(\cdot, \emptyset):=\{\emptyset\}$, and

$$
X \cdot Y:=\operatorname{zip}\left(\operatorname{flip}\left(\operatorname{order}\left(D_{\mathcal{X}}, X\right)\right), \operatorname{flip}\left(\operatorname{order}\left(D_{\mathcal{Y}}, Y\right)\right)\right)
$$

where $D_{\mathcal{X}}$ and $D_{\mathcal{Y}}$ are orders on $\mathcal{X}$ and $\mathcal{Y}$.
Given a tree of pairs, distinct $\in \operatorname{trees}(\mathcal{X} \times \mathcal{Y}) \rightarrow \mathrm{P}(\operatorname{trees}(\mathcal{X} \times \mathcal{Y}))$, returns the set of distinct trees such that the domains of the trees form a function, $\forall T \in \operatorname{trees}(\mathcal{X} \times \mathcal{Y}) \forall U \in \operatorname{distinct}(T) \forall V \in\{U\} \cup \operatorname{ran}(\operatorname{nodes}(U))(\operatorname{dom}(V) \in$ $\mathcal{X} \rightarrow \mathcal{Y})$,

$$
\begin{aligned}
& \operatorname{distinct}(T):= \\
& \qquad \begin{aligned}
&\{U: U \subseteq\{((x, y), R):((x, y), S) \in T, R \in \operatorname{distinct}(S)\}, \\
&\operatorname{dom}(U) \in \operatorname{dom}(\operatorname{dom}(T)): \rightarrow \operatorname{ran}(\operatorname{dom}(T))\}
\end{aligned}
\end{aligned}
$$

where distinct $(\emptyset):=\{\emptyset\}$.
Define paths $\in \operatorname{trees}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{L}(\mathcal{X}))$ as

$$
\operatorname{paths}(T):=\operatorname{paths}(\emptyset, T)
$$

where we define paths $\in \mathcal{L}(\mathcal{X}) \times \operatorname{trees}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{L}(\mathcal{X}))$

$$
\operatorname{paths}(L, T):=\bigcup\{\operatorname{paths}(\operatorname{concat}(L,\{(1, x)\}), R):(x, R) \in T\}
$$

where paths $(L, \emptyset):=\{L\}$.
Define tree $\in \mathrm{P}(\mathcal{L}(\mathcal{X})) \rightarrow \operatorname{trees}(\mathcal{X})$
tree $(Q):=$

$$
\{(h, \operatorname{tree}(\{\operatorname{tail}(J): J \in Q,(1, h) \in J\})): h \in\{\operatorname{head}(L): L \in Q,|L|>0\}\}
$$

where tree $(\emptyset):=\emptyset$.
The function depth $\in \operatorname{trees}(\mathcal{X}) \rightarrow \mathbf{N}$ is defined

$$
\operatorname{depth}(T):=\operatorname{maxr}(\{(L,|L|): L \in \operatorname{paths}(T)\})
$$

The depth of the empty tree is defined as zero, $\operatorname{depth}(\emptyset):=0$.
Define places $\in \operatorname{trees}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{L}(\mathcal{X}) \times \operatorname{trees}(\mathcal{X}))$ as

$$
\operatorname{places}(T):=\operatorname{places}(\emptyset, T)
$$

where we define places $\in \mathcal{L}(\mathcal{X}) \times \operatorname{trees}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{L}(\mathcal{X}) \times \operatorname{trees}(\mathcal{X}))$

$$
\begin{aligned}
& \operatorname{places}(L, T):= \\
& \qquad \bigcup\{\{(M, R)\} \cup \operatorname{places}(M, R):(x, R) \in T, M=\operatorname{concat}(L,\{(1, x)\})\}
\end{aligned}
$$

Define places $(\cdot, \emptyset):=\emptyset$. The places function is related to nodes, $\left\{\left(L_{|L|}, R\right)\right.$ : $(L, R) \in \operatorname{places}(T)\}=\operatorname{nodes}(T)$. The places function is related to paths, $\{L:$ $(L, R) \in \operatorname{places}(T), R=\emptyset\}=\operatorname{paths}(T)$. The places function can be defined in terms of mapNodeAccum, $\operatorname{places}(T)=$ elements $(\operatorname{mapNodeAccum}(\mathrm{id}, T))$, where $\forall x \in \mathcal{X}(\operatorname{id}(x)=x)$.

Define subpaths $\in \operatorname{trees}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{L}(\mathcal{X}))$ as

$$
\operatorname{subpaths}(T):=\operatorname{dom}(\operatorname{places}(T))
$$

The set of subtrees can be constructed from the monoidal product of the sublists of the paths. Define subtrees $\in \operatorname{trees}(\mathcal{X}) \rightarrow \mathrm{P}(\operatorname{trees}(\mathcal{X}))$ as

$$
\operatorname{subtrees}(T):=\left\{\operatorname{tree}(Q): Q \in \prod\{\operatorname{sublists}(L): L \in \operatorname{paths}(T)\}\right\} \cup\{\emptyset\}
$$

The empty tree, $\emptyset$, is a subtree of all trees. The set of immediate subtrees is the subset where exactly one path is an immediate sublist, $\{\operatorname{tree}(\operatorname{paths}(T) \backslash$ $\{L\} \cup\{\operatorname{take}(|L|-1, L)\}): L \in \operatorname{paths}(T)\} \subseteq \operatorname{subtrees}(T)$ where $T \neq \emptyset$. The cardinality of the nodes of immediate subtrees is reduced by one, $\{S: S \in$ $\operatorname{subtrees}(T),|\operatorname{nodes}(S)|=|\operatorname{nodes}(T)|-1\}$ where $T \neq \emptyset$.

An $n$-ary tree $T$ is such that $\forall X \in\{T\} \cup \operatorname{ran}(\operatorname{nodes}(T))(X \neq \emptyset \Longrightarrow$ $|X|=n$ ).

Define list trees listTrees $(\mathcal{X})=\mathcal{L}(\mathcal{X} \times \operatorname{list} \operatorname{Trees}(\mathcal{X}))$. List trees are useful for path-dependent traversal. List trees are constructed from trees given an order $D \in \mathcal{X} \leftrightarrow \mathbf{N}$. The function order $\in(\mathcal{X} \leftrightarrow \mathbf{N}) \times \mathrm{P}(\mathcal{X}) \rightarrow(\mathcal{X} \leftrightarrow \mathbf{N})$, defined below, facilitates the construction of lists, inverse $(\operatorname{order}(D, Y)) \in \mathcal{L}(Y)$. Define listTree $\in(\mathcal{X} \leftrightarrow \mathbf{N}) \times \operatorname{trees}(\mathcal{X}) \rightarrow \operatorname{listTrees}(\mathcal{X})$ as

$$
\operatorname{listTree}(D, T):=\{(i,(x, \operatorname{listTree}(D, T(x)))):(x, i) \in \operatorname{order}(D, \operatorname{dom}(T))\}
$$

The converse function tree $\in \operatorname{listTrees}(\mathcal{X}) \rightarrow \operatorname{trees}(\mathcal{X})$ is defined

$$
\operatorname{tree}(L):=\{(x, \operatorname{tree}(M)):(i,(x, M)) \in L, \operatorname{set}(L) \in \mathcal{X} \rightarrow \operatorname{listTrees}(\mathcal{X})\}
$$

A list tree can be concatenated into a list in a depth-first traversal. Define concat $\in \operatorname{listTrees}(\mathcal{X}) \rightarrow \mathcal{L}(\mathcal{X})$ as

$$
\operatorname{concat}(L):=\text { fold }(\operatorname{accum}, \emptyset, L)
$$

where accum $\in(\mathcal{X} \times \operatorname{listTrees}(\mathcal{X})) \times \mathcal{L}(\mathcal{X}) \rightarrow \mathcal{L}(\mathcal{X})$ is defined

$$
\operatorname{accum}((x, M), Q):=\operatorname{concat}(\operatorname{concat}(Q,\{(1, x)\}), \operatorname{concat}(M))
$$

## B. 7 Binary maps

Binary maps are defined

$$
\mathcal{B}(\mathcal{X}) \subset(\mathbf{N} \times \mathcal{X} \times \mathcal{B}(\mathcal{X}) \times \mathcal{B}(\mathcal{X})) \cup\{\emptyset\}
$$

The function function $\in \mathcal{B}(\mathcal{X}) \rightarrow(\mathbf{N} \rightarrow \mathcal{X})$ is defined

$$
\begin{aligned}
\text { function }((m, x, L, R)) & :=\{(m, x)\} \cup \text { function }(L) \cup \text { function }(R) \\
\text { function }(\emptyset) & :=\emptyset
\end{aligned}
$$

The function domain $\in \mathcal{B}(\mathcal{X}) \rightarrow \mathrm{P}(\mathrm{N})$ is defined as

$$
\text { domain }(B):=\operatorname{dom}(\text { function }(B))
$$

The function range $\in \mathcal{B}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X})$ is defined as

$$
\operatorname{range}(B):=\operatorname{ran}(\text { function }(B))
$$

The function depth $\in \mathcal{B}(\mathcal{X}) \rightarrow \mathbf{N}$ is defined

$$
\begin{aligned}
\operatorname{depth}((\cdot, \cdot, L, R)) & :=1+\operatorname{maximum}(\operatorname{depth}(L), \operatorname{depth}(R)) \\
\operatorname{depth}(\emptyset) & :=0
\end{aligned}
$$

where maximum $(a, b):=\operatorname{if}(a<b, b, a)$.
Binary maps are constrained such that

$$
\forall(m, \cdot, L, \cdot) \in \mathcal{B}(\mathcal{X}) \forall(l, \cdot) \in \operatorname{function}(L)(l<m)
$$

and

$$
\forall(m, \cdot, \cdot, R) \in \mathcal{B}(\mathcal{X}) \forall(r, \cdot) \in \operatorname{function}(R)(m<r)
$$

The function mapBinary $\in(\mathbf{N} \rightarrow \mathcal{X}) \rightarrow \mathcal{B}(\mathcal{X})$ is constrained such that $\forall Q \in \mathbf{N} \rightarrow \mathcal{X}$ (function(mapBinary $(Q))=Q$ ) and such that $\forall M \in \mathcal{B}(\mathcal{X}) \backslash$ $\{\emptyset\}\left(\operatorname{depth}(M) \leq \log _{2} \mid\right.$ function $\left.(M) \mid+1\right)$.

The function find $\in \mathcal{B}(\mathcal{X}) \times \mathbf{N} \rightarrow \mathcal{X}$ is defined

$$
\begin{aligned}
\operatorname{find}((m, x, L, R), i) & :=\operatorname{if}(i=m, x, \operatorname{if}(i<m, \text { find }(L, i), \text { find }(R, i))) \\
\operatorname{find}(\emptyset, i) & :=\emptyset
\end{aligned}
$$

Note that if the binary map contains the empty set, $\emptyset \in \operatorname{range}(M)$, then the find is ambiguous.

A binary map can be represented in a list, $L \in \mathcal{L}(\mathbf{N} \times \mathcal{X} \times \mathbf{N} \times \mathbf{N}) . L$ is constrained such that $\forall(i,(m, x, p, q)) \in L(p \neq 0 \Longrightarrow i<p \leq|L|)$, $\forall(i,(m, x, p, q)) \in L(q \neq 0 \Longrightarrow i<q \leq|L|)$ and $\operatorname{bin}(L) \in \mathcal{B}(\mathcal{X})$. The constructor is defined $\operatorname{bin}(\emptyset):=\emptyset$ and $\operatorname{bin}(L):=(m, x, \operatorname{if}(p \neq 0, \operatorname{bin}(\operatorname{drop}(p-$ $1, L)), \emptyset), \operatorname{if}(q \neq 0, \operatorname{bin}(\operatorname{drop}(q-1, L)), \emptyset))$ where $(m, x, p, q)=L_{1}$.

A binary map can represent a set where there exists an enumeration on the domain. For example, consider order $D$ on some set $X, D \in \operatorname{enums}(X)$, and binary map $B \in \mathcal{B}(X)$ such that flip(function $(B)) \subseteq D$, then function $(B) \in$ $\mathbf{N} \leftrightarrow X$ and $\mid$ function $(B)|=|\operatorname{range}(B)|$.

The binary map type, $\mathcal{B}(\mathcal{X})$, as defined above is an algebraic data type representing a function that is constrained such that the domain is a subset
of the natural numbers, domain $(B) \subset \mathbf{N}$ where $B \in \mathcal{B}(\mathcal{X})$. The comparison operator, $(\leq) \in \mathbf{N} \times \mathbf{N} \rightarrow \mathbf{B}$, is that of the natural numbers. A generalisation would be to supply a partially ordered set $\mathcal{Y}$ as the superset of the domain and implement the find comparison with the poset relation $\mathcal{Y} \times \mathcal{Y}$ so that $(\leq) \in \mathcal{Y} \times \mathcal{Y} \rightarrow \mathbf{B}$. The set of poset binary maps, mapBinaryPosets $(\mathcal{Y}, \mathcal{X})$, is a type class having a constructor of a poset binary map which supplies the poset relation and the function

$$
\text { mapBinaryPoset } \in \mathrm{P}(\mathcal{Y} \times \mathcal{Y}) \times(\mathcal{Y} \rightarrow \mathcal{X}) \rightarrow \text { mapBinaryPosets }(\mathcal{Y}, \mathcal{X})
$$

Given poset relation $R$, which is such that $\forall(a, b) \in R(a \leq b)$ and $\operatorname{dom}(R) \cup$ $\operatorname{ran}(R)=\mathcal{Y}$, and function $F \in \mathcal{Y} \rightarrow \mathcal{X}$, let $B=\operatorname{mapBinaryPoset}(R, F) \in$ $\operatorname{mapBinaryPosets}(\mathcal{Y}, \mathcal{X})$. Then function $(B)=F \in \operatorname{domain}(B) \rightarrow \operatorname{range}(B)$. The binary map type, $\mathcal{B}(\mathcal{X})$, is therefore the special case of the poset of natural numbers, $B=\operatorname{mapBinaryPoset}(\{(i, j): i, j \in \mathbf{N}, i \leq j\}, F) \in$ mapBinaryPosets $(\mathbf{N}, \mathcal{X})$ where $F \in \mathbf{N} \rightarrow \mathcal{X}$. The logarithmic constraint on the depth holds for poset binary maps just as it does for natural number binary maps. Implementing a binary map with a poset may be representationally convenient if the natural number encoding of the domain is too large, for example in cases of factorial complexity.

## B. 8 Definition of powerset

The powerset function $\mathrm{P}=$ powerset $\in \mathrm{P}(\mathcal{X}) \rightarrow \mathrm{P}(\mathrm{P}(\mathcal{X}))$ is the set of all subsets of the argument

$$
\mathrm{P}(A):=\{X: X \subseteq A\}
$$

## B. 9 Definition of function predicate

The isfunc returns true if the given relation is functional. Let $\mathcal{X}$ be the universal set, then isfunc $\in \mathrm{P}(\mathcal{X} \times \mathcal{X}) \rightarrow \mathbf{B}$

$$
\operatorname{isfunc}(A):=\forall(a, b),(p, q) \in A(a=p \Longrightarrow b=q)
$$

or equivalently

$$
\operatorname{isfunc}(A):=|\{a:(a, b) \in A\}|=|A|
$$

Empty relations are defined as functional.

## B. 10 Definition of cross operators

Define $(\times) \in \mathrm{P}(\mathcal{X}) \times \mathrm{P}(\mathcal{Y}) \rightarrow \mathrm{P}(\mathcal{X} \times \mathcal{Y})$ as the cartesian cross of sets to create a relation,

$$
A \times B:=\{(x, y): x \in A, y \in B\}
$$

## B. 11 Definition of mapping operators

Define $(\rightarrow) \in \mathrm{P}(\mathcal{X}) \times \mathrm{P}(\mathcal{Y}) \rightarrow \mathrm{P}(\mathcal{X} \rightarrow \mathcal{Y})$ as a powerset of functional relations

$$
A \rightarrow B:=\{X: X \in \mathrm{P}(A \times B), \text { isfunc }(X)\}
$$

So $A \rightarrow B \subseteq \mathrm{P}(A \times B) \in \mathrm{P}(\mathrm{P}(A \times B))$. Thus we can type the function operator as $(\rightarrow) \subset(\mathrm{P}(\mathcal{X}) \times \mathrm{P}(\mathcal{Y})) \times \mathrm{P}(\mathrm{P}(\mathcal{X} \times \mathcal{Y}))$.
$A \rightarrow B$ is sometimes denoted $B^{A}$.
And $(\leftrightarrow) \in \mathrm{P}(\mathcal{X}) \times \mathrm{P}(\mathcal{Y}) \rightarrow \mathrm{P}(\mathcal{X} \leftrightarrow \mathcal{Y})$ is a powerset of bi-directional functional relations

$$
A \leftrightarrow B:=\{X: X \in \mathrm{P}(A \times B), \text { isfunc }(X), \text { isfunc }(\operatorname{flip}(X))\}
$$

## B. 12 Total specifiers

Given any relation function $(\otimes) \in \mathrm{P}(\mathcal{X}) \times \mathrm{P}(\mathcal{Y}) \rightarrow \mathrm{P}(\mathcal{X} \times \mathcal{Y})$, define the left total subsets $(: \otimes) \in \mathrm{P}(\mathcal{X}) \times \mathrm{P}(\mathcal{Y}) \rightarrow \mathrm{P}(\mathcal{X} \times \mathcal{Y})$ as

$$
A: \otimes B:=\{X: X \in A \otimes B, \operatorname{dom}(X)=A\}
$$

Similarly for right total $(\otimes:) \in \mathrm{P}(\mathcal{X}) \times \mathrm{P}(\mathcal{Y}) \times \mathrm{P}(\mathcal{X} \rightarrow \mathcal{Y})$ as

$$
A \otimes: B:=\{X: X \in A \otimes B, \operatorname{ran}(X)=B\}
$$

And for both $(: \otimes:) \in \mathrm{P}(\mathcal{X}) \times \mathrm{P}(\mathcal{Y}) \rightarrow \mathrm{P}(\mathcal{X} \times \mathcal{Y})$ as

$$
A: \otimes: B:=\{X: X \in A \otimes B, \operatorname{dom}(X)=A, \operatorname{ran}(X)=B\}
$$

For example

$$
A: \rightarrow B:=\{X: X \in \mathrm{P}(A \times B), \text { isfunc }(X), \operatorname{dom}(X)=A\}
$$

or
$A: \leftrightarrow: B:=$
$\{X: X \in \mathrm{P}(A \times B)$, isfunc $(X)$, isfunc $(\operatorname{flip}(X)), \operatorname{dom}(X)=A, \operatorname{ran}(X)=B\}$

## B. 13 Partitions

The partition function $B$ is the set of all partitions of the argument. A partition is a set of non-empty disjoint subsets, called components, which union to equal the argument, $\mathrm{B} \in \mathrm{P}(\mathcal{X}) \rightarrow \mathrm{P}(\mathrm{P}(\mathrm{P}(\mathcal{X}) \backslash\{\emptyset\}))$
$\mathrm{B}(A):=$

$$
\{X: X \subseteq(\mathrm{P}(A) \backslash\{\emptyset\}), \bigcup X=A,(\forall C, D \in X(C \neq D \Longrightarrow C \cap D=\emptyset))\}
$$

Define $\mathrm{B}(\emptyset):=\emptyset$.
The weak partition function $\mathrm{B}^{\prime}$ includes component sets that contain the empty set

$$
\mathrm{B}^{\prime}(A):=\mathrm{B}(V) \cup\{Y \cup\{\emptyset\}: Y \in \mathrm{~B}(V)\}
$$

where $B^{\prime}(\emptyset):=\{\{\emptyset\}\}$.
The Bell number function bell $\in \mathbf{N}_{>0} \rightarrow \mathbf{N}_{>0}$ is defined

$$
\operatorname{bell}(n):=|\mathrm{B}(\{1 \ldots n\})|
$$

The fixed cardinality partition function $S$ is the special case of the partition function in which all partitions have the given cardinality. Define $\mathrm{S} \in \mathrm{P}(\mathcal{X}) \times$ $\mathbf{N}_{>0} \rightarrow \mathrm{P}(\mathrm{P}(\mathrm{P}(\mathcal{X}) \backslash\{\emptyset\}))$ as

$$
\mathrm{S}(A, k):=\{P: P \in \mathrm{~B}(A),|P|=k\}
$$

The Stirling number of the second kind stir $\in \mathbf{N}_{>0} \times \mathbf{N} \rightarrow \mathbf{N}_{>0}$ is is the cardinality of the fixed cardinality partition function $S$,

$$
\operatorname{stir}(n, k):=|S(\{1 \ldots n\}, k)|
$$

So $\bigcup_{k \in\{1 \ldots n\}}\left\{\mathrm{S}(A, k)=\mathrm{B}(A)\right.$ and $\sum_{k \in\{1 \ldots n\}} \operatorname{stir}(n, k)=\operatorname{bell}(n)$.
The partition function cardinality function bellcd $\in \mathbf{N}_{>0} \rightarrow(\mathcal{L}(\mathbf{N}) \rightarrow$ $\mathbf{N})$ computes the histogram of the histograms of the component cardinalities. The partition function cardinality function is such that $\operatorname{bellcd}(n) \in$ $(\{1 \ldots n\}: \rightarrow\{0 \ldots n\}) \rightarrow\{0 \ldots n\}$. It is defined
$\operatorname{bellcd}(n):=$

$$
\left\{\left(L, \frac{n!}{\prod_{(k, m) \in L}(k!)^{m} m!}\right): L \in \prod\{1 \ldots n\} \times\{\{0 \ldots n\}\}, \quad \sum_{(k, m) \in L} m k=n\right\}
$$

The partition function cardinality function recovers the Bell number, $\sum(c$ : $(\cdot, c) \in \operatorname{bellcd}(n))=\operatorname{bell}(n)$.

The partition function cardinality function may be constrained such that the partitions have fixed cardinality. The function stircd $\in \mathbf{N}_{>0} \times \mathbf{N}_{>0} \rightarrow$ $(\mathcal{L}(\mathbf{N}) \rightarrow \mathbf{N})$ computes the special case of the histogram of the histograms of the component cardinalities. The fixed cardinality partition function cardinality function is such that $\operatorname{stircd}(n, i) \in(\{1 \ldots n\}: \rightarrow\{0 \ldots n\}) \rightarrow\{0 \ldots n\}$. It is defined

$$
\begin{aligned}
& \operatorname{stircd}(n, i):= \\
& \qquad\left\{\left(L, \frac{n!}{\prod_{(k, m) \in L}(k!)^{m} m!}\right): L \in \prod\{1 \ldots n\} \times\{\{0 \ldots n\}\},\right. \\
& \left.\quad \sum_{(k, m) \in L} m k=n, \sum_{(\cdot, m) \in L} m=i\right\}
\end{aligned}
$$

or, equivalently in terms of the weak composition function, $\mathrm{C}^{\prime} \in \mathrm{P}(\mathcal{X}) \times \mathbf{N} \rightarrow$ $\mathrm{P}(\mathcal{X} \rightarrow \mathbf{N})$,

$$
\begin{aligned}
& \operatorname{stircd}(n, i):= \\
& \qquad\left\{\left(L, \frac{n!}{\prod_{(k, m) \in L}(k!)^{m} m!}\right): L \in \mathrm{C}^{\prime}(\{1 \ldots n\}, i), \quad \sum_{(k, m) \in L} m k=n\right\}
\end{aligned}
$$

The fixed cardinality partition function cardinality function recovers the Stirling number of the second kind, $\sum(c:(\cdot, c) \in \operatorname{stircd}(n, i))=\operatorname{stir}(n, i)$. The union of the fixed cardinality partition function cardinality function equals the partition function cardinality function, $\bigcup_{i \in\{1 \ldots n\}} \operatorname{stircd}(n, i)=\operatorname{bellcd}(n)$.

The self-partition or uni-partition $S \in \mathrm{~B}(A)$ of non-empty $A \in \mathrm{P}(\mathcal{X}) \backslash\{\emptyset\}$ is the special case $S=\{\{a\}: a \in A\}$. The cardinality of the self-partition is $|S|=|A|$. Define self $\in \mathrm{P}(\mathcal{X}) \rightarrow \mathrm{P}(\mathrm{P}(\mathcal{X}))$ as $\operatorname{self}(X):=\{\{x\}: x \in X\}$. Define the shorthand $X^{\{ \}}=\operatorname{self}(X)$.

The unary-partition $N \in \mathrm{~B}(A)$ is the special case $N=\{A\}$. The cardinality of the unary-partition is $|N|=1$. The unary-partition is the only partition of a singleton set, $\mathrm{B}(\{a\})=\{\{\{a\}\}\}$. Define unary $\in \mathrm{P}(\mathcal{X}) \rightarrow \mathrm{P}(\mathrm{P}(\mathcal{X}))$ as unary $(X):=\{X\}$.

Binary-partitions $Q \in \mathrm{~B}(A)$ are such that $Q \in\{\{X, A \backslash X\}: X \in \mathrm{P}(A), X \neq$ $\emptyset, X \neq A\}$. The cardinality of a binary-partition is $|Q|=2$.

A partition $P$ is a parent of another partition $Q$ if each component in $Q$ intersects with exactly one component in $P$. Define parent $\in \mathrm{P}(\mathrm{P}(\mathcal{X}) \backslash$ $\{\emptyset\}) \times \mathrm{P}(\mathrm{P}(\mathcal{X}) \backslash\{\emptyset\}) \rightarrow \mathbf{B}$

```
parent \((P, Q):=\)
    \((\bigcup P=\bigcup Q) \wedge(\{(D, C): D \in Q, C \in P, D \cap C \neq \emptyset\} \in Q \rightarrow P)\)
```

An equivalent definition is

$$
\operatorname{parent}(P, Q):=(\bigcup P=\bigcup Q) \wedge(Q=\bigcup\{R: C \in P, R \in \mathrm{~B}(C), R \subseteq Q\})
$$

The set of parents can be constructed explicitly. Define parents $\in \mathrm{P}(\mathrm{P}(\mathcal{X}) \backslash$ $\{\emptyset\}) \rightarrow \mathrm{P}(\mathrm{P}(\mathrm{P}(\mathcal{X}) \backslash\{\emptyset\}))$ as

$$
\operatorname{parents}(Q):=\{\{\bigcup C: C \in X\}: X \in \mathrm{~B}(Q)\}
$$

so that $\forall X \subset \mathcal{X} \forall P, Q \in \mathrm{~B}(X)(\operatorname{parent}(P, Q) \Longleftrightarrow P \in \operatorname{parents}(Q))$. The cardinality of the set of parents is $|\operatorname{parents}(Q)|=\operatorname{bell}(|Q|) \leq \operatorname{bell}(|\cup Q|)$.

A partition of disjoint sets can be exploded into a partition. Define explode $\epsilon$ $\mathrm{P}(\mathrm{P}(\mathrm{P}(\mathcal{X}))) \rightarrow \mathrm{P}(\mathrm{P}(\mathcal{X}))$ as explode $(X):=\{\bigcup C: C \in X\}$. If $X$ is a partition of disjoint sets $Q, X \in \mathrm{~B}(Q)$ where $Q \in \mathrm{~B}(\bigcup Q)$, then the exploded result is a partition, explode $(X) \in \mathrm{B}(\bigcup Q)$, and the exploded cardinality is unchanged $|\operatorname{explode}(X)|=|X|$. The set of parents can be defined in terms of explode, parents $(Q)=\{\operatorname{explode}(X): X \in \mathrm{~B}(Q)\}$.

Define a partition sequence as a list $L \in \mathcal{L}(\mathrm{P}(\mathrm{P}(\mathcal{X}) \backslash\{\emptyset\}))$ of partitions such that each element in the list is a parent of the next

$$
|L| \geq 2 \Longrightarrow\left(\forall i \in\{1 \ldots|L|-1\}\left(\operatorname{parent}\left(L_{i}, L_{i+1}\right)\right)\right)
$$

Similarly define a reverse partition sequence as a list $L \in \mathcal{L}(\mathrm{P}(\mathrm{P}(\mathcal{X}) \backslash\{\emptyset\}))$ of partitions such that each element in the list is a child of the next

$$
|L| \geq 2 \Longrightarrow\left(\forall i \in\{1 \ldots|L|-1\}\left(\operatorname{parent}\left(L_{i+1}, L_{i}\right)\right)\right)
$$

Define a partition tree as a tree $T \in \operatorname{trees}(\mathrm{P}(\mathrm{P}(\mathcal{X}) \backslash\{\emptyset\}))$ of partitions such that each node in the tree is a parent-child

$$
\forall(P, Q) \in \operatorname{nodes}(T)(Q \neq \emptyset \Longrightarrow \operatorname{parent}(P, Q))
$$

and define a reverse partition tree as a tree $T \in \operatorname{trees}(\mathrm{P}(\mathrm{P}(\mathcal{X}) \backslash\{\emptyset\}))$ of partitions such that each node in the tree is a child-parent

$$
\forall(P, Q) \in \operatorname{nodes}(T)(Q \neq \emptyset \Longrightarrow \operatorname{parent}(Q, P))
$$

A partition $P$ can be viewed as a disjoint set of equivalent classes. A weighting can be assigned to each element of the partition, $x \in \bigcup P$, equal to its fraction of the cardinality of the component containing it, $1 /|C|$, where $x \in C \in P$. Define weights $\in \mathrm{P}(\mathrm{P}(\mathcal{X}) \backslash\{\emptyset\}) \rightarrow\left(\mathcal{X} \rightarrow \mathbf{Q}_{>0}\right)$ as

$$
\text { weights }(P):=\{(x, 1 /|C|): C \in P, x \in C\}
$$

which is defined if $P$ is a partition, $P \in \mathrm{~B}(\bigcup P)$. The weights are such that $\operatorname{sum}($ weights $(P))=|P| \leq|\bigcup P|$.

## B. 14 Compositions

A composition is a functional relation between some set of objects and the natural numbers $\mathcal{X} \rightarrow \mathbf{N}$. Given a set of objects $X \subset \mathcal{X}$ and a total $n \in \mathbf{N}$, composition functions return all compositions such that each has domain $X$ and sums to $n$. Define the composition function, which excludes 0 , as

$$
\mathrm{C} \in \mathrm{P}(\mathcal{X}) \times \mathbf{N}_{>0} \rightarrow \mathrm{P}\left(\mathcal{X} \rightarrow \mathbf{N}_{>0}\right)
$$

and the weak composition function, which includes 0 , as

$$
\mathrm{C}^{\prime} \in \mathrm{P}(\mathcal{X}) \times \mathbf{N} \rightarrow \mathrm{P}(\mathcal{X} \rightarrow \mathbf{N})
$$

such that

$$
\forall C \in \mathrm{C}(X, n) \cup \mathrm{C}^{\prime}(X, n)\left((\operatorname{dom}(C)=X) \wedge\left(\sum_{x \in X} C_{x}=n\right)\right)
$$

By implication, composition function $\mathrm{C}(X, n)$ is constrained

$$
\forall C \in \mathrm{C}(X, n)(n \geq|X|)
$$

The cardinality of the composition function $\mathrm{C}(\{1 \ldots k\}, n)$ is

$$
|\mathrm{C}(\{1 \ldots k\}, n)|=\frac{(n-1)!}{(k-1)!(n-k)!}
$$

The cardinality of the weak composition function $\mathrm{C}^{\prime}(\{1 \ldots k\}, n)$ is

$$
\left|\mathrm{C}^{\prime}(\{1 \ldots k\}, n)\right|=\frac{(n+k-1)!}{(k-1)!n!}
$$

Note that composition, as defined here, is not to be confused with composition of functions.

## B. 15 Relation functions

Let $\mathcal{X}$ and $\mathcal{Y}$ be universal sets, then the domain is defined dom $\in \mathrm{P}(\mathcal{X} \times \mathcal{Y}) \rightarrow$ $\mathrm{P}(\mathcal{X})$

$$
\operatorname{dom}(A):=\{x:(x, y) \in A\}
$$

and the range, ran $\in \mathrm{P}(\mathcal{X} \times \mathcal{Y}) \rightarrow \mathrm{P}(\mathcal{Y})$

$$
\operatorname{ran}(A):=\{y:(x, y) \in A\}
$$

The inverse, flip $\in \mathrm{P}(\mathcal{X} \times \mathcal{Y}) \rightarrow \mathrm{P}(\mathcal{Y} \times \mathcal{X})$

$$
\operatorname{flip}(A):=\{(y, x):(x, y) \in A\}
$$

The function filter $\in \mathrm{P}(\mathcal{X}) \times \mathrm{P}(\mathcal{X} \times \mathcal{Y}) \rightarrow \mathrm{P}(\mathcal{X} \times \mathcal{Y})$ is defined

$$
\operatorname{filter}(X, A):=\{(x, y):(x, y) \in A, x \in X\}
$$

The inverse of a function, inverse $\in(\mathcal{X} \rightarrow \mathcal{Y}) \rightarrow(\mathcal{Y} \rightarrow \mathrm{P}(\mathcal{X}))$ is defined

$$
\begin{aligned}
\text { inverse }(F) & :=\{(y, \operatorname{ran}(\text { filter }(\{y\}, \operatorname{flip}(F)))): y \in \operatorname{ran}(F)\} \\
& =\{(y,\{x: x \in \operatorname{dom}(F), F(x)=y\}): y \in \operatorname{ran}(F)\}
\end{aligned}
$$

The inverse is sometimes denoted $F^{-1}$. Note that this is a different definition from the convention $\{(Y,\{x: x \in \operatorname{dom}(F), F(x) \in Y\}): Y \subseteq \operatorname{ran}(F)\} \in$ $\mathrm{P}(\mathcal{Y}) \rightarrow \mathrm{P}(\mathcal{X})$.

## B. 16 Dot operator

The set of all bidirectional mappings between two sets of the same cardinality $(\cdot) \in \mathrm{P}(\mathcal{X}) \times \mathrm{P}(\mathcal{Y}) \rightarrow \mathrm{P}(\mathcal{X} \leftrightarrow \mathcal{Y})$

$$
X \cdot Y:=\{Z: Z \in X \leftrightarrow Y,|X|=|Y|,|Z|=|Y|\}
$$

where $\mathcal{X}$ and $\mathcal{Y}$ are the universal set.
The outer dot product is defined where the cardinality of the left argument is greater than or equal to that of the right, $(\cdot=) \in \mathrm{P}(\mathcal{X}) \times \mathrm{P}(\mathcal{Y}) \rightarrow \mathrm{P}(\mathcal{X} \leftrightarrow \mathcal{Y})$

$$
X \cdot=Y:=\{Z: Z \in X \leftrightarrow Y,|X| \geq|Y|,|Z|=|Y|\}
$$

## B. 17 Selections

The set of subsets of given cardinality of a given set, selections $\in \mathrm{N} \times \mathrm{P}(\mathcal{X}) \rightarrow$ $\mathrm{P}(\mathrm{P}(\mathcal{X}))$ is defined

$$
\text { selections }(k, X):=\{Y: Y \subseteq X,|Y|=k\}
$$

There are $n!/(k!(n-k)!)$ of these where $n=|X|$.

## B. 18 Enumerations

The set of all enumerations enums $\in \mathrm{P}(\mathcal{X}) \rightarrow \mathrm{P}(\mathcal{X} \leftrightarrow \mathbf{N})$

$$
\operatorname{enums}(X):=X \cdot\{1 \ldots|X|\}
$$

The cardinality of this function is the number of permutations of its argument $\mid$ enums $(X)|=|X|$ !.

An order $D$ on some set $X$ is a choice of the enumerations, $D \in \operatorname{enums}(X)$. Given the order, any subset can be enumerated, define order $\in(\mathcal{X} \leftrightarrow$ $\mathbf{N}) \times \mathrm{P}(\mathcal{X}) \rightarrow(\mathcal{X} \leftrightarrow \mathbf{N})$

$$
\operatorname{order}(D, Y):=\{(y,|\{(z, i):(z, i) \in Q, i \leq j\}|):(y, j) \in Q\}
$$

where $Q=\left\{\left(y, D_{y}\right): y \in Y\right\}$. So order $(D, Y) \in \operatorname{enums}(Y)$.

## B. 19 Normalisation

Normalising a real valued function $F \in \mathcal{X} \rightarrow \mathbf{R}$ is defined normalise $\in(\mathcal{X} \rightarrow$ $\mathbf{R}) \rightarrow(\mathcal{X} \rightarrow \mathbf{R})$ as

$$
\text { normalise }(F):=\{(x, r / \operatorname{sum}(F)):(x, r) \in F\} \in \mathcal{X} \rightarrow \mathbf{R}
$$

Normalising is undefined if $\operatorname{sum}(F)=0$. Define notation $\hat{F}:=$ normalise $(F)$. If the function is rational valued, $F \in \mathcal{X} \rightarrow \mathbf{Q}$, then the normalised function is also rational valued, $\hat{F} \in \mathcal{X} \rightarrow \mathbf{Q}$, and hence a probability function, $\hat{F} \in \mathcal{P}$.

## B. 20 Aggregation and inclusion functions

The function singleton $\in \mathcal{X} \rightarrow \mathrm{P}(\mathcal{X})$, sometimes called tip, creates a singleton set, $\operatorname{singleton}(x):=\{x\}$. The converse function only $\in \mathrm{P}(\mathcal{X}) \rightarrow \mathcal{X}$ is defined $\operatorname{only}(X):=x$ where $|X|=1$ and $X=\{x\}$. The function only is undefined if $|X| \neq 1$.

Given a relation, the count function creates a functional relation between the domain of the argument and the count of the elements corresponding. Let $\mathcal{X}$ and $\mathcal{Y}$ be the universal set, count $\in \mathrm{P}(\mathcal{X} \times \mathcal{Y}) \rightarrow(\mathcal{X} \rightarrow \mathbf{N})$

$$
\operatorname{count}(A):=\{(a,|\{q:(p, q) \in A, p=a\}|): a \in \operatorname{dom}(A)\}
$$

Given a relation $\mathcal{X} \times \mathcal{Y}$ such that an order operator, enums $(\mathcal{Y})$, or partially ordered set, $(\mathcal{Y}, \leq)$, is defined on the range, $\mathcal{Y}$, the min and max functions returns the minimum/maximum subset, $\max \in \mathrm{P}(\mathcal{X} \times \mathcal{Y}) \rightarrow(\mathcal{X} \rightarrow \mathcal{Y})$

$$
\max (A):=\{(x, y):(x, y) \in A,(\forall(r, s) \in A(s \leq y))\}
$$

We also define the convenience functions

$$
\operatorname{maxd}(A):=\operatorname{dom}(\max (A))
$$

and

$$
\operatorname{maxr}(A):=m
$$

where $\{m\}=\operatorname{ran}(\max (A))$. Note that maxr is undefined for empty sets.
For minimum, $\min \in \mathrm{P}((\mathcal{X} \times \mathcal{Y})) \rightarrow(\mathcal{X} \rightarrow \mathcal{Y})$

$$
\min (A):=\{(x, y):(x, y) \in A,(\forall(r, s) \in A(s \geq y))\}
$$

We also define $\operatorname{mind}(A)$ and $\operatorname{minr}(A)$ similarly.

Similar to the min and max functions are the $\operatorname{bottom}(n)$ and $\operatorname{top}(n)$ functions. Define top $\in \mathrm{N}_{>0} \rightarrow(\mathrm{P}(\mathcal{X} \times \mathcal{Y}) \rightarrow \mathrm{P}(\mathcal{X} \times \mathcal{Y}))$

$$
\begin{aligned}
& \operatorname{top}(n)(A):=\operatorname{top}(\operatorname{maximum}(n-|\max (A)|, 0))(A \backslash \max (A)) \cup \max (A) \\
& \operatorname{top}(0)(A) \quad:=\emptyset
\end{aligned}
$$

Define bottom $\in \mathrm{N}_{>0} \rightarrow(\mathrm{P}(\mathcal{X} \times \mathcal{Y}) \rightarrow \mathrm{P}(\mathcal{X} \times \mathcal{Y}))$
$\operatorname{bottom}(n)(A):=\operatorname{bottom}(\operatorname{maximum}(n-|\min (A)|, 0))(A \backslash \min (A)) \cup \min (A)$
$\operatorname{bottom}(0)(A):=\emptyset$
Thus $\operatorname{top}(1)=\max , \operatorname{bottom}(1)=\min$, and $\operatorname{top}(|A|)(A)=\operatorname{bottom}(|A|)(A)=$ $A$. Define $\operatorname{topd}(n)(A):=\operatorname{dom}(\operatorname{top}(n)(A))$ and similarly $\operatorname{bottomd}(n)(A):=$ $\operatorname{dom}(\operatorname{bottom}(n)(A))$.

Given a zero element in the range, $0 \in \mathcal{Y}$, define inclusion function zero $\in$ $\mathrm{P}(\mathcal{X} \times \mathcal{Y}) \rightarrow(\mathcal{X} \rightarrow\{0\})$

$$
\operatorname{zero}(A):=\{(x, y):(x, y) \in A, y=0\}
$$

Define inclusion function nonzero $\in \mathrm{P}(\mathcal{X} \times \mathcal{Y}) \rightarrow \mathrm{P}(\mathcal{X} \times(\mathcal{Y} \backslash\{0\}))$

$$
\operatorname{nonzero}(A):=\{(x, y):(x, y) \in A, y \neq 0\}
$$

Define inclusion function positive $\in \mathrm{P}(\mathcal{X} \times \mathcal{Y}) \rightarrow \mathrm{P}\left(\mathcal{X} \times \mathcal{Y}_{\geq 0}\right)$

$$
\operatorname{positive}(A):=\{(x, y):(x, y) \in A, y \geq 0\}
$$

Define inclusion function negative $\in \mathrm{P}(\mathcal{X} \times \mathcal{Y}) \rightarrow \mathrm{P}\left(\mathcal{X} \times \mathcal{Y}_{<0}\right)$

$$
\text { negative }(A):=\{(x, y):(x, y) \in A, y<0\}
$$

Define aggregation function sum $\in \mathrm{P}(\mathcal{X} \times \mathbf{R}) \rightarrow \mathbf{R}$

$$
\operatorname{sum}(A):=\sum q:(x, q) \in A
$$

Define arithmetic average as average $\in \mathrm{P}(\mathcal{X} \times \mathbf{R}) \rightarrow \mathbf{R}$

$$
\operatorname{average}(A):=\operatorname{sum}(A) /|A|
$$

which is defined where $|A| \geq 0$.
Define product $\in \mathrm{P}(\mathcal{X} \times \mathbf{R}) \rightarrow \mathbf{R}$

$$
\operatorname{product}(A):=\prod q:(x, q) \in A
$$

## B. 21 Convenience functions

Ceiling of positive reals ceil $\in \mathbf{R} \rightarrow \mathbf{N}$

$$
\operatorname{ceil}(r):=\operatorname{minr}(\{(n, n): n \in \mathbf{N}, n \geq r\})
$$

Floor of positive reals $\mathrm{flr} \in \mathbf{R} \rightarrow \mathbf{N}$

$$
\operatorname{flr}(r):=\operatorname{maxr}(\{(n, n): n \in \mathbf{N}, n \leq r\})
$$

Greater of a pair maximum $\in \mathbf{R} \times \mathbf{R} \rightarrow \mathbf{R}$

$$
\operatorname{maximum}(a, b):=\operatorname{if}(a<b, b, a)
$$

Lesser of a pair minimum $\in \mathbf{R} \times \mathbf{R} \rightarrow \mathbf{R}$

$$
\operatorname{minimum}(a, b):=\operatorname{if}(a<b, a, b)
$$

## B. 22 Big O definition

The Big O function imposes an upper bound. It requires both a functional map to a real and a real multiplier, $\mathrm{O} \in(\mathcal{X} \rightarrow \mathbf{R}) \times \mathbf{R}_{>0} \rightarrow \mathrm{P}\left(\mathcal{X} \rightarrow \mathbf{R}_{\geq 0}\right)$
$\mathrm{O}(A, m):=$
$\left\{X: X \in \mathrm{P}\left(\left\{(x, r): x \in \operatorname{dom}(A), r \in \mathbf{R}, 0 \leq r \leq m A_{x}\right\}\right)\right.$, isfunc $\left.(X)\right\}$
Define $\mathrm{O} \in(\mathcal{X} \rightarrow \mathbf{R}) \rightarrow \mathrm{P}(\mathcal{X} \rightarrow \mathbf{R})$

$$
\mathrm{O}(A):=\mathrm{O}(A, 1)
$$

Similarly Big Omega function imposes an lower bound. It requires a functional map to a real and a real multiplier, $\Omega \in(\mathcal{X} \rightarrow \mathbf{R}) \times \mathbf{R}_{>0} \rightarrow \mathrm{P}(\mathcal{X} \rightarrow \mathbf{R})$

$$
\begin{aligned}
& \Omega(A, m):= \\
& \quad\left\{X: X \in \mathrm{P}\left(\left\{(x, r): x \in \operatorname{dom}(A), r \in \mathbf{R}, r \geq m A_{x}\right\}\right), \operatorname{isfunc}(X)\right\}
\end{aligned}
$$

Define $\Omega \in(\mathcal{X} \rightarrow \mathbf{R}) \rightarrow \mathrm{P}(\mathcal{X} \rightarrow \mathbf{R})$

$$
\Omega(A):=\Omega(A, 1)
$$

## B. 23 Let quantifier

A lozenge $\diamond$ is used to signify the binding of a variable amongst quantifiers. For example $\forall a \in A \diamond b=\mathrm{f}(a) \exists c \in C(b)(\ldots)$.

## B. 24 Set builder notation

This expression

$$
Z=\{\mathrm{z}(x): x \in X, \mathrm{p}(x)\}
$$

where $\mathrm{p}(x)$ is a predicate, is shorthand for

$$
\forall x \in X(\mathrm{p}(x) \Longleftrightarrow \mathrm{z}(x) \in Z)
$$

And

$$
Z=\{\mathrm{z}(x, y): x \in X, y \in Y, \mathrm{p}(x), \mathrm{q}(y)\}
$$

is shorthand for

$$
\forall x \in X \forall y \in Y(\mathrm{p}(x) \wedge \mathrm{q}(y) \Longleftrightarrow \mathrm{z}(x, y) \in Z)
$$

and so on.

## B. 25 if function

Let $\mathbf{B}$ be the set of booleans. Let $\mathcal{X}$ be the universal set. The logical switch function, if $\in \mathbf{B} \times \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{X}$

$$
\forall b \in \mathbf{B} \forall x, y \in \mathcal{X}((b \Longrightarrow \operatorname{if}(b, x, y)=x) \wedge(\neg b \Longrightarrow \operatorname{if}(b, x, y)=y))
$$

## B. 26 Function definition

Let func be a functional relation with a type definition func $\in \mathcal{A} \rightarrow \mathcal{Z}$. Consider the expression

$$
\text { func }(a):=\mathrm{z}(a)
$$

where $\mathrm{z}(a)$ is an expression with free variable $a$ that evaluates to an element in $\mathcal{Z}$. In the case where func is a total function, that is, where there are no other constraints imposed on the domain of the function $\operatorname{dom}(f u n c)=\mathcal{A}$, then the expression is shorthand for

$$
\forall a \in \mathcal{A} \exists \mathrm{z}(a) \in \mathcal{Z}((a, \mathrm{z}(a)) \in \text { func })
$$

In the case that func is a partial function, that is, where there are other constraints $r$ (func) $\in \mathbf{B}$ on the function, then the domain is taken (ambiguously) to be one of the largest possible subsets
func $\in \operatorname{maxd}(\{(F,|\operatorname{dom}(F)|): F \in \mathcal{A} \rightarrow \mathcal{Z}, \mathrm{r}(F),(\forall(a, b) \in F(b=z(a)))\})$
Similarly, with the same caveat for constraints on the domain, if the type definition is func $\in \mathcal{A} \times \mathcal{B} \rightarrow \mathcal{Z}$ then the expression

$$
\operatorname{func}(a, b):=\mathrm{z}(a, b)
$$

is shorthand for

$$
\forall a \in \mathcal{A} \forall b \in \mathcal{B} \exists \mathrm{z}(a, b) \in \mathcal{Z}(((a, b), \mathrm{z}(a, b)) \in \text { func })
$$

and so on.
The identity function id $\in \mathcal{X} \rightarrow \mathcal{X}$ is defined

$$
\operatorname{id}(x):=x
$$

## B. 27 Natural numbers

The set of natural numbers $\mathbf{N}$ is taken to include 0 . The set $\mathbf{N}_{>0}$ excludes 0 .
Define encode $\in \mathbf{N} \leftrightarrow \mathcal{L}$ (bits) which encodes a natural number in the shortest list such that

$$
\forall(i, L) \in \operatorname{encode}\left((L=\emptyset \vee \operatorname{last}(L)=1) \wedge\left(i=\sum\left(2^{j-1} b:(j, b) \in L\right)\right)\right)
$$

Define decode $\in \mathcal{L}$ (bits) $\leftrightarrow \mathbf{N}$ as decode $=$ flip(encode).
Define space $\in \mathbf{N}_{>0} \rightarrow \ln \mathbf{N}_{>0}$ as space $(n):=\ln n$. The length of the encoded natural number is an approximation to the space

$$
(|\operatorname{encode}(n)|-1) \ln 2 \leq \operatorname{space}(n)<(|\operatorname{encode}(n)|) \ln 2
$$

## B. 28 Booleans and bits

The set of boolean values $\mathbf{B}$ is not specified except to constrain the cardinality $|\mathbf{B}|=2$.
The set of bits is defined bits $=\{0,1\} \subset \mathbf{N}$. Define encode $\in \mathbf{B} \rightarrow$ bits as encode $(b):=\operatorname{if}(b, 1,0)$, and define decode $\in \operatorname{bits} \rightarrow \mathbf{B}$ as decode $(i):=i=1$.
